As a final check on the measurements in the very dilute solutions, a flowing electrode using a dilute (0.03%) zinc amalgam was employed in the zinc half-cell for the concentrations 0.001505 *M* and 0.0007016 *M*. The potential of this dilute amalgam electrode against the two-phase zinc amalgam electrode was found to be 0.04750 volt. The voltages given in the table for the two cells referred to are corrected for this difference.

From a large-scale plot of E'_0 against \sqrt{m} , values of E'_0 at round concentrations were read, and the corresponding mean activity coefficients⁹ were calculated by Equation 4, using the value of E_0 determined by the extrapolation described below. These values are given in Table II along with the coefficients calculated from the ion-attraction theory, using Kockel's value for $A = 0.514$ up to where the percentage deviation from the limiting equation becomes enormous.

Discussion of the Results

The experimental values of E'_0 fall so well upon a smooth curve which rapidly approaches linearity below 0.01 *M* that the final slope can be determined with almost no ambiguity by plotting the slope of the curve at even intervals against the corresponding value of \sqrt{m} and obtaining the constant value approached in the most dilute solutions. This final slope is found to be -0.248 , which corresponds to 0.523 for the value of A in Equation 1.

Extrapolating the E'_0/\sqrt{m} curve to zero concentration asymptotic to a straight line with this slope of -0.248 , the electromotive force of the cell when the zinc ions and sulfate ions have activities of 1 molal is found to be 0.41302 volt.

The validity of the ion attraction theory at small concentrations is also made evident by the agreement of the experimental and theoretical activity coefficients given in Table II. Up to 0.005 molal (an ionic strength of 0.02) the agreement is within 2%, and perhaps within the experimental error. This is a very striking fact when it is considered that at 0.005 molal the activity coefficient has already fallen to nearly 0.5.

A scarcely less striking fact is the rapidity with which, as the molality further increases, the actual activity coefficients deviate from those calculated by the limiting equation of the ion attraction theory. Thus, at 0.02 molal the deviation is already 19.1% and at 0.05 molal it is 45.4%. These results illustrate the great error that is made in applying mass-action equations that assume complete ionization and ion activities calculated even by the Debye-Hückel equation to equilibria involving bivalent ions at normalities greater than 0.01 normal. They also show that the theoretical corrections that must be introduced into the limiting equation of the ion attraction theory to make it apply at even moderate

concentrations must be such as will account for the very large deviations in the case of ions of higher valence.

That these corrections cannot consist merely in taking into account the size a of the ion by introducing a factor $(1 + Ba \sqrt{\Sigma mv^2})$ is indicated by the slow increase of this function with the ionic strength. It has indeed been shown by La Mer⁸ and his co-workers and by Schärer¹⁴ that the observed solubility effects cannot be accounted for in this way.

The author wishes to express his appreciation to Professor A. A. Noyes for his interest and helpful suggestions in carrying out this research.

Summary

The preparation of a reproducible lead-lead sulfate electrode has been described. Electromotive-force measurements at 25° on the cell Zn-Hg (2-phase) | ZnSO₄ | PbSO₄ (s) | Pb-Hg (2-phase) have been given over the concentration range 0.0006 to 3.4 molal. The potential of the cell when the ion activities are 1 molal has been found to be 0.41302 volt.

The mean ion activity coefficients for zinc sulfate through this concentration range have been calculated. The rapid decrease of these activity coefficients with increasing concentration is striking. Thus, the value has become 0.42 at 0.01 molal and 0.16 at 0.1 molal.

The experimental results at small concentrations are found to be in good agreement with the limiting equation of the ion-attraction theory. Thus the experimentally found value for the constant in the equation is 0.523, while the calculated value is 0.504 or 0.514, depending on whether Drude's or Kockel's value for the dielectric constant of water is used.

At molalities above 0.005 the deviations between the theoretical and observed values increase with extraordinary rapidity, showing that in the case of ions of higher valence the theoretical equation must have very substantial corrections applied to it, besides that of taking into account the size of the ions.

CONTRIBUTIONS TO THE STUDY OF RUTHENIUM. X. THE
"ISOMERIC" CHLORIDES

BY JAS. LEWIS HOWE

RECEIVED MAY 28, 1927

PUBLISHED OCTOBER 5, 1927

When in 1844 Claus¹ discovered ruthenium, he prepared two double chlorides with potassium, to which he assigned the formulas K_2RuCl_5 and K_2RuCl_6 . The first was formed when the precipitated oxide of ruthenium, or the volatile tetroxide, was dissolved in hydrochloric acid and treated with potassium chloride; the second when aqua regia was used. This was quite in harmony with salts of the other platinum metals. Claus also assigned the probable formula of $RuCl_2$ to the compound giving a conspicuous blue color when ruthenium solutions are treated with zinc, hydrogen sulfide or other strong reducing agents.

Later² it was shown that the supposed K_2RuCl_6 was a nitroso salt, K_2RuCl_5NO , which contains nearly the same percentage of ruthenium. The error of Claus was occasioned by his having determined the chlorine only by loss, and by having considered the atomic weight of ruthenium as 104.57.

The first salt has since the days of Claus passed for K_2RuCl_6 , a pentachloro-ruthenite, though the corresponding cesium and rubidium salts have appeared to be monohydrates, and a monohydrate of the potassium salt has also been described.³ No efforts to oxidize this salt to K_2RuCl_6 have been effective.

Later, Howe⁴ described a new monohydrate of K_2RuCl_5 , which differed very markedly from the former salt in properties, especially in stability toward hydrolysis and in being converted into K_2RuCl_6 by the action of chlorine. This was formed from the earlier K_2RuCl_5 by boiling with dilute alcohol in acid solution, and was called an "aquo" salt. The corresponding rubidium and cesium salts were also prepared, as well as similar salts with bromine⁵ in the place of chlorine. Attention was called to the apparent isomerism between these two series of pentachloro-ruthenites.

The composition of the blue compound, supposed by Claus to be $RuCl_2$, was considered by Joly⁶ to be $RuCl_2OH$, but in our work in this Laboratory⁷

we satisfied ourselves that the compound contains bivalent ruthenium, and is RuCl_2 as Claus inferred, or at least $(\text{RuCl}_2)_x$. Remy⁸ has more recently considered it to contain univalent ruthenium, basing his opinion on its being formed by the reduction of K_2RuCl_6 , two units, as measured by the action of sodium amalgam. Zintl and Zaimis⁹ also assume univalent ruthenium in the blue solution, basing their view on the potentiometric titration of " RuCl_3 " with CrSO_4 or $\text{Ti}_2(\text{SO}_4)_3$, where with one equivalent they obtain a pale yellow solution, while with the next drop the blue begins to appear.

There are thus two problems insufficiently cleared up in connection with the chlorides of ruthenium, (1) the apparent isomerism in the K_2RuCl_6 series and (2) the valence of ruthenium in the blue compound.

Aoyama¹⁰ proposed calling the original K_2RuCl_6 the *alpha* salt, the dehydrated "aquo" salt *beta*, and added a third isomer, formed by the dechlorination of the hexachloro salt, K_2RuCl_6 , in hydrogen chloride gas, which he called a *gamma* salt. Gutbier,¹¹ however, showed that the *beta* and *gamma* salts are identical, and that both, when dissolved in dilute HCl , crystallize out as the "aquo" salt. The *alpha* and *beta* salts he considered to be isomers.

Briggs¹² accounts for the seeming isomerism by assigning the formula $2\text{K}_2\text{RuCl}_6 \cdot 3\text{H}_2\text{O}$ to the "aquo" salt. He states that the water should be weighed directly and not determined by loss, and that the salt must be heated in oxygen, since heating in air gives low results for the water. It is quite true that heating in air gives lower results than heating in oxygen, but the results in air check, especially in the case of the cesium salt, for the formula originally proposed for the "aquo" salt, $\text{Cs}_2\text{RuCl}_6 \cdot \text{H}_2\text{O}$. When heated in oxygen, ruthenium is slightly oxidized to the volatile tetroxide, which may account for the higher results of Briggs.

The reaction between hydrochloric acid and ruthenium tetroxide has been studied by a number of workers in the effort to throw light upon the chlorides. When the volatile tetroxide is collected in hydrochloric acid and potassium chloride added, the ordinary pentachloro salt is obtained, with the ratio K_2RuCl_6 , and this has generally been accepted as containing trivalent ruthenium, though there has been but a single attempt¹³ to verify this. Howe¹⁴ found that by the action of a solution of cesium chloride in concentrated hydrochloric acid a salt was obtained with the formula $\text{Cs}_2\text{RuO}_2\text{Cl}_4$, which is quite unstable; a similar osmium salt was obtained

by Wintrebert.¹⁵ The free acid of the ruthenium salt, $\text{H}_2\text{RuO}_2\text{Cl}_4 \cdot 3\text{H}_2\text{O}$, was prepared by Aoyama¹⁰ by the action of hydrogen chloride gas on the tetroxide. Krauss¹⁶ let RuO_4 act on hydrochloric acid and potassium iodide and estimated the liberated iodine, finding that the ruthenium was reduced five units, that is, apparently, to K_2RuCl_5 . On the other hand, he^{16a} and others¹⁷ have obtained hexachloro-ruthenates, M_2RuCl_6 , either directly from RuO_4 or from the K_2RuO_4 in the peroxide melt; but the conditions of formation of the hexachloro-ruthenates have not been reproducible, and treatment of the "aquo" salts with chlorine has been relied on to prepare these salts. The hexabromo salts have been prepared in an analogous way.

Some two years ago, Charonnat¹³ suggested that the true formula for the ordinary pentachloro salt is $\text{K}_2\text{RuCl}_5\text{OH}$, basing his view upon the action of this salt on potassium iodide, and on the formation of the "aquo" salt by the action of hydrochloric acid on the oxalato-ruthenite, $\text{K}_3\text{Ru}(\text{C}_2\text{O}_4)_3$, in which the ruthenium is undoubtedly trivalent. Owing to lack of any details or analyses, and to the fact that most other ruthenium salts give pentachloro salts on treatment with hydrochloric acid, his view, though correct, has not obtained recognition; to Charonnat belongs the credit for the final solution of this perplexing problem. The fact that the pentachloro salt liberates iodine from potassium iodide has long been known, and Gall and Lehmann¹⁸ have studied this reaction with a view to its analytical possibilities. They have concluded that there is an equilibrium, $\text{RuCl}_3 + \text{HI} \rightleftharpoons \text{RuCl}_2 + \text{HCl} + \text{I}$, which seems to be the case.

This reaction between the pentachloro salt and potassium iodide has recently been worked on in this Laboratory in the effort to complete the third step¹⁹ in the determination of ruthenium, namely, to determine the ruthenium in the RuO_4 distillate. Failing to obtain satisfactory results with potassium iodide, evidently because of the above equilibrium, stannous chloride was tried, and in this work the surprising result was obtained that both K_2RuCl_5 and K_2RuCl_6 were each reduced one unit, and each gave the "aquo" salt on its reduction. In other words, *the valence of ruthenium is four, not only in K_2RuCl_6 , but also in what has always passed for K_2RuCl_5* . The formula of the latter salt proves to be $\text{K}_2\text{RuCl}_5\text{OH}$, as suggested by Charonnat, and it is a one-fourth hydrolyzed hexachloro-ruthenate. This was established both by analysis and also by recrystallization. $\text{K}_2\text{RuCl}_5\text{OH}$ was recrystallized from very concentrated hydrochloric acid and K_2RuCl_6 obtained, while when K_2RuCl_6 was re-

crystallized from a less concentrated hydrochloric acid (under 6–8 *N*), the product was K_2RuCl_5OH . Since this is the ordinarily obtained compound of ruthenium, it would seem probable that the hydrated oxide of ruthenium, usually considered to be $Ru_2O_3 \cdot xH_2O$, is really $RuO_3 \cdot xH_2O$, since its solution always leads to H_2RuCl_5OH .

This also clears up the formation of the "aquo" salt, which is now to be recognized as the ordinary salt of trivalent ruthenium. Of the many different substances used in its formation,²⁰ such as alcohol, glucose, stannous chloride, etc., all are reducing agents, and the reaction is merely the reduction of quadrivalent to trivalent ruthenium. In some cases, as with alcohol, the reduction is slow, and has often failed to go to completion, resulting in impure salts and aberrant analyses. This also explains the ready oxidizability of the "aquo" salt to the hexachloro salt by chlorine, and why the hexachloro salt could not be formed from the pentachloro salt by oxidation.

It further follows from this work that the ruthenium in the blue solution is bivalent, since it is formed by reducing $Ru^{IV}Cl_5OH$ (H_2RuCl_5OH) two units. The yellow solution obtained by Zintl and Zaimis⁹ by its reduction one unit was the solution of the trivalent "aquo" salt.

The following chloro salts of ruthenium would thus seem to be well established; in most of the cases the corresponding bromo salts have also been prepared and are wholly analogous.

A. $M_2Ru^{VI}O_2Cl_4$ ($M = H, Rb, Cs$); the hydrogen salt formed by the action of gaseous hydrogen chloride on RuO_4 ; the rubidium and cesium salts by the action of rubidium or cesium chloride solution in very concentrated hydrochloric acid on RuO_4 .

B. $M_2Ru^{IV}Cl_6$ ($M = NH_4, K, Rb, Cs$); formed by the action of chlorine on $M_2Ru^{III}Cl_5 \cdot H_2O$; by action of very dilute cold hydrochloric acid on the K_2RuO_4 melt;²¹ by recrystallization of $M_2Ru^{IV}Cl_5OH$ from concentrated hydrochloric acid.

B(a). $Cs_2Ru^{IV}Cl_6 \cdot H_2O$; formed by the action of a solution of cesium chloride on a solution of RuO_4 in hydrochloric acid;²² efforts to obtain the rubidium and potassium hydrated salts in pure form were not successful.

C. $M_2Ru^{IV}Cl_5OH$ ($M = NH_4, K, Rb, Cs$); formed whenever a solution of RuO_4 in hydrochloric acid (except in very concentrated acid) is treated with an alkali chloride; when a solution of a ruthenate, M_2RuO_4 , is treated with hydrochloric acid; when the solution of any oxide of ruthenium, except one precipitated from the "aquo" salt, in hydrochloric acid is treated with an alkali chloride; when a hexachloro-ruthenate,

²² Ref. 16 (a), p. 117.

$M_2Ru^{IV}Cl_6$ is recrystallized from hydrochloric acid, unless the latter is very concentrated.

D. $M_2Ru^{III}Cl_6 \cdot H_2O$ ($M = NH_4, K, Rb, Cs$); formed by the reduction of any of the salts of quadrivalent ruthenium in hydrochloric acid solution by alcohol, oxalic acid or other organic substance, stannous chloride or potassium iodide; also by the spontaneous oxidation in the air of the blue solution of bivalent ruthenium.¹⁷ These are the only crystalline salts of trivalent ruthenium, and are properly called pentachloro-ruthenites (rutheniat of Gutbier). It might be wise, however, to continue the use of the term "aquo"-ruthenites to distinguish them from the old pentachloro-ruthenites, which now become pentachloro-(hydroxy-)ruthenates.

E. $M_2Ru^{III}Cl_6$; formed only by the dehydration of the "aquo" salt, or dechlorination of the hexachloro-ruthenates (Aoyama's *gamma* and *beta* salts). These have not been obtained in a crystallized form and cannot, of course, be regarded as definite salts with a coordination number of five, but are of the same nature as the K_2SO_4 and $Al_2(SO_4)_3$ in dehydrated alum.

In all of these salts ruthenium has a coordination number of six and thus one of the few remaining compounds with an apparent coordination number of five is deleted from the list.

Experimental Work

The starting point of all the work described in this paper was ruthenium tetroxide, distilled by a current of chlorine from an alkaline sodium hypochlorite solution of various ruthenium compounds and residues. As the material was free from osmium, the purity of the ruthenium obtained was assured. The hypochlorite solutions were placed in a tubulated retort, chlorine (from a chlorine cylinder) led in until the deep red color of the ruthenate changed into the golden yellow of the tetroxide, when the chlorine stream was cut off and the retort rapidly heated to boiling. The RuO_4 passed over with the steam and was collected in a small amount of concentrated hydrochloric acid in an Erlenmeyer flask immersed in ice-water. With care no loss of the tetroxide occurred. On standing, the RuO_4 was completely converted into either H_2RuCl_6 or H_2RuCl_5OH , according to the concentration of the hydrochloric acid. If the amount of the RuO_4 is small, it dissolves in the hydrochloric acid and the conversion into the chloride is rapid; if the amount is larger, it collects in drops of liquid RuO_4 , which dissolve only slowly. The solutions of the chloride were concentrated to any desired degree and the salts formed by the addition of alkali chloride. If the solutions were quite concentrated, the salts precipitated on addition of the chloride; if more dilute the crystalline salts were obtained on evaporation. A similar procedure was used for recrystallization of the salts, these being dissolved in hot

water sufficiently acidified with hydrochloric acid to prevent further hydrolysis. For the preparation of the "aquo" salts, solutions of quadrivalent ruthenium, either of the acid or of the salts, were boiled in rather dilute condition with about one-fourth their volume of alcohol until the lightening of the color indicated reduction to trivalent ruthenium. Often the reduction was not complete, as was later revealed both by color and by analysis of the salts.

It has been supposed by some that the "aquo" salt is converted into the M_2RuCl_6OH by the action of concentrated hydrochloric acid, and in some of the earlier work in this Laboratory there seemed to be indication of this. To test this point, a particularly pure sample of $K_2Ru^{iii}Cl_6 \cdot H_2O$ was dissolved in dilute hydrochloric acid and twice evaporated on a hot-plate with concentrated hydrochloric acid to crystallization. The only crystals obtained were those of the original "aquo" salt, and the solution retained the color of the pure "aquo" salt. Later it was found that in cases where the quadrivalent salt had apparently been obtained from the trivalent salt by the action of hydrochloric acid, the latter salt had been originally contaminated by the quadrivalent salt owing to incomplete conversion by alcohol.

The difficulty of *complete* conversion of the salts of the three series, M_2RuCl_6 , $M_2Ru^{iv}Cl_6OH$ and $M_2Ru^{iii}Cl_6 \cdot H_2O$, into one another should be emphasized; it results in great difficulty in preparing pure salts for analysis, and is undoubtedly responsible for many irregularities in analytical figures.

The analyses were carried out, as usual, in this Laboratory, by heating the salt in a stream of purified and dried hydrogen and collecting the evolved hydrogen chloride in a solution of silver nitrate. The combustion tube was of Jena glass, one end drawn out somewhat, and so bent as to dip directly into the silver nitrate solution. It was heated in an electric combustion furnace with the top so hinged that the tube could be inspected, if desired, during heating. The salt was contained in a small boat of fused quartz. The precipitated silver chloride was collected and weighed in a Gooch filter and dried in an electric oven at 110° . Thus far the analysis gives, from the loss in weight in the boat, the $Ru + 2MCl$, and, from the weight of the silver chloride, the chlorine "connected with the ruthenium."²³ Any water or hydroxyl present will appear as loss. As already noted, Briggs has called attention to the fact that such a water determination is unreliable, since all the errors fall on the loss. This is brought out by an inspection of a large series of analyses, where the loss

²³ In most cases, the residue in the boat was treated with hot water, the ruthenium filtered, burned and reheated in hydrogen; the alkali chloride evaporated in a fused quartz crucible and weighed. Frequently, as Briggs has pointed out, a little of the alkali chloride is not dissolved out by a single extraction, and hence the ruthenium results are often a little high and those for the alkali chloride correspondingly low. A number of experiments showed that this error was generally less than 0.1%.

shows considerable variation. Further, of course, it does not discriminate between water and hydroxyl. For this reason, in a number of cases, the water from the hydroxyl group was determined directly by absorption in phosphorus pentoxide. As it was necessary to heat the salt to a fairly high temperature to insure the decomposition of the hydroxyl, the chlorine connected with the ruthenium was also evolved. In earlier work this chlorine was retained by passing over heated silver foil; more recently anhydrous sodium carbonate was used. The front of the combustion tube was filled for a distance of ten centimeters with recently heated, anhydrous sodium carbonate, and a layer of the same was placed over the salt in the combustion boat. Air was drawn through the tube by a suction pump, being dried by a calcium chloride tube and a phosphorus pentoxide tube before entering the combustion tube. The absorption phosphorus pentoxide tube was guarded by a calcium chloride tube and two sulfuric acid drying bottles, these serving also as a gage for the velocity of the air current. Several blanks were run before each series of analyses. The temperature used varied, in some cases being sufficiently high to fuse the sodium carbonate. This method was tested on $\text{Rb}_2\text{MnCl}_4 \cdot 2\text{H}_2\text{O}$ and found to be accurate.

In considering the experimental work on each of the three series of chloro salts, the establishment of the formula has been first given, followed by the results of *all* the analyses made, as well as the origin of the salts, except in those cases in which there were evident analytical errors. It has been thought best to give all the analyses, in order that the material may be available to others who are working in this field and who may find some different interpretation.

Work on Series B; the Hexachloro-ruthenates, M_2RuCl_6

As these salts have already been well established as being formed by the action of chlorine on the "aquo" salts, it was further desirable only to determine whether they could also be formed by the action of concentrated hydrochloric acid on the pentachloro-hydroxy-ruthenates, thus confirming the constitution of the latter, and also to determine the amount of reduction in valence by the action of stannous chloride. The ordinary pentachloro-ruthenate (actually $\text{K}_2\text{RuCl}_5\text{OH}$) was recrystallized from concentrated hydrochloric acid. The crystals obtained resembled in every way those of the hexachloro-ruthenate, K_2RuCl_6 .

Anal. Calcd. chlorine removable by hydrogen: for K_2RuCl_6 , 36.13; for $\text{K}_2\text{RuCl}_5\text{OH}$, 28.43; for K_2RuCl_6 , 29.78. Found: 34.89.

It is probable that the conversion into the hexachloro salt was not complete; the analysis of a second crop of crystals, the hydrochloric acid having become less concentrated by evaporation, gave only 27.85% of chlorine, corresponding to the pentachloro-hydroxy salt.

Titration of the recrystallized salt with stannous chloride to the "aquo" salt: Theoretical for reduction of one valence, 25.89; for reduction to bivalent ruthenium, 12.94. Found: ruthenium (six titrations), 24.10 to 25.31%.

This established the fact that the hexachloro salt is formed from the pentachloro

salt by recrystallization from concentrated hydrochloric acid; hence, since oxidation under these conditions is out of the question, the valence of ruthenium in the pentachloro salt is the same as in the hexachloro salt, that is, *four*. From this standpoint the pentachloro salt is to be looked on as a one-fourth hydrolyzed hexachloro salt.

^a (23), (25): K₂RuCl₅OH recrystallized from concentrated hydrochloric acid.

^b (24). Precipitated from concentrated solution of the "aquo" salt by chlorine.

^c Antony's salt (Ref. 21) was prepared by the action of very dilute hydrochloric acid on a potassium ruthenate, K₂RuO₄, melt containing potassium chlorate, and concentrated in a vacuum in the cold. Under these conditions neither further reduction nor hydrolysis took place.

Work on Series C; the Pentachloro-hydroxy-ruthenates, M₂Ru^{iv}Cl₅OH

In establishing the constitution of these salts, the crucial point, aside from the ordinary analysis, is the determination of the water and of the change of valence by the action of stannous chloride or potassium iodide.

The Potassium Salt.—In the two most reliable preparations (8) and (10), second and third crop recrystallizations, we have, as regards water directly determined by absorption in phosphorus pentoxide, the following results.

Anal. Calcd. for K₂RuCl₅OH: H₂O, 2.40; for K₂RuCl₅.H₂O: H₂O, 4.54. Found: 2.79, 2.23.

Results obtained as regards valence, by reduction with stannous chloride to the "aquo" salt:

Theoretical for reduction of one valence, 27.18. Ruthenium (seven²⁴ titrations), 24.05 to 26.64 per cent. The "aquo" salt (trivalent ruthenium) gives no reduction.

In the reduction by potassium iodide, no satisfactory end-point could be obtained, but the results (given below) point also to a reduction of one valence.

The Rubidium and Cesium Salts, Rb₂RuCl₅OH and Cs₂RuCl₅OH.—No new direct determinations of water were made with these salts, and little reliance can be placed on the water analyses of the earlier work, though the existence of a monohydrate of the cesium salt and possibly of the rubidium salt is distinctly pointed out. These salts are too slightly soluble for titration work.

²⁴ Two titrations giving 20.12 and 19.89 are omitted here as the salt was evidently contaminated by "aquo" salt.

These results, and numerous other titration experiments with the free acid (given in the following paper) seem to leave no doubt but that the salts formed when RuO_4 is dissolved in hydrochloric acid and an alkali chloride added, contain quadrivalent ruthenium, and that, unless the acid is very concentrated, the formula of such salts is $\text{M}_2\text{RuCl}_4\text{OH}$. The same is probably true regarding the bromo salts, as they seem to resemble the chloro salts in every particular.

^a Reduction by stannous chloride, iodine-starch indicator; the figures found represent the percentage of ruthenium in the salt, assuming the ruthenium to be reduced one valence.

^b Reduction by KI and titration with $\text{Na}_2\text{S}_2\text{O}_3$ solution and starch indicator. No satisfactory end-point was obtained, and hence these figures can be looked on as only approximate. The results, however, point very clearly to a reduction of one valence, that is, from quadrivalent to trivalent ruthenium.

Origin of salts

(1), (2): Recrystallized salt; dissolved in hot, dilute hydrochloric acid and concentrated acid added to about 6 N; brilliant black crystals.

(3), (4): Crystallized out from mother liquor of (1) while evaporating on hot plate; similar to (1).

(5): Recrystallized from dilute hydrochloric acid; brown.

(6): Recrystallized from 6 N hydrochloric acid on hot plate; black crystals but probably contaminated by a little "aquo" salt.

(7): Solution of RuO_4 in rather strong hydrochloric acid precipitated hot by KCl solution; fine black powder with bluish tint.

(8): Recrystallized salt, second crop; about 5 N acid.

(9): Evaporated filtrate from K_2RuCl_5 formed by leading chlorine into solution of the "aquo" salt; strong hydrochloric acid; evidently contained some unhydrolyzed K_2RuCl_5 .

(10): Third crop from (8).

With the above may be compared the original analyses of the same salt by Claus,²⁵ and the analyses by Miolati and Tagiuri.⁸

^a Crystallized from evaporated solutions of H₂RuCl₅OH and cesium chloride; about 5 N hydrochloric acid.

^b Recrystallized from dilute hydrochloric acid; earlier analyses.²⁶

^c Crystallized from hot solution of H₂RuCl₅OH and cesium chloride in dilute hydrochloric acid on cooling. The water of this analysis corresponds to a monohydrate, Cs₂RuCl₅OH·H₂O (theory, H₂O = 6.04). (Analysis (17) of the rubidium salts points in the same direction, though this salt lost only 0.27 at 145°.) As the solution was only weakly acid, it is not unlikely that such a salt may have crystallized out, but the amount of the salt was too small to make a complete analysis, and this evidence is too slender to establish the existence of a monohydrate.

²⁵ Ref. 1, p. 353.

²⁶ Only a single new analysis of this salt was made, but for the sake of completeness

Work on Series D; the Pentachloro-ruthenites, $M_2Ru^{III}Cl_5H_2O$ (the "Aquo" Series of Howe and Beta Series of Aoyama)

The Potassium Salt.—Briggs¹² considers this salt to have the formula $2K_2RuCl_5 \cdot 3H_2O$, basing his view on his determination of water by loss in two analyses and one determination of water by combustion in oxygen. The recorded analyses of this salt are given below.

^d Loss.

Stannous chloride, even in excess, was found to have no action on this salt; 0.1785 g. of salt was titrated with 0.1 *N* stannous chloride; 0.14 cc. was used, equivalent to 0.81% of quadrivalent ruthenium, thus indicating the presence of a very small quantity of unreduced salt, as generally happens in the reduction by alcohol.

The Cesium Salt, $Cs_2RuCl_5 \cdot H_2O$.—Since the "aquo" salts are not easy to prepare in a state of assured purity, it was hoped to get better results with the cesium salt, which is less soluble. RuO_4 was dissolved in hydrochloric acid, and the diluted solution boiled with alcohol. This solution was then either treated with cesium chloride and evaporated to crystallization, or was first evaporated and precipitated by a solution of cesium chloride. At times the salt was recrystallized from hydrochloric acid of varying strengths, and again solutions of the salt were precipitated by alcohol. The salt was sometimes obtained as fine, rose prisms similar to the potassium salt; sometimes "whetstone" crystals were obtained, similar to uric acid, or these may have been possibly a variety of the rose prisms; the rose prisms were generally accompanied by minute spherules, often adhering to the prisms and of a paler color, or sometimes as a dark powder; in one case (38) a sample consisting almost entirely of rose prisms recrystallized as apparently pure spherules. When precipitated by alcohol the salt was generally obtained as a buff, felt-like mass which under high powers of the microscope seemed to be made up of very minute rose prisms. Efforts to separate different forms of crystals by fractional crystallization were unsuccessful. As will be seen from inspection of the analyses, there are frequently considerable variations, but none of these are large enough to indicate the presence of an impurity differing materially in composition. In particular, no evidence was found of any sesquihydrate, as postulated by Briggs. The water present in the salt could not have been greater than the loss after accounting for the Cl₅, Ru and 2CsCl directly weighed. This loss in no instance exceeded 3.76%, and averaged 3.02 (16 analyses); theory requires 3.20 for the monohydrate, and 4.73 for Briggs'

it is worth while to put the earlier analyses on record in this connection; the composition of the salt was at that time supposed to be $Rb_2Ru^{III}Cl_5 \cdot H_2O$. [Howe, *THIS JOURNAL*, 23, 786 (1901).]

formula for a sesquihydrate. The average of three water determinations by absorption in P_2O_5 is 3.35.

It would thus appear that the formula $Cs_2RuCl_5 \cdot H_2O$ is established, and it is probable that the general formula for the chloro-ruthenites is $M_2RuCl_5 \cdot H_2O$, in which the ruthenium has a valence of *three* and a coordination number of *six*.

Origin of salts

(a): Precipitated by alcohol from blue solution (electrolytically reduced) of $RuCl_3$ which had spontaneously oxidized in presence of hydrochloric acid and cesium chloride; buff powder.²⁶

(b): From evaporation of a solution of Cs_2RuCl_5 containing alcohol; rose prisms.²⁶

(26): From cold conc. hydrochloric acid; fine brown powder; largely "whetstones."

(27): From cold conc. hydrochloric acid; largely minute rose prisms.

(28): From warm conc. hydrochloric acid; dark brown powder; mainly rose prisms.

(29): From hot conc. hydrochloric acid; dark buff; largely spherules with prisms.

(30): From hot conc. hydrochloric acid; buff; chiefly rose prisms.

(31): Precipitated by alcohol; fine buff powder; chiefly rose prisms.

(32), (34): Precipitated by alcohol; fine buff felt; minute rose prisms.

(33): Precipitated by alcohol; darker buff felt than (32) and (34); minute rose prisms.

(35): Solution of RuO_4 in hydrochloric acid diluted and boiled with alcohol until color lightened, cesium chloride added, evaporated and cooled; fourth crop of crystals; almost pure rose prisms.

(36): Same, third crop; rose prisms with very small amount of dark powder.

(37): Same, first crop; rose prisms (?) in whetstone form.

(38): From solution of rose prisms containing some spherules; alcohol added and evaporated on warm plate in vacuum; apparently pure spherules. It may be noted that salts (29) and (38), both consisting largely of spherules, vary rather widely in analysis from theory, but in opposite directions.

Summary

The work described in this paper indicates that there is no isomerism among the known complex chlorides of ruthenium; that what has been

considered the series $M_2Ru^{III}Cl_6$ containing trivalent ruthenium, in reality contains quadrivalent ruthenium, of formula $M_2Ru^{IV}Cl_6OH$; that what has been considered an "aquo" series is actually the ordinary series of trivalent ruthenium, but always crystallizing as a monohydrate of formula $M_2Ru^{III}Cl_6 \cdot H_2O$. In all of these salts the coordination number of ruthenium is six. Also Claus' view that the blue solution of reduced ruthenium contains the metal in bivalent form is again confirmed.

CONTRIBUTIONS TO THE STUDY OF RUTHENIUM. XI A VOLUMETRIC ESTIMATION OF RUTHENIUM

BY JAS. LEWIS HOWE

RECEIVED MAY 28, 1927

PUBLISHED OCTOBER 5, 1927

The estimation of ruthenium, except in crystallized compounds, has always been difficult. Neither hydrogen sulfide nor metals, as zinc or magnesium, precipitate ruthenium completely from any of its solutions, and while it can be precipitated by caustic alkalies, it is impossible to wash the gelatinous precipitate free from salts. Somewhat more than a year ago it was found in this Laboratory¹ that ruthenium in a finely divided form could be completely dissolved in alkaline sodium hypochlorite solution and the ruthenium distilled quantitatively from this solution as ruthenium tetroxide after treatment with a stream of chlorine; but no simple method was found by which the ruthenium in the distillate could be estimated.

The reduction of quadrivalent ruthenium by stannous chloride, as described in the preceding paper, affords a solution of the problem. The volatile ruthenium tetroxide is condensed in concentrated hydrochloric acid, preferably in a small Erlenmeyer flask surrounded by ice. A two-necked Wolff bottle with ground-glass joints may be used if the amount of ruthenium is considerable, but with small quantities (as is usual in the analysis of alloys) we have found no difficulty in condensing all the RuO_4 in an Erlenmeyer flask. After all the ruthenium tetroxide has been reduced by the hydrochloric acid, which is apparent by the disappearance of any drops of liquid ruthenium tetroxide, the solution is boiled until all absorbed chlorine has been eliminated. It is then titrated with a solution of stannous chloride of about 0.05 *N* strength. The stannous chloride solution is standardized immediately before using against 0.1 *N* iodine solution with starch indicator.

In titrating the ruthenium solution, the stannous chloride can be added until the dark, brownish-red solution of quadrivalent ruthenium changes to the light red or rose of trivalent ruthenium. As this end-point is often

¹ Howe and Mercer, *THIS JOURNAL*, 47, 2926 (1925).

not sharp, it is better to use a slight excess of stannous chloride, add starch paste and titrate back with iodine solution. Since the ruthenium of ruthenium tetroxide is reduced only four units by hydrochloric acid, it does not matter whether the hexa- or the pentachloro salt is formed, as both contain quadrivalent ruthenium.² This titration was carried out in concentrated hydrochloric acid, as well as in quite dilute solutions; in hot solutions and in cold solutions; by adding only just sufficient excess of stannous chloride to make an iodine-starch reaction visible, and by adding a large excess of stannous chloride; in no case was there any evidence of conditions of titration making any difference in the results. Titrations of K_2RuCl_6 and of K_2RuCl_5OH gave the same results, as described in the previous paper. Reduction does not go beyond the rose trivalent ruthenium, as was shown by adding a large excess of stannous chloride solution and allowing it to stand for several days. No change was apparent in the solution, nor in any case was there any sign of blue or green, which would have indicated the presence of bivalent ruthenium.

It should be noted that in almost every case the amount of stannous chloride required for reduction was somewhat lower than that called for by theory. Just why this is, is not apparent.³ For this reason, the method cannot be recommended for accurate determination of ruthenium, but it affords a ready method for the approximate evaluation of ruthenium solutions, and also for the determination of ruthenium where only a small amount is present.

Experimental Work

A solution of ruthenium tetroxide in hydrochloric acid was prepared, containing 4.91 mg. of ruthenium per cc., as determined by the evaporation of 10 cc. in a quartz boat, heating in the air and reducing in hydrogen. The ruthenium was reoxidized and reduced without change in weight. Two cc. portions of this solution were then titrated with stannous chloride solutions, varying from 0.08 to 0.03 *N*. As this solution was used as a check in titrating the chlororuthenate salts, it was actually titrated many times. The results, omitting only three which were manifestly in error, are as follows.

TABLE I

RUTHENIUM FOUND, MG. PER CC. IN TEST SOLUTION CONTAINING 4.91 MG.

4.81, 4.58, 4.60, 4.93, 4.98 (excess $SnCl_2$), 4.72, 4.62, 4.81 (in concd. HCl), 4.60, 4.82, 4.82 (very dilute HCl), 5.05, 4.65, 4.94 (warm), 4.75, 4.68, 4.85, 4.82, 4.74 (excess $SnCl_2$ in concd. HCl , hot); average of 19 titrations, 4.766.

² Howe, *THIS JOURNAL*, 49, 2381 (1927).

³ It is possible that it may have been due to the small quantities used, and that the results might have been made to approach the theoretical more closely by using large amounts, or by titrating with more dilute solutions. A more probable explanation is that there was a small quantity of trivalent ruthenium present, which would not be recognized as such by gravimetric analysis, but would affect the volumetric analysis.

TABLE I (Concluded)

AN INVESTIGATION OF THE REACTION OF ALUMINUM WITH THE AMMONIUM SALT OF AURINTRICARBOXYLIC ACID UNDER DIFFERENT EXPERIMENTAL CONDITIONS, AND ITS APPLICATION TO THE COLORIMETRIC DETERMINATION OF ALUMINUM IN WATER

BY JOHN H. YOE AND WILLIAM L. HILL

RECEIVED JUNE 3, 1927

PUBLISHED OCTOBER 5, 1927

Recently Hammett and Sottery¹ described a new qualitative test for aluminum in which the principal reagent is the ammonium salt of aurintricarboxylic acid, now sold under the trade name, "Aluminon." These authors studied the behavior of several of the elements and ions commonly dealt with in qualitative analysis which would be likely to interfere with the test. Middleton² and later Corey and Rogers³ have studied the behavior of several of the less common elements with "Aluminon." A brief summary of the results with respect to the final solution follows.

1. Silicic acid, salts of antimony, bismuth, lead, mercuric mercury, stannic tin and titanium give white precipitates. The qualitative test may be made without a separation.

2. Salts of cadmium, chromium, cobalt, germanium, indium, manganese, nickel, rare earths, thallium, thorium, zinc and zirconium give no precipitates.

3. Ferric salts produce a reddish-brown precipitate which is stable under the same conditions as the aluminum lake. Beryllium gives a lake which cannot be distinguished from aluminum. The gallium lake

⁴ For details see ref. 2.

¹ Hammett and Sottery, *THIS JOURNAL*, **47**, 142 (1925).

² Middleton, *ibid.*, **48**, 2125 (1926).

³ Corey and Rogers, *ibid.*, **49**, 216 (1927).

dissolves with difficulty in 2 *N* ammonium carbonate, leaving a red-colored solution.

4. Phosphates tend to prevent the formation of the lake, and reducing agents such as hydrogen sulfide, sulfur dioxide, etc., destroy the color.

Lundell and Knowles⁴ adopted the "Aluminon" reagent in preference to sodium alizarin sulfonate⁵ since "it requires less time and is more sensitive, particularly in the presence of precipitates such as stannic hydroxide." They found that the final color is unsatisfactory when the ammonium hydroxide-carbonate solution is added too rapidly, or in large excess; also when the amount of aluminum is very small and proportionately large amounts of precipitates are present.

A further investigation seemed well worth while, having for its purpose the study of the effects of changing the several factors in order to determine the optimum conditions for the reaction, with a view towards making a more general application in the field of quantitative analysis.

Apparatus and Reagents

The dark-room consisted of a wooden box of convenient dimensions mounted on a table. The inside of the box was painted a dull black and a curtain of heavy black cloth covered the open side and extended almost to the floor. The source of light was a Bausch and Lomb daylight lamp which was supported on a platform rigidly attached to the wall of the box. The legs of the lamp fitted snugly into holes in the platform and the source of light was thus kept in one position throughout the course of the work. Three strips of wood were screwed to the floor of the box in such a manner that they served as guides for placing the colorimeter always in the same position with respect to the lamp. A colorimeter of the Kennicott-Campbell-Hurley type was employed.

Carefully matched Nessler tubes of 50cc. capacity were employed, the dimensions of the tubes being those established by the American Public Health Association. The tubes were also marked to indicate a volume of 30 cc. The reagents were measured out with precision pipets of the desired capacity. The pipets were labeled so that a given pipet was always used for one solution only, and where necessary these were calibrated.

The purest chemicals obtainable were used in the preparation of the reagents, and the solutions were stored in the dark in Pyrex flasks which were carefully cleaned and steamed out just before being filled. Comparison solutions to which aluminum had not been added gave as a final color the characteristic yellow of the dye.

Reagents

1. Hydrochloric acid, 1 *N* and 4 *N*. 2. Nitric acid, 5 *N*. 3. Ammonium hydroxide, 5 *N*. 4. Ammonium hydroxide-carbonate solution; 250 g. of ammonium carbonate dissolved in a liter of 6 *N* ammonium hydroxide. 5. Ammonium carbonate solution, 5 *N*. 6. Sodium hydroxide solution, 6 *N*. 7. Ammonium acetate solution, 3 *N*. 8. Standard aluminum chloride solution; 8.952 g. of pure aluminum chloride hexahydrate⁶ dissolved in distilled water and diluted to a liter. The mean of three

closely agreeing analyses, carried out according to the method of Blum,⁷ showed that 1 cc. contained 0.999 mg. of aluminum. Ten cc. of this stock solution was diluted to a liter and mixed thoroughly. One cc. of the dilute solution contained 0.010 mg. of aluminum. 9. Solutions of the several salts which were used in studying the effects of ions were prepared so that 1 cc. would contain 10 mg. of the desired ion if the salt were completely dissociated. In the study of positive ions, chlorides or nitrates were used; in all other cases sodium salts were employed. 10. "Aluminon" reagent, 0.1% solution in water. The salt was obtained from the Fales Chemical Co., 74 Cortlandt St., New York City. 11. "Aluminon" reagent, 0.2% solution in water. 12. Methyl red, 0.05% solution in water. 13. Neutral litmus paper. 14. Starch solution, 1%. One gram of potato starch boiled in 100 cc. of distilled water for three hours, water being added from time to time to keep the volume at 100 cc. Transferred while hot to a sterilized, glass-stoppered bottle, and after allowing it to settle the clear supernatant liquid was pipetted out as needed.

Experimental

The order of addition of the reagents, as well as the quantities added, unless otherwise stated, was as follows. To the stated amount of aluminum in a Nessler tube were added 5 cc. of 1 *N* hydrochloric acid, 5 cc. of 3 *N* ammonium acetate and sufficient distilled water to bring the volume to the 30cc. mark. Then 5 cc. of the "Aluminon" reagent was added and the solution mixed thoroughly. It was allowed to stand for five minutes, reckoning the time from the beginning of the addition of the "Aluminon" to the beginning of the addition of the ammonium hydroxide, and 2 cc. of 5 *N* ammonium hydroxide and 10 cc. of 5 *N* ammonium carbonate were added slowly with constant stirring. The solution was diluted to 50 cc., mixed thoroughly and transferred to the colorimeter tubes just before comparison.

The measurements were carried out in such a manner that sufficient time was given for the operator's eyes to become adjusted to the dark before the readings were taken. Two "settings" of the colorimeter were made, one being made as the height of the adjustable column was increased, the other as its height was decreased. In order to obtain the best average value, the first reading was taken a few seconds before the end of the time interval and the second a few seconds afterwards. From the mean of the two readings the intensity was calculated by expressing the mean of the readings at the end of a given time interval as a percentage of the mean of the readings at the end of two minutes, the latter being considered as having an intensity of 100%. Beginning with the measurements on varying quantities of the reagents, the mean of the readings at the end of twenty-five minutes was adopted as the value corresponding to an intensity of 100%.

During the course of the earlier measurements a new standard was prepared for each comparison. However, it was found that considerable time could be saved by preparing a standard solution of the desired strength and allowing it to stand for several hours. After this period the rate of change of color intensity is small, and without appreciable error from this source a whole series of measurements could be made against the same standard. In order to obtain the reading corresponding to an intensity of 100%, 50 cc. of a fresh solution was prepared and allowed to stand for two minutes or twenty-five minutes, depending upon whether the results were to be expressed in terms of the intensity at the end of two minutes or that at the end of twenty-five minutes. At the end of this time the fresh standard was compared with the solution which had stood for several hours, the height of the column of the latter being taken as the reading

⁷ Blum, *THIS JOURNAL*, 38, 1282 (1916); also *Sci. Paper* No. 286, U. S. Bureau of Standards, 1916.

corresponding to an intensity of 100%. A similar comparison was made at the beginning of each series of measurements.

"Aging."—The decrease in color intensity with time after the addition of ammonium hydroxide, or "aging," was studied both in the light and in the dark. In both cases the solutions were allowed to stand in the colorimeter; in the former the colorimeter was removed from the dark room after each reading and placed in the diffused light of a well-lighted laboratory, while in the latter the colorimeter was left in the dark

○ 2 cc. NH_4OH in light; □ 5 cc. NH_4OH in light; ● 2 cc. NH_4OH in dark; ▲ 0.2% "Aluminon" in dark; △ 2 cc. $\text{NH}_4\text{OH}-(\text{NH}_4)_2\text{CO}_3$ in light.

of 0.1% solution, and when the ammonium hydroxide-carbonate reagent was used.

Effect of Varying the Quantities of the Reagents.—The quantities of the reagents were varied one at a time, all other conditions being kept constant. In each instance the temperature was 23° . All solutions were "aged" for 25 minutes and the intensity is given in terms of the intensity of the standard at the end of 25 minutes. The results are shown in Figs. 2 and 3.

Conditions During Lake Formation.—Three variable conditions were

room. The results are shown in Fig. 1. The results for two concentrations of ammonium hydroxide are given. When 1 cc. of ammonium hydroxide was added in the neutralization, in which case the final solution was just neutral to litmus paper, the color intensity was about 20% higher than when 2 cc. was used. For higher concentrations of ammonium hydroxide, Fig. 3 may be studied. Measurements were made on solutions containing different aluminum concentrations. The results were identical, and, unless otherwise stated, an aluminum content of 0.1 mg. has been adopted as the standard in all measurements. For comparison, curves are shown in Fig. 1 for "aging" when 0.2% "Aluminon" solution was employed instead

studied, namely, (1) the time allowed for the lake to form, (2) the temperature at which the lake was formed and (3) the volume of the solution at the time the lake was formed. In (2), Nessler tubes containing the mixture of aluminum, hydrochloric acid and ammonium acetate solutions were permitted to stand in a water-bath for ten minutes before the addition

Fig. 2.—Variation in quantities of reagents.

of the dye, which was also at the temperature of the bath. Upon the addition of the ammonium hydroxide, the Nessler tubes were removed from the bath and placed in the rack until time for comparison. The results are shown in Figs. 4 and 5.

Presence of Other Ions.—The stated quantities of the ions were added to Nessler tubes containing 0.1 mg. of aluminum just before the

addition of the hydrochloric acid. The intensity of solutions containing 150 mg. of iodide, nitrate, nitrite and sulfate ions, respectively, was sensibly the same as that of the standard containing only aluminum. The effects

Fig. 3.—Variation in quantities of reagents. ○ NH₄Ac; ● (NH₄)₂CO₃; △ NH₄OH.

of the orthophosphate ion and silica are shown graphically in Fig. 6, while that for iron is given in Table I. The intensity of the solution containing 0.01 mg. each of iron and aluminum was too weak for com-

TABLE I
EFFECT OF IRON ON THE COLOR INTENSITY

Mg. of iron	Mg. of aluminum	Intensity
0.00	0.10	100
.01	.10	100
.03	.10	121
.01	.01	?

TABLE II
EFFECT OF CERTAIN COMMON IONS ON THE COLOR INTENSITY

Ion	Intensity 1 mg. of ion	Intensity 10 mg. of ion
Cu ⁺⁺	100	...
CrO ₄ ⁻⁻	112	Too intense for comparison
Co ⁺⁺	110	Too intense for comparison
Mn ⁺⁺	117	Very turbid
Ni ⁺⁺	108	138
Ca ⁺⁺	102	Very turbid
Mg ⁺⁺	102	115
PO ₄ ⁻⁻⁻	(5 mg.) 107 (turbid)	Very turbid

parison in the colorimeter but comparison in the Nessler tubes showed a distinct difference. An attempt was made to prevent the iron lake from forming by the addition of citric acid, with the result that neither the iron nor the aluminum lake was formed in its presence. The results for several other ions which were studied in less detail are shown in Table II. The presence of 0.01 mg. of sulfur as sodium sulfide did not alter the intensity appreciably, but with 0.1 mg. present the intensity was reduced to 94.

Limits of the Test for Colorimetric Work.—With 0.001 mg. of aluminum in a 50cc. Nessler tube the color could not be distinguished from that of a "blank" which contained no aluminum. A faint pink was perceptible when 0.002 mg. of aluminum was present. The lake did not settle out with 0.5 mg. of aluminum present but the solution was too highly colored

for comparison with the colorimeter employed in this work. With 1 mg. of aluminum a slight coagulation was observed after one hour, with 3 mg. the lake had coagulated at the end of ten minutes, and with 5 mg. the coagulated lake had begun to settle at the end of ten minutes. In these

Fig. 4.—Time for lake formation and temperature.

Fig. 5.—Variation in volume at lake formation.

experiments 2 cc. of ammonium hydroxide was added. An increase in the quantity of alkali hastened the process of coagulation.

A few observations were made on the effect of adding starch as a pro-

TECTIVE COLLOID just before the addition of the ammonium hydroxide, with a view towards stabilizing the lake with the higher concentrations of aluminum. The results for 3 mg. of aluminum are summarized below.

Time in minutes	No starch added	1% starch solution added	
		5 cc.	10 cc.
10	Coagulated	Suspended	Suspended
20	Settled	Began coagulating	Suspended
180	Signs of coagulation

The effect of starch on the stability of the color intensity was determined using 0.1 mg. of aluminum.

Cc. of 1% starch solution added.....	0.00	0.5	1.0	5.0	10.0
Intensity of color after 25 minutes....	100	106	106	100	82

In the determination of the "sensitiveness" of the test, the experimental method of Horn and Blake⁸ was used. A series of five solutions was

Fig. 6.—Orthophosphate ion and silica.

prepared in marked Nessler tubes of 50cc. capacity, such that the aluminum content of each solution differed from the one immediately before it in the series by a constant amount, the concentration of aluminum in the third solution being that at which the sensitiveness was to be determined. After standing for 25 minutes the tubes were arranged out of their regular order, and four men, separately and unaided, attempted to rearrange them in their proper order. Several such sets of tubes were prepared in which the difference in aluminum content was constant for a given set, though differing from series to series, until finally a series was obtained which could barely be rearranged with certainty by four different persons. The aluminum increment in this series was taken as the amount

⁸ Horn and Blake, *Am. Chem. J.*, 36, 195 (1906).

of aluminum necessary to produce a difference in the color intensity barely perceptible with certainty at the concentration of the third tube in the series. According to Horn's definition, the reciprocal of this increment in milligrams is the sensitiveness at the given concentration. This procedure was repeated at several concentrations. The results are shown in Table III, in which, according to the nomenclature of Horn, V is the volume in liters of the solution which contains one gram atom of aluminum; B is the milligrams of aluminum in 50 cc. of the solution; Δ is the amount of aluminum in milligrams necessary to produce a perceptible difference in the intensity of 50 cc. of a solution containing B mg. of aluminum; S is the sensitivity and equal to the reciprocal of Δ and $B' = B + \Delta$. The sensitivity curve for aluminum is shown in Fig. 7, in which the square roots of V and S have been employed for convenience in plotting.

Fig. 7.—Sensitivity curve.

TABLE III
SENSITIVENESS

V	B	Δ	S	B'	Δ/B'	\sqrt{V}	\sqrt{S}
1,355	1.000	Too intense for determination					
2,710	0.500	0.025	40	0.525	0.048	52	6.3
13,550	.100	.009	111	.109	.083	116	10.6
27,000	.050	.0045	222	.0545	.083	165	15.0

1,355,000	.001	Matched solution to which no aluminum had been added					

Determination of Aluminum in Water.—Four samples of water of different iron content were analyzed for aluminum by the three methods described below. The results in parts per million are given in Table IV.

1. The aluminum was determined gravimetrically according to the method given in "Standard Methods of Water Analysis," American Public Health Association, 6th ed., New York, 1925, except that the hydroxides of aluminum and iron were precipitated by adding 5 *N* ammonium hydroxide until the solution was just neutral to methyl red. The iron was determined colorimetrically by the thiocyanate method.

2. A direct determination of the aluminum was made using "Aluminon;" 100–200

cc. of the sample, after the addition of 1-2 cc. of 4 *N* hydrochloric acid, was evaporated to dryness on the water-bath, and the residue ignited at dull redness for a few minutes to destroy any organic matter. After cooling, the ignited residue was taken up with a few drops of 4 *N* hydrochloric acid and 5 cc. of hot water and filtered in order to remove the small amount of silica which had separated. After washing the filter three times with small portions of hot water, the combined filtrate with washings was made neutral to litmus paper by adding 4 *N* hydrochloric acid and transferred to a 50cc. Nessler tube. After the addition of 5 cc. of 1 *N* hydrochloric acid, 5 cc. of 3 *N* ammonium acetate and sufficient distilled water to bring the volume to 30 cc., 5 cc. of 0.1% "Aluminon" solution was added and mixed. When the solution had stood for five minutes, 5 cc. of 5 *N* ammonium hydroxide and 10 cc. of 5 *N* ammonium carbonate were added slowly with constant stirring. The solution was now diluted to 50 cc. and mixed, and after standing for twenty minutes it was compared against standard aluminum solutions in Nessler tubes which were prepared and "aged" in a similar manner. In order to correct for the iron, a quantity of iron equivalent to that found in (1) was added to the standard.

3. In this case the aluminum was separated from the iron. A 300-550cc. sample of the water was treated as stated in (1) above until the precipitates of aluminum and iron hydroxides were filtered the first time. This precipitate was dissolved in 5 cc. of warm 5 *N* nitric acid by pouring the acid through the filter three times, and finally washing the filter three times with small quantities of hot water. The combined filtrate with washings was evaporated on the hot-plate to 1 cc., made strongly alkaline with 6 *N* sodium hydroxide, brought to boiling and filtered through a very small filter paper. The filter was washed three times with small quantities of hot water, and the filtrate with washings, after being made neutral to litmus paper by the addition of hydrochloric acid, was transferred to Nessler tubes and cooled. The procedure was completed from this point in (2) above.

TABLE IV
DETERMINATION OF ALUMINUM IN WATER

Sample	Iron (p.p.m.)	Aluminum (p.p.m.)		
		Method 1, gravimetric	Method 2, direct detn.	Method 3, separation of Fe
I	0.00	0.05	0.05	0.05
II	.66	1.03	.22	1.09
III	.23	0.51	.10	0.41
IV	5.00	.59	.12	.62

Discussion

The results for "aging" with 2 cc. of ammonium hydroxide, where the solutions were "aged" in the light and dark, respectively, are represented graphically in Fig. 1. There is little difference at any time between the intensities in the two cases. Although the curves diverge from each other in the manner which is to be expected if light has an appreciable effect on the stability of the color, the maximum difference of about 2% is within the limits of the experimental error. Thus, the rate of decrease in intensity appears to be independent of the diffused light of the laboratory.

The lower curves in Fig. 1 show the effect of the concentration of the ammonium hydroxide. Here, as in each case studied, the period of "aging" may be divided into two parts according to whether the slope

of the curve is "steep" or "flat." With the addition of ammonium hydroxide a comparatively short interval begins, in which the rate of decrease in intensity is very rapid. This period merges into the second and comparatively long period of slow change in intensity. With 2 cc. of ammonium hydroxide the first stage is 35 minutes long, while with 5 cc. this time is almost halved; however, in the latter instance the intensity is decreased by about 15% in the second period.

In Figs. 2 and 3 are shown the effects of varying the quantities of the reagents. The intensity increases with the concentration of hydrochloric acid to a maximum value, then drops rapidly on a further increase in the acid concentration. With an increase in the quantity of ammonium hydroxide, the intensity decreases along a curve which is very similar to the curves for "aging." The effect of ammonium carbonate is least of all, being a decrease in intensity of about 15% for 13 cc. of the reagent. In the case of the other three reagents the intensity increases with the concentration.

For the colorimetric determination of aluminum with "Aluminon" a procedure has been given which is in accord with the facts brought out in the foregoing curves. The quantities of the reagents, the time given for lake formation and all other conditions have been chosen, where possible, so that slight variations in the several factors will produce a minimum effect on the final color intensity and, therefore, a minimum error in the determination. Since the test is fairly sensitive to a change in the acid concentration, the solution to be examined for aluminum must be neutral at the time the hydrochloric acid is added. Furthermore, since the curves for the change in intensity with temperature and the time at lake formation are quite steep, it is obvious that the unknown solution and the standards must be at the same temperature during lake formation, and that the time intervals must also be of equal length. Where the analyst has the time, something in accuracy may be gained by giving a longer period for the lake to form.

Certain substances interfere with the test, and in this connection the effect of several ions likely to be encountered in water analysis has been studied. One mg. of silica or 2 mg. of HPO_4^{--} may be present without the results being impaired. While the orthophosphate ion tends to give low results by preventing the formation of the aluminum lake, the normal phosphate ion causes a turbidity which tends towards high results. Similarly, calcium and manganese produce turbid solutions. Some numerical values for the permissible quantities per 50 cc. of solution are given in Table II.

The results in Table I seem to indicate that iron may be present with aluminum in the ratio of 1:10 without vitiating the results. However, if as much as a few hundredths of a milligram of iron is present, a separa-

tion is necessary regardless of the ratio, since the combined iron and aluminum lakes will give a solution which is too deeply colored for accurate comparison. A fairly rapid procedure for the separation of iron from aluminum has been described with which results have been obtained by the "Aluminon" method for several samples of water that agree closely with the values for the aluminum content found by the longer and more tedious gravimetric method.

With a colorimeter of the Kennicott-Campbell-Hurley type, quantities of aluminum less than 0.01 mg. in 50 cc. of comparison solution do not yield a coloration sufficiently intense for accurate comparison; and with amounts of the order of 0.5 mg. in 50 cc., a volume of less than 50 cc. must be used in the colorimeter. When 50cc. Nessler tubes are employed, the lower limit of the test is 0.002 mg. The lake is stable, that is, it does not coagulate until after 40-60 minutes when 2 cc. of ammonium hydroxide is used with 1 mg. of aluminum present in 50cc. of solution. With the higher concentrations of aluminum the lake may be stabilized by using starch as a protective colloid; thus, by using a type of colorimeter with which very small volumes of solutions can be compared the range can be extended to cover the more concentrated solutions.

A series of interesting papers on "Variable Sensitiveness in Colorimetry" have been published by Horn⁹ and by Horn and Blake.¹⁰ For convenience the sensitiveness is defined as the reciprocal of the weight in milligrams of the colored solute which is necessary to produce a difference in intensity in 50 cc. of solution that is just perceptible with certainty. These authors made a series of measurements with several colored salts over wide ranges of dilution in order to determine the way in which the sensitiveness varies with the total concentration of the colored solute. In connection with their study on copper sulfate solutions, the following conclusions were reached:

"1. The amount of copper that will produce, at different concentrations, a difference in color that can be just distinguished is not a constant weight, but is a constant fraction of the total weight of copper present. Exceptions occur when the solutions are too dilute or too concentrated."

Symbolically, Δ/B' is a constant.

"2. Whenever the difference in color between copper solutions is estimated as just perceptible, the ratio between the two quantities of copper in the solutions compared is always the same.

"3. The sensitiveness varies inversely as the total copper. $BS = B_1S_1 = B_2S_2 = \text{a constant.}$ "

In application to colorimetric analysis, it is suggested that, "every colorimetric method has at least one maximum of sensitiveness;" that

⁹ Horn, *Am. Chem. J.*, **35**, 253 (1906).

¹⁰ Horn and Blake, *ibid.*, **36**, 195, 516 (1906).

the best working range for a colorimetric method is that over which the ratio Δ/B' is constant; that the percentage error is the same for all concentrations within this range; and that on the basis of the psychophysical law known as Weber's Law, these relations are generally true throughout colorimetry.

The sensitivity curve for aluminum is shown in Fig. 7. This curve manifests a change in slope in the vicinity which corresponds to an aluminum concentration of 0.1 mg., and, in the light of the statements above, this is the upper limit of the range in which Δ/B' is constant. For comparison, the values for the ratios Δ/B' and B/B' found by Horn and those obtained for aluminum are given below.

	CrO_4^{--}	Cu^{++}	$[\text{Cu}(\text{NH}_3)_4]^{++}$	Aluminum-lake
Δ/B'	0.08 ^a	0.09	0.056	0.083
B/B'	.96 ^a	.92	.95	.92

^a Calculated from Horn's data, Ref. 9.

Summary

An experimental study of the new reagent for aluminum, the ammonium salt of aurintricarboxylic acid, has been made and quantitative measurements of the effects of the following variables were obtained: (1) time, (2) temperature, (3) volume, (4) concentration of reagents and (5) the presence of other ions.

The range of the test has been determined for colorimetric work and a means of extending the range so as to include higher aluminum concentrations has been found. The sensitiveness of the test has also been determined.

Based upon the results of the experimental study, a quantitative method for the colorimetric determination of aluminum by the ammonium salt of aurintricarboxylic acid has been developed and applied to the direct determination of aluminum in potable water.

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. III THE ELECTRIC MOMENTS OF CERTAIN ORGANIC MOLECULES IN CARBON TETRACHLORIDE SOLUTION

BY IGNACE J. KRCHMA AND JOHN WARREN WILLIAMS

RECEIVED JUNE 6, 1927

PUBLISHED OCTOBER 5, 1927

In the preceding paper of this series,¹ as well as in a number of other articles,^{2,3,4} it has been shown that the concept of molar polarization introduced by Debye⁵ has made possible a treatment of dielectric constant and density data for certain binary liquid mixtures such that the electric moments of the solute molecules can be calculated provided they are dissolved in a medium which has no electric moment itself. It was stated¹ that liquids such as carbon tetrachloride, carbon bisulfide, pentane, hexane and benzene should act as suitable solvents of this type. The purpose of this paper is to present the results of calculations of the electric moments of certain organic molecules from measurements of the dielectric constants and the densities of their solutions in carbon tetrachloride. The mathematical expressions necessary for this calculation were presented in the previous paper and will not be repeated here.

Method

Two distinct methods were used for the determination of the dielectric constants of the binary mixtures. The first, an electrical resonance method, was described in some detail in the first paper of this series.⁶ The second was one of the so-called bridge methods. It was necessary to use this second method for certain of the binary mixtures since a resonance method of the type referred to above fails for liquids which have any appreciable electrical conductance.

Since the bridge as set up contains several novel features it will be briefly described. It is shown diagrammatically in Fig. 1. The instantaneous potential of an alternating current for any given instant is determined by the "phase angle" obtained in a vectorial consideration of the inductance and capacitance. The phase angle of the current at the point "a" must equal the phase angle of the current at "b" in order that the points "a" and "b" be at equal potential at all times and that no current be detectable in "G." Since the phase angle is dependent on the resistance, inductance and capacitance in the arms, then in this sort of bridge a balance of resistance and inductance is required along with a balance of capacitance.

A bridge of this kind lends itself to the measurement of the capacitance of a "leaky" condenser (that is, one having a conducting or current-absorbing dielectric) since it involves a simultaneous balance of resistance, capacitance and inductance. A "leaky" condenser may be treated as a capacitance with a large resistance in parallel or a small resistance in series.⁷ In either case a condition of balance may be obtained by simultaneous adjustment of capacitance and resistance in the proper arms of the bridge. Therefore, determinations of the capacitance may be made as if the resistance were not there. The determination of the dielectric constant may then be accomplished in the usual manner.

The source of alternating current is "D," which in this case is simply a Hartley circuit. A honeycomb coil, "E," is placed in inductive relation to the inductance "F" of the Hartley circuit. A two stage amplifier, "G," made by the General Radio Co., Cambridge, Mass., serves to detect the signals. "R₁" and "R₂" are non-inductive resistance (Curtis) coils of 1000 ohms each. In arm "3" is placed a variable air capacitance "C₁" of 2000 MMF, shunted by a resistance "R₃," variable by steps between 10 and 10,000 ohms. In the fourth arm of the bridge is placed the standard variable condenser, "C₂," in parallel with the dielectric cell, "C_x," and a continuously variable, non-inductive, liquid resistance "R_x." A large unknown resistance, "R₄," is set up by the "leaky" condenser "C_x." The dielectric cell and the standard condenser are the same as employed in the resonance circuit and have been described previously.⁶ Condensers

"C₁," "C₂" and "C_x" are so arranged that the stator plates are attached to the ground "d," thus effecting a shielding the same as in the resonance circuit.

The principle of detection is briefly as follows. Oscillations of a very high frequency are set up in "D." Oscillations of a frequency approaching that of "D" are set up in "G." When the current flows between "a" and "b," audible beats are set up between the two frequencies, which cease when the bridge is balanced. By proper adjustment of the capacitances and inductances of the two circuits, "D" and "G," it is possible to obtain a loud ringing tone in the telephones which yields a sharp,

narrow, distinct minimum entirely free from confusion by harmonics. A minimum of width corresponding to 1.5 MMF may be obtained.

Of course this arrangement, employing a very high frequency, is very susceptible to small irregularities in the inductance or capacitance of the bridge arms. By the ordinary methods of balance such an arrangement would be incapable of producing accurate results, since a bridge of this kind is certain to have its balance ratio affected by change of frequency,⁸ and a change of inductance or capacitance in the bridge as is required by the ordinary methods of balance would necessarily alter the frequency greatly. This is true since it is difficult to obtain capacitanceless, inductanceless resistances and leads, and under the usual conditions a so-called "frequency" bridge is almost unavoidable. It is the difficultly controlled stray capacitances and inductances that exist in all ordinary apparatus that cause the trouble. In the apparatus as set up this difficult feature of the very high frequency bridge is avoided by employment of the variable dielectric cell and the continuously variable non-inductive resistance " R_4 ." The measurement is carried out as follows. The bridge is first brought to balance, having " R_3 ," " C_1 ," " C_2 ," " C_x " and " R_4 " all attached as in Fig. 1. The plates of " C_x " are set at a position "A" exactly as in the case of the resonance circuits. The bridge being in balance for this point, " C_x " is adjusted to a point we may again call "B," whereupon " R_x " also changes. The condition of balance is then quite simply restored by adjustment of the standard variable condenser " C_2 " and the non-inductive liquid resistance " R_4 ." Knowing from the resonance method what the capacitance change produced by the change of " C_x " from "A" to "B" in air is, the dielectric constant of a liquid is obtained simply by dividing the change in " C_2 " necessary to restore bridge balance when " C_x " contains that liquid, by this value in air.

The advantage of this method of balance is at once apparent. The arms "1," "2" and "3" are held non-variable for a measurement. Hence for the condition of balance at "B" the relations between the capacitances, resistances and inductances must equal those at "A." Thus we obtain a measurement without change of arm ratios and the fact that we may have a "frequency" bridge presents no difficulties. This method even eliminates the necessity of using Curtis coils at " R_1 " and " R_2 " or of having " R_3 " non-inductive.

The fact that the bridge method described above gives reliable results for the dielectric constants of the mixtures is indicated by a comparison with the results obtained by the electrical resonance method. In a large number of cases it was possible to measure the dielectric constants of the pure liquids and their solutions by both resonance and bridge methods, and in every case a very good agreement was found.

⁸ Ref. 7, p. 186.

The densities of the pure liquids and of the solutions were determined at the same temperature at which their dielectric constants were measured, namely, 25°. An Ostwald-Sprengel pycnometer was used for the purpose. A Pulfrich refractometer was used to measure their refractive indices, also at 25°.

Purification of Materials

Carbon Tetrachloride.—The carbon tetrachloride used was the highest grade material which could be obtained from the Eastman Kodak Company. Since no trace of sulfides was found, it was simply dried and fractionated; b. p. (760 mm.) 76.45–76.52°.

Methyl Acetate.—This material was obtained from the Eastman Kodak Company. It was shaken with a concentrated potassium carbonate solution and washed with water. A rough drying was effected with anhydrous potassium carbonate; then it was completely dehydrated with phosphorus pentoxide. It was fractionated in the usual manner; b. p. (760 mm.) 57.0–57.2°.

Ethyl Acetate.—The ethyl acetate, also obtained from the Eastman Kodak Company, was subjected to a treatment similar to that of the methyl acetate; b. p. (760 mm.) 76.7–76.9°.

Acetone.—The acetone used was an Eastman Kodak Company product. It was crystallized out with sodium iodide and distilled directly from this compound. It was then thoroughly dried (six months) over boric anhydride and fractionated; b. p. (760 mm.) 56.00–56.05°.

Ethyl Alcohol.—A 99% alcohol was purified by the method described by Noyes.⁹

iso-Amyl Alcohol.—This was a Kahlbaum product. After standing over anhydrous copper sulfate for a number of months, it was digested over unslaked lime and fractionated; b. p. (760 mm.) 131.2–131.7°.

The benzene, toluene, chloroform and ethyl ether were purified in the manner described in the preceding papers of this series and their physical constants were essentially the same as those previously reported.

With the exception of the solvent, carbon tetrachloride, all liquids were fractionated immediately before use.

Experimental Results

The experimental work is summarized in Table I. The columns of this table give, from left to right, the mole fraction of the carbon tetrachloride which was used as the solvent, $M.F._{CCl_4}$; the refractive index of the solution, n_D^{25} ; the density of the solution, d_4^{25} ; the observed dielectric constant at 25°, ϵ ; the molar polarization of the solution, $P_{1,2} = \frac{\epsilon - 1}{\epsilon + 2} \frac{f_1 m_1 + f_2 m_2}{d} = f_1 P_1 + f_2 P_2$; and the molar polarization of the second component, $P_2 = \frac{P_{1,2} - f_1 P_1}{f_2}$.

The dielectric constant data for solutions of benzene, toluene, chloroform and ethyl ether in carbon tetrachloride were obtained using the electrical resonance method and are accurate to within one-tenth of one per cent. The dielectric constant data for the other binary mixtures were obtained using the bridge method described above. Wherever possible these

Intensity of color after 25 minutes....	100	106	106	100	82

In the determination of the "sensitiveness" of the test, the experimental method of Horn and Blake^a was used. A series of five solutions was

Fig. 6.—Orthophosphate ion and silica.

prepared in marked Nessler tubes of 50cc. capacity, such that the aluminum content of each solution differed from the one immediately before it in the series by a constant amount, the concentration of aluminum in the third solution being that at which the sensitiveness was to be determined. After standing for 25 minutes the tubes were arranged out of their regular order, and four men, separately and unaided, attempted to rearrange them in their proper order. Several such sets of tubes were prepared in which the difference in aluminum content was constant for a given set, though differing from series to series, until finally a series was obtained which could barely be rearranged with certainty by four different persons. The aluminum increment in this series was taken as the amount

^a Horn and Blake, *Am. Chem. J.*, 36, 195 (1906).

of aluminum necessary to produce a difference in the color intensity barely perceptible with certainty at the concentration of the third tube in the series. According to Horn's definition, the reciprocal of this increment in milligrams is the sensitiveness at the given concentration. This procedure was repeated at several concentrations. The results are shown in Table III, in which, according to the nomenclature of Horn, V is the volume in liters of the solution which contains one gram atom of aluminum; B is the milligrams of aluminum in 50 cc. of the solution; Δ is the amount of aluminum in milligrams necessary to produce a perceptible difference in the intensity of 50 cc. of a solution containing B mg. of aluminum; S is the sensitivity and equal to the reciprocal of Δ and $B' = B + \Delta$. The sensitivity curve for aluminum is shown in Fig. 7, in which the square roots of V and S have been employed for convenience in plotting.

Fig. 7.—Sensitivity curve.

Determination of Aluminum in Water.—Four samples of water of different iron content were analyzed for aluminum by the three methods described below. The results in parts per million are given in Table IV.

1. The aluminum was determined gravimetrically according to the method given in "Standard Methods of Water Analysis," American Public Health Association, 6th ed., New York, 1925, except that the hydroxides of aluminum and iron were precipitated by adding 5 *N* ammonium hydroxide until the solution was just neutral to methyl red. The iron was determined colorimetrically by the thiocyanate method.

2. A direct determination of the aluminum was made using "Aluminon;" 100–200

cc. of the sample, after the addition of 1-2 cc. of 4 *N* hydrochloric acid, was evaporated to dryness on the water-bath, and the residue ignited at dull redness for a few minutes to destroy any organic matter. After cooling, the ignited residue was taken up with a few drops of 4 *N* hydrochloric acid and 5 cc. of hot water and filtered in order to remove the small amount of silica which had separated. After washing the filter three times with small portions of hot water, the combined filtrate with washings was made neutral to litmus paper by adding 4 *N* hydrochloric acid and transferred to a 50cc. Nessler tube. After the addition of 5 cc. of 1 *N* hydrochloric acid, 5 cc. of 3 *N* ammonium acetate and sufficient distilled water to bring the volume to 30 cc., 5 cc. of 0.1% "Aluminon" solution was added and mixed. When the solution had stood for five minutes, 5 cc. of 5 *N* ammonium hydroxide and 10 cc. of 5 *N* ammonium carbonate were added slowly with constant stirring. The solution was now diluted to 50 cc. and mixed, and after standing for twenty minutes it was compared against standard aluminum solutions in Nessler tubes which were prepared and "aged" in a similar manner. In order to correct for the iron, a quantity of iron equivalent to that found in (1) was added to the standard.

3. In this case the aluminum was separated from the iron. A 300-550cc. sample of the water was treated as stated in (1) above until the precipitates of aluminum and iron hydroxides were filtered the first time. This precipitate was dissolved in 5 cc. of warm 5 *N* nitric acid by pouring the acid through the filter three times, and finally washing the filter three times with small quantities of hot water. The combined filtrate with washings was evaporated on the hot-plate to 1 cc., made strongly alkaline with 6 *N* sodium hydroxide, brought to boiling and filtered through a very small filter paper. The filter was washed three times with small quantities of hot water, and the filtrate with washings, after being made neutral to litmus paper by the addition of hydrochloric acid, was transferred to Nessler tubes and cooled. The procedure was completed from this point in (2) above.

TABLE IV
DETERMINATION OF ALUMINUM IN WATER

Sample	Iron (p.p.m.)	Aluminum (p.p.m.)		
		Method 1, gravimetric	Method 2, direct detn.	Method 3, separation of Fe
I	0.00	0.05	0.05	0.05
II	.66	1.03	.22	1.09
III	.23	0.51	.10	0.41
IV	5.00	.59	.12	.62

Discussion

The results for "aging" with 2 cc. of ammonium hydroxide, where the solutions were "aged" in the light and dark, respectively, are represented graphically in Fig. 1. There is little difference at any time between the intensities in the two cases. Although the curves diverge from each other in the manner which is to be expected if light has an appreciable effect on the stability of the color, the maximum difference of about 2% is within the limits of the experimental error. Thus, the rate of decrease in intensity appears to be independent of the diffused light of the laboratory.

The lower curves in Fig. 1 show the effect of the concentration of the ammonium hydroxide. Here, as in each case studied, the period of "aging" may be divided into two parts according to whether the slope

of the curve is "steep" or "flat." With the addition of ammonium hydroxide a comparatively short interval begins, in which the rate of decrease in intensity is very rapid. This period merges into the second and comparatively long period of slow change in intensity. With 2 cc. of ammonium hydroxide the first stage is 35 minutes long, while with 5 cc. this time is almost halved; however, in the latter instance the intensity is decreased by about 15% in the second period.

In Figs. 2 and 3 are shown the effects of varying the quantities of the reagents. The intensity increases with the concentration of hydrochloric acid to a maximum value, then drops rapidly on a further increase in the acid concentration. With an increase in the quantity of ammonium hydroxide, the intensity decreases along a curve which is very similar to the curves for "aging." The effect of ammonium carbonate is least of all, being a decrease in intensity of about 15% for 13 cc. of the reagent. In the case of the other three reagents the intensity increases with the concentration.

For the colorimetric determination of aluminum with "Aluminon" a procedure has been given which is in accord with the facts brought out in the foregoing curves. The quantities of the reagents, the time given for lake formation and all other conditions have been chosen, where possible, so that slight variations in the several factors will produce a minimum effect on the final color intensity and, therefore, a minimum error in the determination. Since the test is fairly sensitive to a change in the acid concentration, the solution to be examined for aluminum must be neutral at the time the hydrochloric acid is added. Furthermore, since the curves for the change in intensity with temperature and the time at lake formation are quite steep, it is obvious that the unknown solution and the standards must be at the same temperature during lake formation, and that the time intervals must also be of equal length. Where the analyst has the time, something in accuracy may be gained by giving a longer period for the lake to form.

Certain substances interfere with the test, and in this connection the effect of several ions likely to be encountered in water analysis has been studied. One mg. of silica or 2 mg. of HPO_4^{--} may be present without the results being impaired. While the orthophosphate ion tends to give low results by preventing the formation of the aluminum lake, the normal phosphate ion causes a turbidity which tends towards high results. Similarly, calcium and manganese produce turbid solutions. Some numerical values for the permissible quantities per 50 cc. of solution are given in Table II.

The results in Table I seem to indicate that iron may be present with aluminum in the ratio of 1:10 without vitiating the results. However, if as much as a few hundredths of a milligram of iron is present, a separa-

tion is necessary regardless of the ratio, since the combined iron and aluminum lakes will give a solution which is too deeply colored for accurate comparison. A fairly rapid procedure for the separation of iron from aluminum has been described with which results have been obtained by the "Aluminon" method for several samples of water that agree closely with the values for the aluminum content found by the longer and more tedious gravimetric method.

With a colorimeter of the Kennicott-Campbell-Hurley type, quantities of aluminum less than 0.01 mg. in 50 cc. of comparison solution do not yield a coloration sufficiently intense for accurate comparison; and with amounts of the order of 0.5 mg. in 50 cc., a volume of less than 50 cc. must be used in the colorimeter. When 50cc. Nessler tubes are employed, the lower limit of the test is 0.002 mg. The lake is stable, that is, it does not coagulate until after 40-60 minutes when 2 cc. of ammonium hydroxide is used with 1 mg. of aluminum present in 50cc. of solution. With the higher concentrations of aluminum the lake may be stabilized by using starch as a protective colloid; thus, by using a type of colorimeter with which very small volumes of solutions can be compared the range can be extended to cover the more concentrated solutions.

A series of interesting papers on "Variable Sensitiveness in Colorimetry" have been published by Horn⁹ and by Horn and Blake.¹⁰ For convenience the sensitiveness is defined as the reciprocal of the weight in milligrams of the colored solute which is necessary to produce a difference in intensity in 50 cc. of solution that is just perceptible with certainty. These authors made a series of measurements with several colored salts over wide ranges of dilution in order to determine the way in which the sensitiveness varies with the total concentration of the colored solute. In connection with their study on copper sulfate solutions, the following conclusions were reached:

"1. The amount of copper that will produce, at different concentrations, a difference in color that can be just distinguished is not a constant weight, but is a constant fraction of the total weight of copper present. Exceptions occur when the solutions are too dilute or too concentrated."

Symbolically, Δ/B' is a constant.

"2. Whenever the difference in color between copper solutions is estimated as just perceptible, the ratio between the two quantities of copper in the solutions compared is always the same.

"3. The sensitiveness varies inversely as the total copper. $BS = B_1S_1 = B_2S_2 = \text{a constant.}$ "

In application to colorimetric analysis, it is suggested that, "every colorimetric method has at least one maximum of sensitiveness;" that

⁹ Horn, *Am. Chem. J.*, **35**, 253 (1906).

¹⁰ Horn and Blake, *ibid.*, **36**, 195, 516 (1906).

the best working range for a colorimetric method is that over which the ratio Δ/B' is constant; that the percentage error is the same for all concentrations within this range; and that on the basis of the psychophysical law known as Weber's Law, these relations are generally true throughout colorimetry.

The sensitivity curve for aluminum is shown in Fig. 7. This curve manifests a change in slope in the vicinity which corresponds to an aluminum concentration of 0.1 mg., and, in the light of the statements above, this is the upper limit of the range in which Δ/B' is constant. For comparison, the values for the ratios Δ/B' and B/B' found by Horn and those obtained for aluminum are given below.

	CrO_4^{--}	Cu^{++}	$[\text{Cu}(\text{NH}_3)_4]^{++}$	Aluminum-lake
Δ/B'	0.08 ^a	0.09	0.056	0.083
B/B'	.96 ^a	.92	95	.92

^a Calculated from Horn's data, Ref. 9.

Summary

An experimental study of the new reagent for aluminum, the ammonium salt of aurintricarboxylic acid, has been made and quantitative measurements of the effects of the following variables were obtained: (1) time, (2) temperature, (3) volume, (4) concentration of reagents and (5) the presence of other ions.

The range of the test has been determined for colorimetric work and a means of extending the range so as to include higher aluminum concentrations has been found. The sensitiveness of the test has also been determined.

Based upon the results of the experimental study, a quantitative method for the colorimetric determination of aluminum by the ammonium salt of aurintricarboxylic acid has been developed and applied to the direct determination of aluminum in potable water.

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. III THE ELECTRIC MOMENTS OF CERTAIN ORGANIC MOLECULES IN CARBON TETRACHLORIDE SOLUTION

BY IGNACE J. KRCHMA AND JOHN WARREN WILLIAMS

RECEIVED JUNE 6, 1927

PUBLISHED OCTOBER 5, 1927

In the preceding paper of this series,¹ as well as in a number of other articles,^{2,3,4} it has been shown that the concept of molar polarization introduced by Debye⁵ has made possible a treatment of dielectric constant and density data for certain binary liquid mixtures such that the electric moments of the solute molecules can be calculated provided they are dissolved in a medium which has no electric moment itself. It was stated¹ that liquids such as carbon tetrachloride, carbon bisulfide, pentane, hexane and benzene should act as suitable solvents of this type. The purpose of this paper is to present the results of calculations of the electric moments of certain organic molecules from measurements of the dielectric constants and the densities of their solutions in carbon tetrachloride. The mathematical expressions necessary for this calculation were presented in the previous paper and will not be repeated here.

Method

Two distinct methods were used for the determination of the dielectric constants of the binary mixtures. The first, an electrical resonance method, was described in some detail in the first paper of this series.⁶ The second was one of the so-called bridge methods. It was necessary to use this second method for certain of the binary mixtures since a resonance method of the type referred to above fails for liquids which have any appreciable electrical conductance.

Since the bridge as set up contains several novel features it will be briefly described. It is shown diagrammatically in Fig. 1. The instantaneous potential of an alternating current for any given instant is determined by the "phase angle" obtained in a vectorial consideration of the inductance and capacitance. The phase angle of the current at the point "a" must equal the phase angle of the current at "b" in order that the points "a" and "b" be at equal potential at all times and that no current be detectable in "G." Since the phase angle is dependent on the resistance, inductance and capacitance in the arms, then in this sort of bridge a balance of resistance and inductance is required along with a balance of capacitance.

A bridge of this kind lends itself to the measurement of the capacitance of a "leaky" condenser (that is, one having a conducting or current-absorbing dielectric) since it involves a simultaneous balance of resistance, capacitance and inductance. A "leaky" condenser may be treated as a capacitance with a large resistance in parallel or a small resistance in series.⁷ In either case a condition of balance may be obtained by simultaneous adjustment of capacitance and resistance in the proper arms of the bridge. Therefore, determinations of the capacitance may be made as if the resistance were not there. The determination of the dielectric constant may then be accomplished in the usual manner.

The source of alternating current is "D," which in this case is simply a Hartley circuit. A honeycomb coil, "E," is placed in inductive relation to the inductance "F" of the Hartley circuit. A two stage amplifier, "G," made by the General Radio Co., Cambridge, Mass., serves to detect the signals. "R₁" and "R₂" are non-inductive resistance (Curtis) coils of 1000 ohms each. In arm "3" is placed a variable air capacitance "C₁" of 2000 MMF, shunted by a resistance "R₃," variable by steps between 10 and 10,000 ohms. In the fourth arm of the bridge is placed the standard variable condenser, "C₂," in parallel with the dielectric cell, "C_x," and a continuously variable, non-inductive, liquid resistance "R_x." A large unknown resistance, "R₄," is set up by the "leaky" condenser "C_x." The dielectric cell and the standard condenser are the same as employed in the resonance circuit and have been described previously.⁶ Condensers

"C₁," "C₂" and "C_x" are so arranged that the stator plates are attached to the ground "d," thus effecting a shielding the same as in the resonance circuit.

The principle of detection is briefly as follows. Oscillations of a very high frequency are set up in "D." Oscillations of a frequency approaching that of "D" are set up in "G." When the current flows between "a" and "b," audible beats are set up between the two frequencies, which cease when the bridge is balanced. By proper adjustment of the capacitances and inductances of the two circuits, "D" and "G," it is possible to obtain a loud ringing tone in the telephones which yields a sharp,

narrow, distinct minimum entirely free from confusion by harmonics. A minimum of width corresponding to 1.5 MMF may be obtained.

Of course this arrangement, employing a very high frequency, is very susceptible to small irregularities in the inductance or capacitance of the bridge arms. By the ordinary methods of balance such an arrangement would be incapable of producing accurate results, since a bridge of this kind is certain to have its balance ratio affected by change of frequency,⁸ and a change of inductance or capacitance in the bridge as is required by the ordinary methods of balance would necessarily alter the frequency greatly. This is true since it is difficult to obtain capacitanceless, inductanceless resistances and leads, and under the usual conditions a so-called "frequency" bridge is almost unavoidable. It is the difficultly controlled stray capacitances and inductances that exist in all ordinary apparatus that cause the trouble. In the apparatus as set up this difficult feature of the very high frequency bridge is avoided by employment of the variable dielectric cell and the continuously variable non-inductive resistance " R_4 ." The measurement is carried out as follows. The bridge is first brought to balance, having " R_3 ," " C_1 ," " C_2 ," " C_x " and " R_4 " all attached as in Fig. 1. The plates of " C_x " are set at a position "A" exactly as in the case of the resonance circuits. The bridge being in balance for this point, " C_x " is adjusted to a point we may again call "B," whereupon " R_x " also changes. The condition of balance is then quite simply restored by adjustment of the standard variable condenser " C_2 " and the non-inductive liquid resistance " R_4 ." Knowing from the resonance method what the capacitance change produced by the change of " C_x " from "A" to "B" in air is, the dielectric constant of a liquid is obtained simply by dividing the change in " C_2 " necessary to restore bridge balance when " C_x " contains that liquid, by this value in air.

The advantage of this method of balance is at once apparent. The arms "1," "2" and "3" are held non-variable for a measurement. Hence for the condition of balance at "B" the relations between the capacitances, resistances and inductances must equal those at "A." Thus we obtain a measurement without change of arm ratios and the fact that we may have a "frequency" bridge presents no difficulties. This method even eliminates the necessity of using Curtis coils at " R_1 " and " R_2 " or of having " R_3 " non-inductive.

The fact that the bridge method described above gives reliable results for the dielectric constants of the mixtures is indicated by a comparison with the results obtained by the electrical resonance method. In a large number of cases it was possible to measure the dielectric constants of the pure liquids and their solutions by both resonance and bridge methods, and in every case a very good agreement was found.

⁸ Ref. 7, p. 186.

The densities of the pure liquids and of the solutions were determined at the same temperature at which their dielectric constants were measured, namely, 25°. An Ostwald-Sprengel pycnometer was used for the purpose. A Pulfrich refractometer was used to measure their refractive indices, also at 25°.

Purification of Materials

Carbon Tetrachloride.—The carbon tetrachloride used was the highest grade material which could be obtained from the Eastman Kodak Company. Since no trace of sulfides was found, it was simply dried and fractionated; b. p. (760 mm.) 76.45–76.52°.

Methyl Acetate.—This material was obtained from the Eastman Kodak Company. It was shaken with a concentrated potassium carbonate solution and washed with water. A rough drying was effected with anhydrous potassium carbonate; then it was completely dehydrated with phosphorus pentoxide. It was fractionated in the usual manner; b. p. (760 mm.) 57.0–57.2°.

Ethyl Acetate.—The ethyl acetate, also obtained from the Eastman Kodak Company, was subjected to a treatment similar to that of the methyl acetate; b. p. (760 mm.) 76.7–76.9°.

Acetone.—The acetone used was an Eastman Kodak Company product. It was crystallized out with sodium iodide and distilled directly from this compound. It was then thoroughly dried (six months) over boric anhydride and fractionated; b. p. (760 mm.) 56.00–56.05°.

Ethyl Alcohol.—A 99% alcohol was purified by the method described by Noyes.⁹

iso-Amyl Alcohol.—This was a Kahlbaum product. After standing over anhydrous copper sulfate for a number of months, it was digested over unslaked lime and fractionated; b. p. (760 mm.) 131.2–131.7°.

The benzene, toluene, chloroform and ethyl ether were purified in the manner described in the preceding papers of this series and their physical constants were essentially the same as those previously reported.

With the exception of the solvent, carbon tetrachloride, all liquids were fractionated immediately before use.

Experimental Results

The experimental work is summarized in Table I. The columns of this table give, from left to right, the mole fraction of the carbon tetrachloride which was used as the solvent, $M.F._{CCl_4}$; the refractive index of the solution, n_D^{25} ; the density of the solution, d_4^{25} ; the observed dielectric constant at 25°, ϵ ; the molar polarization of the solution, $P_{1,2} = \frac{\epsilon - 1}{\epsilon + 2} \frac{f_1 m_1 + f_2 m_2}{d} = f_1 P_1 + f_2 P_2$; and the molar polarization of the second component, $P_2 = \frac{P_{1,2} - f_1 P_1}{f_2}$.

The dielectric constant data for solutions of benzene, toluene, chloroform and ethyl ether in carbon tetrachloride were obtained using the electrical resonance method and are accurate to within one-tenth of one per cent. The dielectric constant data for the other binary mixtures were obtained using the bridge method described above. Wherever possible these

⁹ Noyes, *THIS JOURNAL*, 45, 857 (1923).

values were checked using the more accurate resonance method. This was always possible in the case of the solutions containing the highest mole fractions of the solvent. It may be pointed out here that these are the

^b Values do not fall on smooth curve.

most important points of the whole curve, since it is the electric moment of a single solute molecule completely surrounded by the electrically inert solvent molecules that is desired. The value of the molar polarization of the second component is obtained by taking a tangent to the $P_{1,2}$ -mole fraction curve at the point where the mole fraction of the reference liquid is unity and prolonging it to cut the axis where the mole fraction of the solute is unity. The dielectric constant data obtained for these binary mixtures are accurate to within three-tenths of one per cent.

Discussion of Results

The results obtained from the dielectric constant and density data using carbon tetrachloride as a non-polar solvent for certain organic molecules are in all respects similar to those obtained from the binary liquid mixtures considered in the preceding paper¹ in which benzene was used as the solvent. As before, the assumption is made that the polarization due to the non-polar solvent, carbon tetrachloride, is always directly proportional to its mole fraction in solution. The results obtained for the various binary mixtures reported in this article seem to indicate the correctness of this assumption.

It is convenient to divide the systems studied into two groups. For a detailed discussion of this method of grouping of the systems the reader is referred to the article in which the benzene systems are reported.¹

GROUP 1.—Those in which the molar polarization of the second component, P_2 , is constant throughout the whole range of concentration.

1. Carbon Tetrachloride-Benzene
2. Carbon Tetrachloride-Toluene

GROUP 2.—Those in which P_2 is not a constant.

3. Carbon Tetrachloride-Chloroform
4. Carbon Tetrachloride-Ethyl Ether
5. Carbon Tetrachloride-Methyl Acetate
6. Carbon Tetrachloride-Ethyl Acetate
7. Carbon Tetrachloride-Acetone
8. Carbon Tetrachloride-Ethyl Alcohol
9. Carbon Tetrachloride-*iso*-Amyl Alcohol

Calculation of the Electric Moments of the Molecules

The electric moments of the solute molecules have been calculated from the values of their molar polarizations, P_2 . This molar polarization contains two terms, a polarization due to an orientation effect, P'_2 , and a polarization due to a deformation effect, P''_2 . Since the polarization due to the deformation of the molecule may be approximated by the familiar Lorenz-Lorentz formula,^{1,2,3,10} the polarization due to the orientation effect may be calculated. This term contains the electric moment of the molecule, μ , in the following manner, $P'_2 = \frac{4\pi}{3} N \frac{\mu^2}{3kT}$, where the symbols have their usual significance.¹

The electric moments of the several solute molecules, calculated from dielectric constant and density of their solutions in carbon tetrachloride, are given in Table II.

TABLE II
ELECTRIC MOMENTS OF SOLUTE MOLECULES AT 25°

Molecule	P''_2 , cc.	P'_2 cc.	$\mu \times 10^{18}$
Benzene	25.8	0.9	0.06
Toluene	30.3	3.4	.40
Chloroform	21.3	28.5	1.15
Ethyl ether	23.0	33.0	1.24
Methyl acetate	18.0	60.0	1.67
Ethyl acetate	22.2	64.8	1.74
Acetone	16.0	154.0	2.70
Ethyl alcohol	16.0	57.5	1.63
<i>iso</i> -Amyl alcohol	13.0	73.0	1.85

Discussion of Table of Electric Moments

The value of the electric moment of benzene is of considerable interest. Smyth,¹¹ using various physical constants, calculated its moment to be

¹⁰ Lorentz, *Wied. Ann.*, 9, 641 (1880).

¹¹ Smyth, *THIS JOURNAL*, 46, 2151 (1924).

0.2×10^{-18} , a value so small as to be indistinguishable from zero by the method of calculation employed and recognized by Smyth as indicating that the molecule of benzene had little, if any, moment. Sanger¹² concluded from a careful consideration of the accurate measurements of the dielectric constant of liquid benzene by Graffunder¹³ that the moment of the benzene molecule must be practically zero. The value presented above for benzene in the liquid state indicates that if benzene has any moment at all it must be of an exceedingly small magnitude and must, therefore, be considered as experimental verification of the calculations and conclusions of Smyth and Sanger.

The toluene molecule is found to have a moment $\mu = 0.40 \times 10^{-18}$. This value is, without doubt, more reliable than the value (0.52×10^{-18}) reported in the previous paper.¹ It was stated in that article that the latter value was somewhat larger than might have been predicted, and the reasons were given.

Chloroform and ethyl ether are found to have moments which are almost identical in value with those calculated from the dielectric constant and density data of their solutions in benzene, which, in turn, were shown to be in excellent agreement with values found by other investigators.^{1,2,14}

The values obtained for the methyl acetate and ethyl acetate molecules are not widely different in magnitude. There can be no doubt from the results of the experimental work that the moment of the ethyl acetate molecule, in carbon tetrachloride solution at least, is the larger of the two. This tends to confirm the statement of Smyth¹¹ that organic molecules having longer carbon chains will have higher electric moments. His statements are again confirmed by the calculations reported above for the ethyl alcohol and *iso*-amyl alcohol molecules. Their moments are of the expected order of magnitude. Miss Lange² determined the moments of a number of the three, four and five carbon alcohols in benzene solution, finding values between 1.53 and 1.83×10^{-18} . *Iso*-amyl alcohol was assigned the value 1.76×10^{-18} . The value for the moment of ethyl alcohol was not reported by this investigator. Her values show this tendency to increase as the length of the carbon chain is increased.

Acetone gives the largest moment of any molecule reported in this paper. It is a fact that the measurements of the dielectric constants for the system carbon tetrachloride-acetone were the most difficult of any of the systems herein reported, yet satisfactory check determinations were obtained for the concentrations studied. The greatest uncertainty lies in the extrapolation of the tangent to the $P_{1,2}$ -mole fraction carbon tetrachloride curve to obtain the molar polarization, P_2 , of a single acetone molecule completely

¹² Sanger, *Physik. Z.*, 27, 165 (1926).

¹³ Graffunder, *Ann. Physik.*, 70, 225 (1923).

¹⁴ Sanger, *Physik. Z.*, 27, 556 (1926)

surrounded by carbon tetrachloride molecules. A slight movement of the position of the tangent makes considerable difference in the P_2 value obtained. Extreme care has been taken to obtain an accurate tangent, and it is believed that the value reported for the moment of the acetone molecule is significant. It is in excellent agreement with the value, $\mu = 2.61 \times 10^{-18}$, reported by Loeb¹⁸ in his recent book.

Summary

1. Dielectric constant and density data at 25° for eight binary liquid mixtures have been determined at various concentrations. The systems studied were solutions of toluene, chloroform, ethyl ether, methyl acetate, ethyl acetate, acetone, ethyl alcohol and *iso*-amyl alcohol dissolved in carbon tetrachloride.

2. The various systems have been grouped according to whether or not the molar polarization of the solute in solution changes with concentration.

3. The electric moments of each of the solute molecules in carbon tetrachloride solution have been calculated using the Langevin-Debye modification of the Clausius-Mossotti Law. These results have been critically discussed. Wherever possible they have been compared with the results obtained by other investigators.

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. IV BENZENE AS A SOLVENT FOR CERTAIN SOLID SUBSTANCES

BY JOHN WARREN WILLIAMS AND RUDOLPH J. ALLGEIER

RECEIVED JUNE 6, 1927

PUBLISHED OCTOBER 5, 1927

The previous papers of this series^{1,2,3} have dealt with the dielectric constants of binary liquid mixtures of particular types. The systems to be discussed in this article consist of a solvent, benzene, and certain solid solutes, substances which, with one exception, have been described in the literature as being relatively non-polar in character. The solubility relations of these systems as well as of a number of other similar systems have been the subject of considerable study, the chief results of which are given by Hildebrand.⁴ This author points out that they are governed by certain regularities, particularly as regards their relative internal pressures; and yet numerous exceptions to these generalizations

are known and have been the subject of much speculation. The terms "polar" and "non-polar" are continually used in such discussions, terms which can be but qualitative in nature. The present authors believe that if sufficient dielectric constant data were available for solutions of the type referred to above, the polarities of the molecules involved might be quantitatively expressed and certain explanations given to account for irregular solubility relations, for certain it is that the dielectric constant gives the most direct evidence that is available concerning polarity. The accumulation of these data will, of course, require a number of years and the results on the benzene systems to be given in this paper can only be considered as a beginning. The work is being continued in this Laboratory.

For the present it is of sufficient interest to calculate the electric moments of the various solute molecules in the electrically inert solvent, benzene. These moments are to be calculated from dielectric constant and density data, using the Langevin⁵-Debye⁶ concept of molar polarizability. The equations actually used have been presented in the second paper of this series.² In all cases the symbols used in that paper have been retained.

Method

The method used for the determination of the dielectric constant of the benzene and of its solutions was the electrical resonance method described in the first paper of the series,¹ using the same frequency, 10^6 cycles per second. The measurements were made at 25°.

Density determinations on the solutions were made. In all cases a fifty cc. pycnometer of the Ostwald-Sprengel type was used.

Purification of Materials

Benzene.—The benzene, obtained from the Eastman Kodak Company, was treated in the usual manner to remove thiophene, after which it gave no test for this substance. It was purified by fractional crystallizations and distillations until the liquid gave practically the same physical constants as are given by Richards and Shipley.⁷ The fraction used boiled between 80.15 and 80.22°, corrected to 760 mm. pressure, and had a density, d_{25}^{25} , 0.8748.

Benzoic Acid (C_6H_5COOH).—This material, obtained from the Mallinckrodt Chemical Company, was recrystallized from toluene and sublimed. The final product was in the form of pure, white crystals having a melting point of 121.8°.

Phenol (C_6H_5OH).—This substance, obtained from Merck and Company under the label "U. S. P.—C. P.—Loose Crystals" was melted and fractionally distilled. The fraction used boiled between 179.5 and 180.0°.

Iodine (I_2).—The iodine, a Mallinckrodt product, was simply resublimed and used without further treatment.

Antimony Iodide (SbI_3).—This material was obtained through the kindness of

⁵ Langevin, *Ann. chim. phys.*, 5 [8], 70 (1905).

⁶ Debye, *Physik. Z.*, 13, 97 (1912); "Handbuch der Radiologie" (Marx), 6, 597 (1925).

⁷ Richards and Shipley, *THIS JOURNAL*, 41, 2022 (1919).

Mr. R. W. Gooding of this University. It had been subjected to a very careful purification by repeated recrystallizations from carbon tetrachloride.

Stannic Iodide (SnI_4).—The stannic iodide was a Kahlbaum product which had been carefully preserved in a pure condition. It was presented by Professor J. H. Walton of this department.

Silver Perchlorate (AgClO_4).—This salt was prepared by the G. Frederick Smith Manufacturing Company of Urbana, Illinois. Dr. Smith⁸ did not give details of the method used except to say that it was dehydrated in vacuo at 135° for thirty hours and at ordinary pressure for sixty hours at the same temperature. It gave no test for perchloric acid.

Experimental Results

The experimental data are presented in Table I. The columns of this table give, from left to right: the per cent. by weight of benzene which was used as solvent, %, C_6H_6 ; the mole fraction of benzene, M. F., C_6H_6 ; the density of the solution, d_{25}^{25} ; the observed dielectric constant of the solution, ϵ ; the molar polarization of the solution, $P_{1,2} = \frac{\epsilon - 1}{\epsilon + 2} \cdot \frac{f_1 m_1 + f_2 m_2}{d}$ = $f_1 P_1 + f_2 P_2$; and the molar polarization of the second component, $P_2 = \frac{P_{1,2} - f_1 P_1}{f_2}$.

97.64	.9909	.8940	2.597	30.85	477.0

It will be observed that these data differ from those of the previous articles^{2,3} in that it was not possible to determine the densities and dielectric constants of the solutions over a wide range of concentration. In the case of the binary liquid mixtures the two components were mutually soluble in all proportions. In the case of the solid substances used as solutes in Table I it was possible to make the measurements over but a small range of concentration, due to their limited solubility. However, with one exception (antimony tri-iodide) it was possible to dissolve enough of the solute in benzene so that when the molar polarization of the solution, $P_{1,2}$, was plotted against mole fraction of the solvent, a curve was obtained from which a significant value for the molar polarization of the second component or the solute, P_2 , resulted. It was found for each of the five

solutes reported that its molar polarization in solution was exactly proportional to its mole fraction in solution over the range of its solubility. Thus, taking the tangent to the $P_{1,2}$ curve at the point where the mole fraction of the solvent is unity and prolonging it to cut the axis where the mole fraction of the other component would be unity consisted simply of a mathematical extrapolation.

Calculation of the Electric Moments of the Molecules

The electric moments of the various solute molecules have been calculated from their molar polarizations after the manner described in the second article of this series,² using the equation $P_2 = P'_2 + P''_2$, where P'_2 = polarization due to orientation of molecule = $\frac{4\pi}{3} N \frac{\mu^2}{kT}$; and P''_2 = polarization due to deformation of molecule = $\frac{n_0^2 - 1}{n_0^2 + 2} \cdot \frac{M}{d}$.

The term P''_2 has been approximated in each case using data obtained either from the Landolt-Börnstein "Tabellen" or from Volume I of the "International Critical Tables." If these values are in error by 5 cc., an improbable value, the electric moments as reported are not changed by a correction of this magnitude since they have been reported to two significant figures only.

The electric moments of solute molecules, computed as indicated above, are presented in Table II.

TABLE II
ELECTRIC MOMENTS OF SOLUTE MOLECULES AT 25°

Molecule	P_2	P'_2	P''_2	$\mu \times 10^{18}$
C_6H_5COOH	43.5	24.6	19	1.0
C_6H_5OH	89.0	27.7	61	1.7
I_2	60.2	20	40	1.4
SnI_4	26.7	30	...	0.0
$AgClO_4$	477.0	16	461	4.7

Discussion of Table of Electric Moments

C_6H_5COOH .—It has been shown by Nernst⁹ from distribution experiments that benzoic acid in benzene solution undergoes a polymerization which may be represented by means of the equation $2C_6H_5COOH \rightarrow (C_6H_5COOH)_2$. It is difficult at present to state exactly what the effect of this association is upon the value of the electric moment reported in the above table. Values for the electric moments of water and ammonia in liquid or associated condition, and in vapor or non-associated condition, reported by Smyth¹⁰ indicate that the effect of association is to lower the electric moment.

¹⁰ Smyth, *THIS JOURNAL*, **46**, 2151 (1924).

C₂H₅OH.—The value of the moment of this molecule was reported in a preceding paper of this series.² It is in excellent agreement with the value calculated by Smyth¹¹ from the experimental data of Philip and Haynes,¹² and will not be discussed further here.

I₂.—The magnitude of the moment found for the iodine molecule was higher than might have been expected, since that molecule has been considered as a symmetrical one. A symmetrical molecule should, of course, give no moment, a fact which has actually been shown experimentally for gases like hydrogen and nitrogen.¹³ However, Lewis¹⁴ has explained that a symmetrical molecule like iodine may become polarized in one direction or another. This polarization means that the molecule will have an electric moment. Lewis shows that this polarization extends to a slight ionization in the case of iodine, and that bromine, chlorine, fluorine and hydrogen, in the order named, show a diminishing tendency toward this ionization. Table III, presented below, shows that this is also the order of decreasing electric moments or, what is equivalent, the order of decreasing polarity.

TABLE III

COMPARISON OF MOMENTS OF HALIDE MOLECULES AND HYDROGEN

Molecule.....	Iodine	Bromine	Chlorine	Fluorine	Hydrogen
$\mu \times 10^{18}$	1.4	0.58 ¹⁵	0.13 ¹⁶	0.0 ¹³

In making the calculation for the electric moment of the iodine molecule the chemical changes taking place upon its solution have not been considered. These chemical changes have been discussed at length by Hildebrand.¹⁷ The present authors are of the opinion that these changes in the dilute iodine solutions did not materially affect the accuracy of the calculation, the result of which is reported above. In the method used for the calculation of the moment it is necessary to assume that the polarization due to the solvent, in this case benzene, is always directly proportional to its mole fraction in solution. This assumption, as has already been indicated,² may lead to somewhat erroneous conclusions since it does not take into account what has been termed the chemistry of solution. However, the solution of iodine in benzene has been found to be ideal with respect to its molar polarization in solution over the range

of concentration studied, since when this molar polarization is plotted against the mole fraction of the solvent a straight line results. This fact seems to eliminate the possibility of chemical interference.

SnI₄.—That the stannic iodide molecule would show a zero moment might have been predicted from atomic structure considerations. It has always been considered as a "non-polar" substance by Hildebrand¹⁸ in his solubility studies. The value for its moment reported in this paper is of interest in connection with the study of its solubility relations which have recently been reported by that author with one of his collaborators.¹⁸

AgClO₄.—The solubility relations of this interesting substance in benzene have been studied by Hill.¹⁹ This author states that a molecular complex, AgClO₄·C₆H₆, is formed when AgClO₄ is added to benzene. The value found for the moment of this molecule is very large; nevertheless it is believed to be significant. As in the case of the iodine the molar polarization-mole fraction curve is a straight line over the range of concentration studied, again indicating the elimination of possible chemical interference.

Summary

1. Dielectric constant and density data have been obtained for benzene solutions of benzoic acid, phenol, iodine, stannic iodide, antimony triiodide and silver perchlorate.

2. By means of the Debye modification of the Clausius-Mossotti Law these data have been used to calculate the electric moments of the various solute molecules.

3. The results of these calculations have been discussed with particular reference to the conceptions of atomic structure and to solubility relationships.

THE POTENTIAL OF A PROPOSED STANDARD FORM OF COPPER AND THE ACTIVITY OF COPPER SULFATE¹

BY RALPH F. NIELSEN AND DENTON J. BROWN

RECEIVED JUNE 6, 1927

PUBLISHED OCTOBER 5, 1927

This research was undertaken in connection with the attempt to find a standard form of copper for use in potential measurements involving various compounds of copper. The potential of the copper electrode in copper sulfate solution has been measured by numerous investigators, using various forms of copper, and the results always depended on the method of preparing the electrodes. Lewis and Lacey² give the value 0.3928 volt for the electromotive force of the cell $\text{Cu} \mid \text{CuSO}_4(0.05 \text{ } M) \mid \text{Hg}_2\text{SO}_4 \mid \text{Hg}$, using a copper sponge prepared by rapid electrolysis of copper sulfate on a platinum point. They found a considerable number of cells to agree within several tenths of a millivolt, using various current densities in preparing the copper. We have been unable to obtain reproducible results using copper prepared by their method, and invariably the copper lost its reducing activity slowly upon standing under concentrated copper sulfate solution. The following table gives the relative potentials of a sample of copper prepared by this method at the time indicated.

TABLE I
RELATIVE POTENTIALS

Day.....	11/19/26	11/23/26	11/29/26	12/3/26
E.m.f.....	0.1595	0.1551	0.1531	0.1523

In addition, pieces of wire and sheet were heated to a temperature near the melting point of copper in an atmosphere of nitrogen and slowly cooled. These gave values somewhat lower, although we could not obtain constant results. These facts are in agreement with a rather generally accepted theory that metals freshly precipitated by violent reduction are abnormally high in their reducing power. In fact, a copper sponge obtained by the action of zinc dust on copper sulfate solution gave exceptionally high values. All our values were admittedly higher than those of Lewis and Lacey, but we can see no reason why their values should be selected as standard.

It became necessary to find a form of copper which gave constant results that could easily be reproduced by any investigator, and we finally

¹ This paper is an abstract of part of the work done by Ralph F. Nielsen toward the degree of Doctor of Philosophy at the University of Nebraska. The problem of the determination of free energies of copper compounds was selected by him at the suggestion of Professor Merle Randall of the University of California, and the work of this paper was found necessary in carrying out the problem.

² Lewis and Lacey, *THIS JOURNAL*, 36, 804 (1914).

decided to use a two-phase electrolytic amalgam in our work. By accurately determining the standard potential of this form of copper, we can easily correct our subsequent data on various copper compounds when a justifiable standard form of copper is found. We made a number of measurements involving copper sulfate solution, making use of this amalgam. The copper amalgam was prepared by electrolysis of a half-molal solution of copper sulfate, slightly acidified, using about five amperes per square decimeter of mercury surface and a copper anode. The amalgam was kept under this solution after preparation. Mercurous sulfate was prepared by electrolysis of a 25% solution of sulfuric acid, using about five amperes to a square decimeter and a rapid stirrer which just grazed the mercury surface, according to the method of Hulett.³ The copper sulfate used had been recrystallized from an acidified solution of the best c. p. crystals obtainable, and the solutions were made up gravimetrically from a stock solution standardized iodimetrically with metallic copper as primary standard. Molality is taken as moles per kilogram of water in vacuum. Conductivity water and distilled mercury were used in preparing the reagents. Measurements were made on a Leeds and Northrup "Type K" potentiometer, using a new Weston cell with a Bureau of Standards Certificate. The thermostat consisted of a bath of distilled water maintained at $25 \pm 0.05^\circ$. The mercurous sulfate electrodes were always placed in glass-stoppered flasks, rotated in the thermostat for several hours and then put into dry electrode vessels of the usual type. All heating and regulating circuits were shut off during the measurements and all connections were made by means of mercury. We measured the following cells, each value being the mean of four different cells, none deviating more than a tenth of a millivolt from the mean. The four cells were obtained by cross combinations among two electrodes of each kind.

TABLE II
CELL MEASUREMENTS

Cu (amalgam)	CuSO ₄ (0.05 M)	Hg ₂ SO ₄	Hg	0.3874 volt
Cu (amalgam)	CuSO ₄ (0.1 M)	Hg ₂ SO ₄	Hg	.3784 volt
Cu (amalgam)	CuSO ₄ (0.2 M)	Hg ₂ SO ₄	Hg	.3697 volt
Cu (amalgam)	CuSO ₄ (0.4 M)	Hg ₂ SO ₄	Hg	.3592 volt

The cell Cu(amalgam) | CuSO₄(sat.) | Hg₂SO₄ | Hg has been measured by Cohen, Chattaway and Tombrook,⁴ by Obata⁵ and by Öholm⁶ using reagents prepared as above. The mean value from the last two investigators is 0.3467 volt \pm 0.0001. As a check on our preparations we re-

³ Hulett, *Phys. Rev.*, **32**, 32 (1900).

⁴ Cohen, Chattaway and Tombrook, *Z. physik. Chem.*, **60**, 706 (1907).

⁵ Obata, *Proc. Phys. Math. Soc. Japan*, [3] **2**, 223 (1920).

⁶ Öholm, *Medd. Vetenskapsakad. Nobelinst.*, **5**, N:04, 1 (1919).

peated these measurements and obtained $0.3468 \text{ volt} \pm 0.0001$. Since we were afraid that we had not washed all the acid from the crystals of copper sulfate before making up our solutions, we recrystallized some from a neutral solution and repeated the measurements at $0.2 \text{ } M$ concentration. We obtained perfect agreement, however, with the above. Since we found that we could not avoid the formation of a green precipitate at the mercurous sulfate electrode in the case of the $0.05 \text{ } M$ solution, this solution contained a drop of nitric acid in a liter of the solution. This should not affect the activity coefficient noticeably if the degree of hydrolysis is small; and, indeed, it was found to have no effect in the $0.1 \text{ } M$ solution. We did not think it advisable to carry these measurements into more dilute solutions owing to the solubility of mercurous sulfate.

As a further check on our activity coefficients we combined our electrodes in the following way,

These cells gave, respectively, $0.0089 \text{ volt} \pm 0.0001$; $0.0105 \text{ volt} \pm 0.0001$; $0.0190 \text{ volt} \pm 0.0001$.

Employing the values of the two tables, we obtain the following series of activity coefficients:

TABLE III					
ACTIVITY COEFFICIENTS					
M	0.05	0.1	0.2	0.5	1.38
γ216	.153	.107	.064(4)	0.0378

The value of 0.216 for the $0.05 \text{ } M$ solution was taken from Lewis and Randall.⁷ These values are about three per cent. lower than theirs, but are undoubtedly more nearly correct, since their calculations from freezing point measurements were not corrected for the heat of dilution.

For the standard potential of copper amalgam we obtain -0.3502 volt , based on the mean activity of the ions in copper sulfate solution. The copper amalgam used above seems to be a good standard form of copper for use in potential measurements. It is easily reproducible and, since it is a two-phase amalgam, its potential is independent of the relative quantities of copper and mercury within rather wide limits. The General Electric Company has prepared single, unstrained crystals of copper, and we attempted to obtain some from them, to see if they would give the same potential as the amalgam. They had none on hand, however, which had not been strained, so we did not perform this experiment.

⁷ Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., New York City, 1923.

Summary

The choice of a standard form of copper for use in potential measurements was discussed.

The standard potential of copper amalgam and the activity coefficients of copper sulfate over a limited range were determined.

THE CATALYTIC SYNTHESIS OF WATER VAPOR IN CONTACT WITH METALLIC GOLD¹

BY ARTHUR F. BENTON AND JOSEPH C. ELGIN²

RECEIVED JUNE 13, 1927

PUBLISHED OCTOBER 5, 1927

Introduction

In a previous communication³ evidence was presented to show that the mechanism of water formation over a reduced silver catalyst involves collisions of gaseous hydrogen with adsorbed oxygen on that fraction of the surface not covered by adsorbed water. In this case the reaction kinetics proved to be relatively simple.

Metallic gold like metallic silver does not form definite compounds by direct combination at ordinary pressures with either hydrogen or oxygen.⁴ Their similarity in chemical properties would lead one to expect that the reactions in contact with the two metals would exhibit similar kinetics and mechanism. The present investigation shows that this is not the case, although the adsorption phenomena for the two metals are similar.

Bone and Wheeler⁵ have studied the hydrogen-oxygen combination in contact with gold gauze at 250° by a circulatory method. They state that the results for gold and silver were analogous; namely, that the rate of reaction was roughly proportional to the pressure of hydrogen, but independent of the pressure of oxygen, and that the activity of the catalyst was greatly stimulated by previous heating in hydrogen but not in oxygen. This latter effect was further investigated by Chapman, Ramsbottom and Trotman.⁶

The experimental method and the conclusions of Bone and Wheeler have been discussed and criticized in other places.³ The difficulties

inherent in the manometric method of measuring contact catalytic reactions were avoided in the present study by use of the flow method, which allowed the attainment of a "steady state" under each set of conditions. The kinetics of the reaction have been accurately determined, the adsorptions of hydrogen and oxygen by the gold catalyst measured and an attempt made to deduce a mechanism for the catalytic reaction.

Experimental Method

Apparatus.—The apparatus was the same as that employed in the investigation of the reaction in contact with metallic silver. Suitably purified gas mixtures were passed over the catalyst maintained at constant temperature in an electric furnace, and the progress of the reaction was followed by weighing the water absorbed in a calcium chloride tube from the exit gases during time intervals of five minutes.

Preparation of the Catalyst.—A 6% solution of C. P. gold chloride was heated to 80° and a slight excess of a 6% solution of sodium carbonate added with constant stirring. The mixture was then heated to boiling for thirty minutes. The precipitated gold hydroxide was washed repeatedly by decantation, then filtered off and the washing continued until no chloride could be detected in the wash water. The layer next to the filter paper was discarded, and the remainder dried in an oven at 100°.

The hydroxide was reduced in a current of dried hydrogen. The reduction was started at about 5°, but the temperature increased slowly as reaction proceeded. The temperature was maintained at 35° for fifteen hours, after which it was slowly raised to 100° and maintained until no water could be detected in the exit gas.

The reduced gold thus obtained was placed in the catalyst furnace and heated in a stream of dry oxygen at 200° for two hours. This sample of gold was used throughout the experiments, and gave detectable conversion at 100°. It was 2.1 cm. in diameter and approximately 2 cm. high, giving an apparent volume of 7 cc. Its weight was 8.78 g.

Procedure.—The procedure used with silver was followed. The uniform preliminary treatment of the catalyst with hydrogen for an hour previous to each run was made at 130°. The total rate of flow was maintained constant at 50.0 cc. (0°, 760 mm.) per minute throughout the experiments.

Check runs were made alternately throughout the investigation. During the first ten runs no material change in catalyst activity was noted. The small changes which occurred in the later runs were corrected for by adding to or subtracting from the yield in each run the percentage amount per run necessary to make the checks agree.

Experimental Results on Reaction Kinetics

One hundred thirty degrees proved to be a convenient temperature at which to investigate the reaction kinetics. The results of typical catalytic runs are shown in Fig. 1, in which the yield of water per five minute interval is plotted as a function of time.

With oxygen in excess the initial course of the reaction could not be followed due to the time required to sweep from the furnace the hydrogen

used in the preliminary treatment. Here attainment of the "steady state" required a much longer time than when hydrogen was present in excess. In the previous work with silver, the "steady state" was always reached within an hour of the start of a run, irrespective of which gas was present in excess.

When hydrogen was used in excess, determinations of the oxygen present in the exit gas showed that the rate at which oxygen disappeared was equivalent to the rate of water formation. This fact indicates that oxygen was not continuously taken up and retained by the catalyst in any considerable amount. From experiments with oxygen in excess, a similar conclusion was drawn in regard to hydrogen.

Fig. 1.—Variation of yield with time in typical runs. Curves I (Run 7) and II (Run 6) are with excess hydrogen, and oxygen equivalent to 40.4 and 20.2 mg. of water per five minutes, respectively. Curve III (Run 12) is with excess oxygen, and hydrogen equivalent to 40.4 mg. of water per five minutes.

With constant total flow rate the influence on the yield of oxygen pressure, hydrogen pressure and temperature, as well as the effect of water vapor and of preliminary treatment of the catalyst with oxygen, have been studied.

Effect of Oxygen Pressure.—To determine the effect of oxygen pressure on the rate, experiments were made at 130° with excess hydrogen and with amounts of oxygen equivalent to from 10 to 100 milligrams of water per five minutes. The average partial pressures corresponding to these quantities may be seen in Table I. In order to keep the flow constant and at the same time vary the oxygen pressure, the flow of hydrogen was suitably adjusted to allow for variations in the volume of oxygen introduced. The average hydrogen pressures, therefore, vary

slightly, but due to the excess of hydrogen this does not exert a marked influence upon the yield, as will be shown below. The variation is taken care of quantitatively in the final equation summarizing the kinetic results.

TABLE I
EFFECT OF OXYGEN PRESSURE ON THE YIELD

Run no.	Total flow rate, 50 cc. per minute.		Temperature, 130°		Yield, mg. of water per five minutes	
	Oxygen, cc. per min.	Barometer, mm.	Av. hydrogen press., mm.	Av. oxygen press., mm.	Calcd.	Obs.
5	5.02	745.7	661.6	66.7	40.4	9.2
6	2.51	749.9	706.0	31.7	20.2	6.4
7	5.02	749.0	664.2	66.8	40.4	9.4
8	1.25	750.1	727.0	15.8	10.1	4.6
9	5.02	756.0	670.5	67.1	40.4	9.3
10	12.55	757.0	551.9	180.1	101.0	13.0

These experiments show that the rate of the reaction in contact with gold, unlike the case of silver, is a function of the oxygen pressure. Although the yield appears to be approximately proportional to the square root of the oxygen pressure under these conditions, the true relation can be found only by taking into consideration the effect on the yield of the varying quantities of water vapor produced. This effect forms the subject of a later section.

Effect of Hydrogen Pressure.—The influence of hydrogen pressure was next investigated, using small hydrogen concentrations in excess oxygen. Quantities of hydrogen equivalent to 10 to 100 milligrams of water per five minutes were used. The alternate check runs showed a gradual change in activity during the series. Run 16 was chosen as the standard since this seemed best to represent the state of activity existing in the series with excess hydrogen. The yields of the present runs have been corrected to this standard by adding or subtracting the required amounts in the manner previously indicated. Run 19 was used in relating the results of Tables I and II. The corrected yields of runs 5

TABLE II
EFFECT OF HYDROGEN PRESSURE ON THE YIELD

^a Excess hydrogen.

to 19 are thus based, as closely as possible, on the same state of catalyst activity. The data obtained for the effect of hydrogen pressure are given in Table II.

From these experiments it is seen that when oxygen is present in large excess the rate of water formation is markedly dependent upon the hydrogen pressure. The apparent proportionality to the first power of the pressure of this gas must be corrected, as in the case of oxygen, for the variations in the pressure of water vapor. Incidentally it may be mentioned that the largest conversion obtained was with an approximately stoichiometric mixture.

Effect of Water Vapor.—A series of five runs was made to determine the effect on the yield of water vapor initially present in the entering gas. The desired concentration of water vapor was added by passing the entering gas through a saturating train containing distilled water at the required temperature. Table III gives the data obtained.

TABLE III
EFFECT OF WATER VAPOR ON THE YIELD

Excess hydrogen. Temperature, 130°. Total flow, including entering water vapor, 50 cc. per minute.

Run no.	Barometer, mm.	Oxygen cc. per min.	Mg. water per 5 min. in entering gas	Mg. water per 5 min. in exit gas	Yield, mg. of water per five minutes	
					Obs.	Corr.
23	743.4	5.02	0.0	9.6	9.6	8.6
24	740.4	5.02	5.6	9.2	3.6	3.4
25	739.9	5.02	0.0	8.6	8.6	8.6
26	743.0	5.02	1.6	10.2	8.6	7.2
27	743.7	5.02	0.0	11.4	11.4	8.6

Water vapor initially present in the reacting gases markedly decreases the rate of water formation. The effect is greater when larger amounts of water are present. However, the retardation in these experiments is not nearly so marked as that observed with silver. This undoubtedly is to be attributed to the higher temperature used in the present instance. The retarding influence exhibited by water vapor can be ascribed to the adsorption of water vapor on the gold surface, which largely prevents contact with the reacting gases.

Temperature Coefficient.—To ascertain the variation of yield with temperature, the run with excess hydrogen and an oxygen concentration equivalent to 40.4 milligrams of water per five minutes was made at several temperatures. Due to increased yield at higher temperatures, the average pressures of hydrogen and oxygen varied somewhat through the series. The yields have, therefore, been corrected to a hydrogen pressure of 660 mm. and an oxygen pressure of 67 mm., using the data previously obtained for the effect of the pressures of these gases. Due to the large excess of hydrogen, the corrections for variation in its average pressure are practically negligible. The results are recorded in Table IV.

TABLE IV

EFFECT OF TEMPERATURE ON THE YIELD

An excess of hydrogen was used. Total flow rate, 50 cc. per min.

Run no.	Temp., °C.	Av. hydrogen press., mm.	Av. oxygen press., mm.	Yield, mg. of water per 5 min.		
				Obs.	Corr. for activity	Corr. for activ. and gas press.
19	130	664.6	67.8	8.6	8.6	8.6
20	145	651.2	58.1	19.2	19.2	20.9
21	130	662.3	67.5	8.6	8.6	8.6
22	151	637.9	48.5	29.1	25.7	31.2
23	130	658.8	66.4	9.6	8.6	8.6

If the logarithms of the corrected yields are plotted against the reciprocals of the absolute temperatures a straight line is obtained. The slope of this line when multiplied by -4.58 gives a value of 20,800 calories for the apparent heat of activation (E). This is about 8000 calories larger than the value obtained with a silver catalyst. The actual temperature coefficient for a 10 degree rise is 1.95 for the interval 130–140° and 1.88 for the interval 145–155°. The average temperature coefficient with silver was 1.6.

Effect of Preliminary Heating of the Catalyst in Oxygen.—In the runs made to determine the effect of preliminary treatment of the catalyst with each reacting gas all other conditions were identical. The results are shown in Table V.

TABLE V

EFFECT OF PRELIMINARY TREATMENT OF THE CATALYST

Temp., 130°. Excess hydrogen. Flow rate, 50 cc. per min. Calcd. yield, 40.4 mg.

Run no.	Preliminary heating at 130°		One quarter	Obs. yield, mg. of water per 5 min.		
	In hydrogen, hours	In oxygen, hours		Time from start, hours	One	Two
27	1	11.4	11.4	11.4
28	...	1	26.2	16.0	13.2	...
29	1	...	11.6	12.0	12.8	13.0
30	...	6.5	31.0	23.8	18.6	17.8
31	1	...	16.4	15.2	15.2	...
32	9	...	10.4	11.6	12.8	13.8

These experiments show that the gold is a more active catalyst after preliminary heating in oxygen. The stimulating effect was not lasting, a maximum yield being obtained at first, followed by a gradual decrease toward a normal one after several hours' time. Preliminary treatment with oxygen for six and one-half hours is more effective and enduring than treatment for one hour.

Sieverts⁷ found that gold *absorbs* neither hydrogen nor oxygen under any conditions examined, and the measurements described below show that under the prevailing conditions oxygen but not hydrogen is appreciably *adsorbed*. The effect observed is, therefore, presumably to be con-

⁷ Sieverts, *Z. physik. Chem.*, 60, 179 (1907).

sidered as an increase in yield due to oxygen treatment rather than a decrease due to hydrogen.

The difference between the total quantity of water obtained in a run following treatment with oxygen and that which would be obtained over the same period in a normal run, in which the catalyst was previously heated in hydrogen, was many times greater than the amount equivalent to the volume of oxygen which the subsequent adsorption experiments showed was taken up by the catalyst. The increased yield is not, therefore, simply the conversion of the oxygen adsorbed during the preliminary treatment. The presence of oxygen initially on the surface produces some distinctive influence on the rate of the reaction which gradually disappears as the reaction proceeds.

A proposed explanation of the observed phenomena will be considered in the discussion.

Adsorption Measurements

Apparatus and Procedure.—The adsorption measurements were made by the usual static method. The essential features of the apparatus were a bulb containing the gold connected by 3-way stopcocks to a mercury manometer, a Töpler pump, a gas buret with mercury as retaining liquid and generating and purifying lines for the gases employed.

The adsorptions at each pressure were determined in separate experiments. The bulb was evacuated at the desired temperature (generally 130°) and the gas admitted up to a definite pressure. The pressure change was followed at frequent intervals until it became very small. Occasional readings were then taken until successive ones over about six hours' time were identical, when equilibrium was assumed to have been reached. The volume adsorbed at each pressure was determined by subtracting from the total volume admitted the volume of gas in the free space. The latter was measured with nitrogen, which was assumed not to be measurably adsorbed.

The bulb was evacuated at 130° immediately following an experiment, and the gas pumped off measured. Adsorbed oxygen could not be pumped from the surface at this temperature and it was therefore necessary to burn it off with hydrogen after each measurement. The hydrogen recovered after this process was measured. The amount disappearing was closely equivalent to the volume of oxygen which was found to remain on the surface after an oxygen run.

The sample of gold used in the catalytic experiments was employed. Some of it was lost in transferring to the adsorption bulb so that its weight was reduced to 7.94 g.

Results.—The oxygen adsorption isotherm for 130° is shown in Fig. 2. The results of the measurements are summarized in Table VI.

Attempts were made to measure hydrogen adsorption at 25° on the gold surface covered with adsorbed oxygen, but no adsorption could be detected under such conditions.

The measurements show that considerable quantities of oxygen are adsorbed, but a scarcely measurable amount of hydrogen. Although the hydrogen was quantitatively recoverable, only a few tenths of a cubic centimeter of oxygen could be pumped off at 130° after an experiment

with this gas. It is evident that the adsorption of oxygen at equilibrium is very nearly independent of the pressure.

TABLE VI
ADSORPTIONS BY 7.94 G. OF GOLD

Gas	Temp., °C.	Vol. introduced, cc.	Vol. in free space, cc.	Final press., mm.	Vol. adsorbed, cc.

In the range of the measurements the oxygen adsorption at apparent equilibrium increases with increasing temperature. At about 650 mm. pressure the gold took up 3.57 cc. at 98°, 4.78 cc. at 130° and 5.73 cc. at 157°. At first glance these results would seem to indicate a negative heat of adsorption. This conclusion would, however, be justifiable only in case true equilibrium is attained at each temperature. To test this point further, the oxygen adsorption at 130° and 650 mm. pressure was repeated, the measurement being continued for forty-eight hours after apparent equilibrium had been reached. Without removing the oxygen, the temperature was raised to 157° and the system allowed to come to equilibrium. The adsorptions so determined were in agreement with those found in the previous experiments. The temperature was then lowered to 130°. Although this temperature was maintained for eighty hours no decrease occurred in the amount of gas adsorbed. Hence we must conclude that, in spite of the apparent constancy of the pressure, true equilibrium was not attained in the first part of the experiment.

Rate of Oxygen Adsorption.—Typical curves showing the rate of oxygen adsorption at different temperatures and pressures are shown in Fig. 3, in which manometer readings are plotted against the square root of the time, this function being chosen merely for convenience. It will be noted that the rate decreases markedly with decreasing temperature.

Pressure in mm. of mercury.

Fig. 2.—Oxygen adsorption isotherm at 130°.

Thus at 130° approximately twenty-four hours were required for apparent equilibrium to be established, one hundred and eight hours at 98°, while at 25° only 4 mm. pressure drop, corresponding to an adsorption of 0.1 cc. of gas, occurred in seven hours. Curves III and IV of Fig. 3 show that

Fig. 3.—Decrease of pressure with time in the adsorption of oxygen. Curve I is for 98° and 752 mm. and Curve II for 157° and 735 mm. pressure. Curves III and IV are for 130° and 776 and 94 mm. initial pressures, respectively.

the rate of adsorption is nearly independent of the gas pressure. During the first minute the rate is slightly higher at the higher pressures, but thereafter no appreciable difference was observed. Experiments at intermediate pressures, not shown in Fig. 3, confirm these results.

In the previous work with silver, slow rates of oxygen adsorption were also encountered, but to a less pronounced degree than in the present experiments with gold. The slow rate of adsorption cannot be attributed to oxidation of the gold in the ordinary sense since it is well established that this metal is not oxidized by oxygen under any conditions. The possibility that the slow disappearance of oxygen is due to solution appears improbable in view of Sieverts' measurements,⁷ which indicate that massive gold does not dissolve

this gas in appreciable quantities at any temperature. It seems necessary to conclude that at least that part of the gas taken up at low pressures, which is the major portion, is in the adsorbed state.

Discussion

Kinetics.—The treatment of the kinetics in flow systems is much simplified by expressing the yield as a function of the average pressures of the various gases instead of employing the more accurate method of integration. We have previously shown⁸ that this approximation is justifiable unless the conversion approaches completion.

Since water vapor markedly retards the reaction, presumably because of extensive adsorption on the catalyst surface, the effect of changes in the pressure of this gas must be included in the consideration of the kinetics,

⁸ Benton, *Ind. Eng. Chem.*, 19, 494 (1927).

It has been shown by Langmuir⁹ that the fraction of a surface not covered by adsorbed gas is given by the expression $1/(1 + ap)$, where p is the gas pressure and a is a constant at a given temperature. For large adsorptions this reduces to $1/ap$. We may, therefore, write for the yield in the reaction under consideration

$$Y = kp_h^m \cdot p_o^n / ap_w$$

where p_h , p_o and p_w are the averages of the inlet and exit pressures of hydrogen, oxygen and water, respectively, k is the reaction-rate constant and m and n are constants to be determined by comparison with experiment. In the present work the rate of flow was maintained constant, and, therefore, p_w is proportional to Y . Hence,

$$Y^2 = k \cdot p_h^m \cdot p_o^n$$

This expression shows that the exponents of the pressures of the hydrogen and oxygen should be twice as great as those which are obtained when the retarding effect of the water vapor is neglected. Since the results of Tables I and II indicate that the apparent exponents are unity and 0.5, respectively, before correcting for the effect of the water, the true kinetic equation evidently should be

$$Y = k \cdot p_h^2 \cdot p_o / (1 + ap_w)$$

This may be put in the form

$$\frac{p_h^2 \cdot p_o}{Y} = \frac{1}{k} (1 + ap_w) = \frac{1}{k} + k'Y$$

If this relation satisfies the data, the points obtained by plotting $p_h^2 \cdot p_o / Y$ against Y at constant temperature should fall on a straight line. Fig. 4 shows that this is the case for the results of Tables I and II considered separately. It is possible that the failure of the points obtained with excess oxygen and with excess hydrogen, respectively, to fall on the same curve is due to a real difference in kinetics in the two cases, but in view of the uncertainty in the correction of the separate series to the same state of catalyst activity, it is felt that no stress should be laid on this point.

Reaction Mechanism.—It has been shown previously that an active silver catalyst adsorbs oxygen to an extent nearly independent of the pressure, but does not adsorb hydrogen. It would appear reasonably certain, therefore, that during catalysis the active parts of the silver surface are largely covered with adsorbed oxygen under all conditions. In agreement with this result the rate of water formation was found to be independent of oxygen pressure and directly proportional to the pressure of hydrogen. Since a gold catalyst adsorbs the gases in question in a similar manner, it would appear that the kinetics with gold should be similar to those with silver. With gold, however, the yield is proportional to the

⁹ Langmuir, *THIS JOURNAL*, 40, 1370 (1918).

square of the hydrogen pressure and to the first power of the oxygen. Since in both cases the oxygen adsorptions at equilibrium are nearly independent of the pressure, the only basis upon which to explain this difference in reaction kinetics appears to lie in the fact that the *rate* of oxygen adsorption on gold is considerably slower than on silver. More than half of the equilibrium adsorption on silver occurs instantaneously, while less than a quarter occurs thus with gold. Nevertheless, it is evident

Fig. 4.—The combined effect on the yield of hydrogen, oxygen and water-vapor pressures at constant temperature. Upper curve, Runs 12–18, Table II (with excess oxygen); lower curve, Runs 5–10, Table I (with excess hydrogen).

In view of the much slower rate of adsorption and the shorter time of preliminary treatment of the gold, it is probable that this metal did not become so nearly covered with oxygen during preliminary treatment with this gas as did the silver. This consideration, combined with the hypothesis that only oxygen adsorbed next to a bare space on the surface is readily capable of reaction with hydrogen, would explain the difference in the effect produced on silver and gold by previous oxygen treatment. In one experiment with silver before which it was heated in oxygen for a

that this explanation alone is inadequate to account for all the facts, since the rate of adsorption of oxygen by gold is almost entirely independent of the pressure.

The possibility exists that the rate of adsorption which is of importance in the catalysis may differ from the rates here measured. This could be true if the oxygen which is active catalytically forms only a small fraction of the total oxygen which is adsorbed. It is not improbable that the catalytically active centers are to be identified with the fraction of the surface which exhibits an intermediate adsorptive activity, as suggested by Beebe.¹⁰ This point should be capable of experimental proof by a study of the adsorptions and kinetics over a catalyst poisoned under carefully controlled conditions.

¹⁰ Beebe, *J. Phys. Chem.*, **30**, 1538 (1926).

shorter time and at a lower temperature, the yield was increased in the same manner that was found in the case of gold.

It does not seem possible to deduce a reaction mechanism from the present experiments which will offer a satisfactory explanation for the dependence of the yield upon the square of the hydrogen pressure. A mechanism based on the interaction of adsorbed oxygen with two hydrogens adsorbed on adjacent spaces on the catalyst surface will not account for the observed kinetics, since it may readily be shown that with the relative adsorptions found for the two gases this assumption requires the velocity of reaction to be proportional to the square of the hydrogen pressure, but *inversely* proportional to the oxygen. It seems necessary to conclude that the essential mechanism is the collision of gaseous hydrogen with adsorbed oxygen. If it is required that two gaseous hydrogen molecules strike adsorbed oxygen simultaneously for reaction to occur, dependence on the square of the hydrogen pressure necessarily follows. This offers a possible explanation, but one which is rather unsatisfactory for a heterogeneous reaction of this type, especially in view of the probability that the adsorbed oxygen is at least partially dissociated into atoms.

It is probable that an explanation of the result of Bone and Wheeler that the kinetics were independent of oxygen pressure is to be sought in the higher temperature used by them. At increased temperatures the rate of oxygen adsorption would be greatly increased, so that the catalytically active centers would be largely covered with oxygen under all conditions. This could also explain their result that previous oxygen treatment decreased the rate of combination.

Summary

A study has been made of the catalytic formation of water vapor from hydrogen and oxygen in the presence of a reduced gold catalyst in the temperature range 130–150°, including measurements of the reaction kinetics by the flow method and determinations of the adsorptions of the two gases. The principal results are as follows.

1. The rate of reaction varies as the square of the hydrogen pressure and the first power of the oxygen pressure, and is approximately inversely proportional to the pressure of water vapor. Preliminary treatment of the catalyst with oxygen produces a large but transitory increase in yield. The average temperature coefficient is 1.92.

2. Under the conditions of the catalysis hydrogen is adsorbed by gold in scarcely measurable amount. Oxygen, on the other hand, is strongly adsorbed, the quantity taken up increasing with increasing temperature, but being practically independent of the pressure. The rate of its adsorption is very slow; it is practically independent of the gas pressure and increases with increasing temperature.

In spite of the similarity in chemical properties of gold and silver, the kinetics of the hydrogen-oxygen combination over the two metals show little in common. It appears that no simple mechanism for the reaction in contact with gold is adequate to account for the observed results.

STUDIES IN PHOTSENSITIZATION. I

BY JOHN R. BATES AND HUGH S. TAYLOR

RECEIVED JUNE 29, 1927

PUBLISHED OCTOBER 5, 1927

The field of photosensitization by mercury vapor has been extended during the past year to processes which do not involve hydrogen. Dickinson and Sherrill¹ showed that ozone was formed from the collision of excited mercury atoms and oxygen. Since the energy of the quantum corresponding to the 2536.7 Å. line is insufficient to decompose an oxygen molecule, they assumed that the reaction occurred through the collision of an excited and normal oxygen molecule.

Olson and Meyers,² investigating in more detail the reaction between hydrogen and ethylene reported by Marshall and Taylor, have shown that the reaction does not go smoothly to form ethane. Ethylene itself is polymerized, there being at the beginning of the reaction an increase in pressure which falls off again as the polymerization proceeds. They also found that the rate of the hydrogen-ethylene reaction was proportional to the square root of the hydrogen concentration.

Senftleben³ has found that the excited mercury atoms will decompose water vapor. Measuring the change in heat conductivity of water vapor when mixed with varying amounts of hydrogen and oxygen, he found that the change which occurred when water vapor and mercury were illuminated indicated that hydrogen was the sole product in the vapor phase. He, therefore, postulated the formation of hydrogen peroxide which condensed out.

The work here presented has as its object an attempt to broaden the field still further by the development of improvements in light sources for use in photosensitized processes and for general photochemical purposes, and by a study of a number of photosensitized and photochemical reactions. Those investigated are the hydrogenation and polymerization of ethylene and acetylene, the reaction of hydrogen and oxygen to form hydrogen peroxide and the decomposition of water, ammonia, ethylene, ethyl and methyl alcohols, acetone, formic acid, hexane, benzene and

ethylamine. A preliminary report on part of this work has already been published.⁴

Apparatus and Methods

The experimental arrangement used at the beginning of this work will be designated as the static system and was modeled directly after that of Taylor and Marshall. It consists of a quartz reaction chamber of about 100cc. capacity joined by capillary tubing to a mercury manometer, gas buret system and oil pump. An electric contact between a sealed-in platinum wire and the mercury in the manometer was used to keep the reaction system at constant volume and the course of the reaction was determined by a change in pressure. A change of 0.5 mm. could be detected. In the photosensitized studies the quartz vessel was immersed in a tank through which water was constantly running, with a vertical Cooper-Hewitt arc of the ordinary type at a distance of about 5 mm. from the vessel. Mercury vapor was furnished by about 1 cc. of mercury placed in the quartz tube. When the purely photochemical reactions were under observation the arc was placed outside the tank and allowed to run hot, the light reaching the reaction system through a quartz window in the side of the tank.

Fig. 1.

The inefficiency of this method was soon quite evident. It had many disadvantages. The arcs, which were run at 10 amperes and 18 volts, deteriorated rapidly. The mercury-vapor pressure in the reaction system could not be controlled independently of that in the arc, which had to be kept low to prevent reversal. Finally, only a very small fraction of the resonance light emitted by the arc could be used in the reaction.

These difficulties were overcome by the development of a cooled mercury arc, based on one used by Langmuir⁵ to study the characteristics of arcs at different vapor pressures. The arc proper is made entirely of G702P Pyrex glass with tungsten leads (Fig. 1). Through the center are two concentric quartz tubes R_1 and R_2 . R_1 is the reaction vessel while R_2 is a water jacket to prevent R_1 from becoming overheated by the action of the arc. The outside glass system is sealed to the quartz by means of rubber composition tape and an outside layer of Gooch crucible tubing, wired and shellacked. This permits operation at 100°. It is advisable, however, to have these seals protected by the two coils of lead pipe D, through which cold water may be kept

⁴ Taylor and Bates, *Proc. Nat. Acad. Sci.*, 12, 714 (1926).

⁵ Langmuir, *Gen. Elec. Rev.*, 27, 538 (1924).

running. N is the negative electrode and A, B, C₁ and C₂ are all positive. N and A are tungsten leads covered with just sufficient mercury to cause the two surfaces to come together on jarring the system. An arc is formed which immediately jumps to B, which is a nickel cone welded to tungsten. This serves the purpose of an electrode and at the same time deflects the mercury vapor from N against the walls of the bulb, which is kept in a water-bath. This regulates the vapor pressure in the arc to that of mercury at the temperature of the bath. The arc can be brought up to electrodes C₁ and C₂ by breaking down the space charge with the induction coil, the secondary of which is shown at I. C₁ and C₂ are two nickel cylindrical electrodes.

The wiring connections are shown in the drawing. The potential necessary depends to a large extent upon the geometry of the arc. In the one in use for this work R₂ is 45 cm. long and 2.5 cm. in diameter; R₁ is 37 cm. long and 1.5 cm. in diameter, the surrounding glass arc being 40 cm. long and 5 cm. in diameter. The side tubes containing C₁ and C₂ are 3.5 cm. in diameter and 5 cm. long. The side tube with the bulb and mercury reservoir is 30 cm. long and 3.5 cm. in diameter, while the diameter of the bulb is 6 cm. This has a drop of 35 volts from C₁ and C₂ to N when running at 18 amperes. The slide wire resistances are of such size and capacity (depending on the voltage of the power source) that the current from A to N is 0.5 ampere, B to N, 5 amperes, and from C₁ and C₂ to N up to 10 each. C₁ and C₂ must have separate resistances or the current would flow entirely to one of them, giving an unevenly distributed discharge. After the arc has been started, electrode B may be disconnected, but A should remain in the circuit to insure a steady arc.

Due to leaks around the seals it was not found feasible to run the arc without a mercury pump in continual operation. If the arc is run with air present in too large quantities, not only do the electrodes become oxidized, causing the arc to emit a pink glow, but the mercury tends to wet the glass between A and N, making it impossible to start. When the arc is first set up or after a long period of disuse the nickel electrodes must be degassed by the passage of a higher current than is ordinarily used.

The temperature of the water in R₂ should if possible be kept above that of the bulb to prevent distillation of mercury from N, which would cut down the light reaching the reaction.

In practice this system has always been used as a means of studying reactions by a flowing method. The gases, before entering R₁, are saturated with mercury at any desired temperature (usually about 50°) by passing them through a glass spiral, in every turn of which is a globule of mercury. In this way the gas passes over 15–20 separate surfaces and is insured of complete saturation. It was by this means that we were able to show that the idea of Rideal and Hirst that the reactions were some sort of catalytic phenomenon in which the mercury surface played a part was erroneous. For the first time the reactions were conducted in the absence of liquid mercury, and yet we obtained rates which were enormously greater than theirs. More concerning the general characteristics and optimum running conditions of the arc will be set forth in that part of this paper which deals with the hydrogen-oxygen reaction.

In the course of these studies it became desirable to do some work involving absorption spectra, for which a fairly intense source of continuous low wave length (2500–1900 Å.) ultraviolet light was necessary. A search of the literature revealed that the best means of producing such light must lie either in a high-frequency discharge under water⁶ or a hydrogen discharge tube.⁷ As ordinarily employed these are not very

⁶ Henri, "Études de Photochemie," Gauthier-Villars et Cie., Paris, 1919, p. 8.

⁷ Tingey and Gerke, *THIS JOURNAL*, **48**, 1838 (1926).

intense and exposures of at least an hour are necessary for spectrographic work.

Attempts to put more energy into an under-water discharge failed, due to the disruptive force of such discharges, which not only make a suitable container difficult to devise, but also cause the spark to emit iron lines as well as the continuous spectrum.

The hydrogen discharge tube yielded better results. This was made of 702EJ Pyrex glass joined at the two points S to 702P to allow the tungsten electrodes to be sealed into the system. These were of 40-mill wire, bent in the form of a spiral with two turns. They are placed 50 cm. apart and in such a position as to allow the light from the discharge to pass through the center of one and out by the quartz window P, sealed on with de Khotinsky cement. The two bulbs were 8 cm. in diameter and the joining tube 5 cm. A 5 kilowatt 110-volt transformer, delivering 25,000 volts on the secondary, was used to excite the discharge. It was run with 60 volts and 140-120 amperes on the primary. The hydrogen pressure was about 17 mm. The tube had to be continuously cooled with a blast of air and could not be run for more than one minute at a time, since it became hot enough to soften and collapse. This, however, was quite sufficient for an exposure, as the accompanying spectrographs (Fig. 5) show.

The lines are mostly those of mercury and a band unidentified. No effort was made to remove them as they are outside the range desired for study and in that region where the more easily obtained tungsten filament serves the purpose.

The Polymerization and Hydrogenation of Ethylene and Acetylene

The work on ethylene was done in the fall of 1925 prior to the publication of Olson and Meyers. It is in entire accord with their observations at low pressures and in some cases makes possible an interpretation of the mechanism involved.

Tank hydrogen purified by passing over hot platinized asbestos and phosphorus pentoxide was used. Tank ethylene, which showed a purity of 99.5% on analysis, was used directly after drying with phosphorus pentoxide. Acetylene was prepared by dropping water on calcium carbide covered with alcohol and was purified by a chain of wash bottles containing concentrated sulfuric acid and solutions of cupric and ferric chloride, mercuric chloride and sodium hydroxide and finally dried over soda lime and by passing through a trap surrounded with carbon dioxide-ether mush. The static system was employed.

The data of a typical run are shown in Table I. The arc was burning at 17 volts and 10 amperes. The alternate jumps of rate at the end of the reaction are due to the inability to read pressure changes to less than 0.5 mm.

Ethylene which had not been subjected to the action of excited mercury gave no test. It will be shown later that hydrogen can also be identified as one of the products.

Returning to the use of the static system, the polymerization of acetylene was investigated. Unlike ethylene, acetylene is polymerized to the yellow solid cuprene both in ultraviolet light and also by excited mercury atoms. The rate of reaction is greater with the cooled arc and the layer of cuprene is heaviest in that part of the reaction system adjacent to the arc, while with the hot arc a more even distribution of the solid is obtained.

Fig. 3

The layer formed prevents a prolonged run, since it soon cuts down the light intensity and slows down the reaction.

The effect of illuminating a hydrogen - acetylene - mercury mixture with the cooled arc was of much interest. Cuprene was deposited on all portions of the reaction vessel except that adjacent to the arc, which became coated with a colorless oil. The cuprene which condenses in this region is immediately acted upon by the hydrogen atoms. This is a very pretty proof of the fact, known from the work of R. W. Wood⁹ on the absorption of the 2536.7 Å. line by mercury vapor,

that all the activation of mercury atoms occurs in a very thin layer just inside the quartz wall upon which the light falls. In a typical run, 465 mm. of hydrogen and 219 mm. of acetylene were illuminated for thirty hours, giving a final pressure of 412 mm. An analysis of the resulting gases showed from a 32.8cc. sample, 31.4 cc. of hydrogen and 1.4 cc. of unsaturated hydrocarbons. There were no saturated hydrocarbons in the gas phase.

Discussion

The polymerization of ethylene, it can be shown, is the result of an extremely complex series of reactions. The collision of an ethylene molecule and an excited mercury atom very evidently results in the reaction

The reactions

⁹ Wood, "Researches in Physical Optics," Columbia University Press, 1913.

are very definitely barred. The first requires 138 kilogram calories. Both, moreover, are not possible because the chances of two hydrogen atoms combining are negligible compared to the probability of formation of a free ethyl group by a collision between a hydrogen atom and the large excess of ethylene molecules present, and experiment shows hydrogen and an increase in pressure, neither of which would be possible under those circumstances.

The subsequent reactions which may occur are many, but most of these would be of a second order compared with a particular few. The acetylene may be polymerized in the two ways

There is also the possibility of the acetylene activated by (2) or (3) reacting in some way with the ethylene. The hydrogen may be dissociated

with the consequent reactions

Unpublished work by Mr. W. H. Jones, mentioned by Taylor,¹⁰ has shown that free ethyl groups, liberated in ethylene, produce reactions which ultimately result in the formation of high-boiling hydrocarbons

Ethyl groups formed in (5) would react in this manner. Our results on the hydrogenation of acetylene show, by the absence of saturated hydrocarbons in the gas phase, that ethane is not formed by the action of acetylene and hydrogen.

These reactions fit in for the most part with the experimental data found on the polymerization. It is to be remarked that not only the primary reaction (1) originates in the narrow zone where mercury atoms in the 2^3P_1 state are present, but also the secondary reactions, with the exception of (3). Olson and Meyers observed that when their arc was allowed to heat up during the initial rise or at any time during the polymerization, no change in pressure occurred. This shows that (3) either does not occur or is of a much lower order of magnitude in the presence of ethylene in large excess. So that, while (1) will be occurring all the time, the subsequent reactions will depend upon the concentrations of hydrogen and acetylene in the zone containing the excited mercury. The initial rise will be regulated by the tendency of these molecules to

¹⁰ Taylor, *Proc. Am. Phil. Soc.*, **65**, 96 (1926).

diffuse away. By a comparison of the initial rise obtained by Olsen and Meyers with ours, we find them to be proportionately greater at low pressures. For example at 0.85 mm. the rise is 0.145, or $\frac{1}{6}$ of the total pressure; at 0.62 mm. it is 0.125, or $\frac{1}{6}$, and at 250 mm. it is 2 mm. or $\frac{1}{180}$ of the original total pressure. This is in accord with the influence of diffusion of acetylene and hydrogen on the initial rise, since the rate of diffusion would vary inversely as the pressure.

The overrunning of the theoretical stopping point in the hydrogenation is also explained by this mechanism. As the concentration of ethylene is increased, the probability of reactions (1) and (7) taking place is increased and so the overrunning is greater.

Hydrogen Peroxide from Hydrogen and Oxygen

Marshall has already reported the formation of hydrogen peroxide as an intermediate step in the photosensitized reaction of hydrogen and oxygen to water, as was predicted from the original chain mechanism postulated for this reaction by Taylor and Marshall. With the development of the new type of arc, giving sufficient energy to employ the flowing method which is necessary for the study of formation of hydrogen peroxide, we have investigated the conditions which favor its production.

Tank hydrogen and oxygen were passed through a tube containing phosphorus pentoxide, saturated with mercury as has been described and then passed through the arc. Hydrogen peroxide was frozen out in a trap surrounded with carbon dioxide snow and ether and titrated against 0.1 *N* potassium permanganate. The rate of flow of the two gases was determined by two water flow meters, calibrated over the desired range.

Preliminary experiments showed that the hydrogen peroxide was due entirely to the mercury present, and was not formed if the gases were sent through the arc without being saturated with mercury vapor. Ozone, however, was present in both cases, as was determined by bubbling the products through a potassium iodide solution, and by the odor. This showed that ozone was not the agent which produced the peroxide.

In Table III is given a summary of the results which show that it is possible to obtain hydrogen peroxide as the sole product by having a fairly rapid rate of flow and an excess of hydrogen.

TABLE III
FORMATION OF HYDROGEN PEROXIDE

Rate of flow, liters per hour		Time of run, min.	Mg. total product	KMnO ₄	Mg. H ₂ O ₂	H ₂ O/Hg
H ₂	O ₂					
100	50	10	..	4.1	7.2	82
60	29	10	6	3.5	6	113
101	28	16	7	4.3	7.3	157
19	11	22	6	0.85	1.5	37
14	51	20	5	.38	0.5	8

The arc was run at 13 amperes with the surrounding bath at 17°. The temperature of the saturator was 25°. The total products were found by weighing and the hydrogen peroxide was calculated from the titration. In the final column are the ratios of mercury atoms entering the system to hydrogen peroxide molecules formed. It can be seen from this that the efficiency of the mercury decreases with increasing oxygen concentration and either too high or, especially, too low rates of flow.

By increasing the temperature of the saturation by mercury a much higher yield of hydrogen peroxide was obtained. In these runs, however, it was found impossible to make any satisfactory measurements of the ratios of total products to hydrogen peroxide.

TABLE IV

FORMATION OF HYDROGEN PEROXIDE AT INCREASED TEMPERATURE OF SATURATION BY MERCURY

No.	Rate of flow, liters per hour		Temp. of bath, °C.	Cc. of 1 N KMnO ₄	Mg, H ₂ O ₂	H ₂ O ₂ /Hg
	H ₂	O ₂				
1	99	49	17	34.7	59	95
2	93	48	17	51.5	82.4	115

8	100	10	17	38.7	61.9	145
9	100	50	1	29.6	47.3	73.9
10	100	50	1	25.7	41.2	70.7
11	97	50	17	58.4	93.5	164
12	94	49	18	44.0	70.4	127
13	97	49	30	38.6	61.8	109
14	96	49	40	23.5	37.6	67
15	93	49	45	18.6	29.8	54

The arc was operated at 35 volts, 18 amperes, with the mercury saturation at 50°. Each run lasted 10 minutes. In Run 15, with the bath at 45°, the arc became constricted.

In all of these experiments the mercury appeared at the end of the reaction tube, just beyond the illuminated area, in the form of the oxide. Practically no oxide was deposited in the reaction vessel proper. The large number of hydrogen peroxide molecules formed per mercury atom entering shows that each atom is activated many times in passing through the illuminated zone. In Run 7, where the ratio of hydrogen peroxide to mercury is 258, each mercury atom must absorb and transfer at least 43 quanta, according to Marshall's measurements, which shows 6 molecules formed for every quantum absorbed. The atoms can be shown to have been in the illuminated zone two seconds in this run, which gives a time interval of 0.04 second between activations. This is enormously

larger than the value usually assigned to the life of an excited mercury atom in the 2^3P_1 state (10^{-2} sec.). These facts, however, show that the formation of the mercuric oxide is a secondary effect, probably due to the decomposition of the peroxide on the mercury. The non-reproducibility of the results may be accounted for by this, and by photochemical decomposition of the peroxide.

The last seven runs illustrate the efficiency of the arc at various vapor pressures of mercury and very clearly indicate the range of $10\text{--}20^\circ$ as the best operating temperature.

Photosensitized Decompositions

The dissociation of ethylene into hydrogen and acetylene very naturally led to an examination of the possibilities of other such processes brought about by excited mercury atoms. Water, ammonia, ethylene, methyl and ethyl alcohols, hexane, benzene, acetone, formic acid and ethylamine were all decomposed and those products of decomposition which passed through a liquid-air trap analyzed. No substance studied was unaffected by the excited mercury.

Fig. 4.

The experimental arrangement is shown in Fig. 4. The substance under examination is placed in A_1 and vacuum distilled to A_2 . A_1 is cut out by the stopcock and with liquid air around A_2 and the arc running the whole system is pumped down until the McLeod gage reads about 10^{-5} mm. The pump is then shut off and traps T_1 and T_2 are cooled in liquid air. The substance is then distilled over with the arc not running, as a blank, and the pressure read. This is necessary as some of the materials studied dissolve appreciable quantities of gas at liquid air temperatures. By distilling and pumping out, however, it is possible to obtain only very small pressure increases upon subsequent distillations. The largest

of these is of the order of 10^{-3} mm., which is negligible in comparison with those obtained by the decompositions. The arc is then started and the substance again distilled. The distilling gas is saturated with mercury in the spirals and after passing through the arc all condensable material taken out at T_1 and T_2 , the remaining gases being collected in the bulb of the gage. A run lasted, usually, for about 10 minutes. The pressure is recorded at frequent intervals, at first on the McLeod gage, and then on a side tube reading higher pressures. The gases which pass through the liquid air are nitrogen, oxygen, hydrogen, carbon monoxide and methane. These can be analyzed by means of the platinum filament and copper oxide tube. The mercury cut off at M is raised and the trap T_3 immersed in liquid air. The glowing filament will cause a decrease in pressure if there is oxygen present, but in the presence of methane and no oxygen there is a slight increase, due to the decomposition of the hydrocarbon. This increase was thus a useful indication of the absence of air. When there is such an increase, or when a decrease occurred to a constant pressure, the filament is turned off and the copper oxide heated. Carbon monoxide, hydrogen and methane are thus removed and the residual gas (in the case of ammonia and ethylamine) assumed to be nitrogen. The relative amounts of carbon dioxide and water in the products of combustion can be found by replacing the liquid air around T_3 by carbon dioxide snow and again reading the pressure.

When a comparison is desired between the photosensitized and photochemical reactions the mercury saturator is removed and the whole system cut down and cleaned with nitric acid to remove mercury. The pumping is then carried out for four or five hours through a liquid-air trap which prevents any diffusion of mercury vapor back to the reaction system.

The following typical data from two runs illustrate the method.

AMMONIA—saturated with mercury at 50°		FORMIC ACID (Hg at 50°)	
	Pressure in mm. of Hg		Pressure in mm. of Hg
5 minute blank run with arc off	2×10^{-4}	10 minutes blank	3×10^{-4}
arc running		arc running	
1 minute	0.55	1 minute	3.5
3 minutes	2.3	3 minutes	10.8
5 minutes	3.9	6 minutes	24.4
8 minutes	6.1	arc off	
10 minutes	7.8	Filament	24.4
arc off		CuO	0.7
Filament burning ten minutes	7.8	Changing liquid air to CO ₂	
Copper oxide tube heated two hours	0.87		17.8

A summary of the results is presented in Table V. The pressures recorded are those resulting from a ten-minute run.

^a Six minutes' operation.

sition is probably due to the flowing method used. Senftleben, who found only hydrogen in his reaction vessel after decomposition, was employing a static system, and ozone formed either by low wave length light or excited mercury is known to attack mercury to give the oxide. This does not preclude the possibility of the formation of hydrogen peroxide as an intermediate step. Senftleben has pointed out that the only initial process of decomposition possible with the energy obtained from a quantum of 2536.7 Å. is the dissociation of a water molecule into a hydrogen atom and an hydroxyl group.

The secondary reactions

are all equally probable and not all water molecules originally dissociating would result in the formation of hydrogen and hydrogen peroxide. This fits in with our results in that the efficiency of the mercury in dissociating water is low compared with the other processes, with the exception of benzene. A test of the products contained in the trap showed no hydrogen peroxide, but any condensing there would be immediately decomposed by the mercury present.

The fact that there is an excess of hydrogen (73%) over stoichiometric proportions (67%) can be explained as being due to the same processes which caused Senftleben to obtain no oxygen at all.

Ammonia.—The results on the photochemical and photosensitized decompositions of ammonia are the most important observed in these studies. As can be seen from the table the ratio of the photosensitized to photochemical rates is 200:1, showing that decomposition of ammonia is brought about by energy equivalent to a quantum of wave length 2536.7 Å.

Furthermore, in both types of reaction there is present in the product an excess of hydrogen over stoichiometric proportions (75%). This points to the formation of an intermediate compound such as hydrazine which is removed by the liquid air. The condensate in one of our runs of long duration was tested with a solution of silver nitrate after the ammonia had evaporated off. A black precipitate insoluble in an excess of ammonia was obtained. The reason for the presence of more hydrogen (96%) in the photochemical reaction products than in the photosensitized process (89%) is probably explained by Dickinson and Mitchell¹¹ who published a note on ammonia decomposition simultaneously with our original report. Using a static system, they obtained these same differences to a greater extent (87 and 70%) and explained them by the clean-up effect shown by hydrogen which has been dissociated by the action of excited mercury. This clean-up would naturally be greater in a static system than in one in which gases were continuously flowing.¹²

These new facts make possible a better conception of the mechanism of the photochemical decomposition of ammonia than has been given heretofore. Warburg¹³ measured the quantum yield and found it to be 4 quanta per molecule for light of wave length 2025–2140 Å. Kuhn¹⁴ has made, more recently, a very comprehensive study of the reaction, measuring quantum yields for various temperatures, pressures and wave lengths. Using the same interval of the spectrum as did Warburg, he obtained a yield of 2–2.5 $h\nu$ /mol. for 20°. If he increased the temperature, the efficiency of the light rose also, till at 500° the yield was 0.3 $h\nu$ /mol. The velocity increased proportionally with the quantum yield, being 9 times as great at 500° as at 20°. This temperature coefficient, which amounts to about 50% for every 100° does not obey the ordinary Arrhenius equation but remains constant with $(K_T + 10)/K_T = 1.05$ over the whole range studied. The reaction is independent of the pressure between 5 mm. and 900 mm. Using only the line at 2063 Å. he found that the quantum yield decreased to 10 $h\nu$ /mol. He showed, further, that the reaction rate became smaller as the decomposition proceeded, due apparently to the hydrogen formed, which has a very strong retarding effect on the reaction. Nitrogen was without effect. From these facts he derived a mechanism which not only does not account for the intermediate

¹¹ Dickinson and Mitchell, *Proc. Nat. Acad. Sci.*, **12**, 692 (1926).

¹² The presence of larger percentages of hydrogen in our reaction products than in those of Dickinson and Mitchell is probably due to our use of a flowing method. In a static system the intermediate products would remain in the illuminated zone and would be further decomposed to nitrogen and hydrogen, while in a flowing system they are immediately removed from the illuminated area and condensed in the traps.

product found by us, but which is also impossible according to the latest available values for the heats of dissociation of hydrogen and nitrogen.

Kuhn assumed that following the absorption of a quantum by a molecule

the activated molecule might return to the normal state by reëmission or react according to one of the following equations

However, the first of these is endothermic to the extent of 63,000 cal., if we accept the values of 260,000 cal. and 100,000 cal. for the heats of dissociation of nitrogen and hydrogen. He further suggests that the reason for the high quantum yields at elevated temperatures is the formation of hydrogen and nitrogen by this reaction

This is in direct contradiction to his explanation of the slowing up of the reaction in the presence of hydrogen, which he says is caused by the activated ammonia molecules dissociating hydrogen molecules by collisions of the second kind

The fact that the quantum of 112,000 cal. will decompose ammonia shows that there is necessary no additional activation other than the absorbed quantum which is equivalent to 128,000 cal. The molecules reacting have the same energy as the average energy of all the molecules. This is further demonstrated by the fact that the temperature coefficient remains constant. The explanation of the low quantum yield by assuming reëmission of the light by some of the molecules before reaction can take place does not agree with the independence of the reaction of any pressure change. If such were the case, a lowering of the mean free path 180 times, which corresponds to a pressure change from 5 to 900 mm., should affect the reaction. The proportionality of the rise in quantum yield and the increased velocity also indicate that every absorbing molecule reacts.

From these considerations we have been led to suggest a mechanism which, while not entirely satisfactory, is in better accord with all the data available. After the absorption

every activated molecule undergoes an initial reaction. This may occur in either of two ways

If (3) were the process occurring, the amino group would then react either with an ammonia molecule or a hydrogen molecule, if any were present.

While exact thermal data are of course unavailable on Reactions (4) and (5), it is quite probable that they will go.¹⁵

It is to be observed that these reactions would result in little or no pressure change and so would not be measured in the quantum yields. The decomposition of hydrazine would determine the measured reaction. This might occur photochemically, thermally or both. The sudden drop in yield to 10 $h\nu$ /mol. when a narrower band of spectrum is used points to the inability of hydrazine to absorb these wave lengths. The deficiency of the yield at low temperatures would be due to the reversal of Reaction (4). The increased yield and velocity with rising temperature might be due to a faster decomposition of the hydrazine preventing this reversal, or to a more rapid recombination of hydrogen atoms, which would be effective in the same way. In connection with the latter, it is of interest that the value of the temperature coefficient corresponds to the increase in collision frequency. A more detailed treatment of this phase of the reaction is not feasible, however, with the evidence on hand.

It may be pointed out that Reaction (5) and the reversal of (4) would account for both the slowing up of the reaction with time and the large retarding effect of admixed hydrogen.

There are several difficulties with this mechanism. It does not account for the fact observed by Warburg that hydrogen does not affect the reaction at low temperatures, nor is the maximum quantum yield of two in accord with Kuhn's value of three for high temperatures. However, there is no alternative explanation which fits the sum total of the data as well as this one, which is certainly a step in the right direction.

An attempt was made to show the presence of hydrazine after illumination of ammonia by the hydrogen discharge tube already described. It was hoped that absorption bands would appear which would differ from those of ammonia. We were, however, unable to detect any change in the absorption spectrum of ammonia after illumination for fifteen minutes.

In the course of this work it was observed that instead of a single band at 2260 Å., as reported by Leifson,¹⁶ there were two distinct bands. Measurements showed them to extend from 2266–2262 Å. and from 2262–2259 Å. (Fig. 5). The next band toward lower wave lengths, which marks the beginning of the series of bands described by Leifson as extending down to 1500 Å., begins at 2254 Å. It was not possible to distinguish the exact limits of the interval separating the two bands and so the center was recorded. A densitometer curve of one of the plates is given in Fig. 6.

¹⁶ Leifson, *Astrophys. J.*, 63, 73 (1926).

Ethylene.—The resulting products from the decomposition of ethylene (H_2 , 88%; C_2H_2 , etc., 12%) bear out in general the conclusions already advanced concerning the decomposition of this substance. The appearance of hydrocarbons in the gas phase after cooling in liquid air, however, seems to indicate that there are reactions occurring other than a pure

Fig. 5.

dehydrogenation. There is a possible explanation of this in that any ethane formed, and also ethylene, would exert a constant, small vapor pressure at liquid-air temperatures and be burned by the copper oxide. In support of this is the fact that we were never able to burn these products to less than 0.3 mm. pressure, even with liquid air surrounding the trap.

Fig. 6.

Ethyl and Methyl Alcohols.—The decomposition of the alcohols takes place through the intermediate formation of the aldehydes. Tests for acetaldehyde and formaldehyde were given by the products condensed in the liquid-air traps. While ethyl alcohol was apparently more easily decomposed, the ratio of the photosensitized to photochemical decomposition was greater in the case of methyl alcohol.

Hexane.—Hexane showed the largest divergence between the photosensitized and photochemical rates. Here again the process seems to be one of dehydrogenation, with only a small amount of hydrocarbon appearing in the gas phase.

Benzene.—While the pressure of the gaseous products is here the lowest obtained (0.3 mm.), it does not necessarily hold that this is due to the inefficiency of the excited mercury atoms in decomposing this substance. A heavy, tarry residue is deposited on the reaction vessel and a strong odor of diphenyl is present. If the reaction brought about by the mercury is one of dehydrogenation, as it is in most of the cases, it is evident that a hydrogen atom must be split off, since each carbon has but one hydrogen attached.

The probability of two hydrogen atoms recombining before reacting with a benzene molecule is extremely small, which would account for the small amount of gas formed. The appearance of such large proportions of hydrocarbons (40%) can be accounted for only upon the assumption that, in addition to dehydrogenation, a mercury atom, by transferring the energy, can also bring about a complete rupture of the benzene ring.

Formic Acid.—The decomposition of formic acid can take place in two ways

Ramsperger and Porter¹⁷ have shown that on illumination with a hot arc 64% of the decomposition occurs according to (1). Our results show, with the excited mercury, 76%. This is of much interest since it proves that the same quantum of energy transferred by a mercury atom can decompose a molecule in two ways. This cannot be due to the photochemical reaction, since the latter is only 0.25% of the total reaction, and we get 24% going according to (2). There are two means whereby the mercury atom may accomplish this "two type" decomposition. It may involve a steric effect of the collision of the mercury atoms and the molecule, or it may be that the energy, once transferred, is distributed in different ways among the vibrational degrees of freedom and thus brings about two kinds of reactions. Some evidence as to which is the case is being sought in this Laboratory at the present time by illumination of formic acid with monochromatic light. If both types of reaction still occur, it is purely a matter of the distribution.

Acetone.—This substance is so photosensitive itself that only a twofold increase in velocity was observed. In the photosensitized reaction, however, the product condensing in the liquid-air trap had a yellow color which was absent in the purely photochemical reaction.

Ethylamine.—This is another example of the type of reaction exhibited by ammonia. An intermediate compound is formed, giving a large excess of hydrogen in both types of decomposition.

Summary

1. A new type of cooled mercury arc for use in mercury sensitized and general photochemical reactions has been described.
2. By increasing the energy input into a high-pressure hydrogen discharge a continuous ultraviolet spectrum to 1900 Å. can be obtained and recorded with short exposure.
3. Ethylene condenses under the influence of excited mercury atoms with an initial rise in pressure. This does not occur by the action of light alone. The initial rise is due to the formation of acetylene and hydrogen and is regulated by the diffusion of these products from the zone of the excited mercury atoms.
4. Acetylene is polymerized by both excited mercury atoms and by ultraviolet light. Acetylene cannot be hydrogenated by hydrogen activated by excited mercury.
5. Hydrogen peroxide, formed in the mercury photosensitized reaction between hydrogen and oxygen, can be obtained as the sole product under certain conditions.
6. Water, ammonia, ethylene, ethyl and methyl alcohols, benzene, hexane, formic acid, acetone and ethylamine are decomposed by excited mercury atoms.
7. The decomposition products of ammonia show an excess of hydrogen over stoichiometric proportions. A mechanism is advanced for the photochemical decomposition of ammonia based on this and other data. The absorption spectrum of ammonia has been studied.

THE MAGNETIC SUSCEPTIBILITIES OF THE POSITIVE IONS OF VANADIUM

BY SIMON FREED

RECEIVED JULY 5, 1927

PUBLISHED OCTOBER 5, 1927

The view of Lewis¹ that the magnetic moments associated with the electrons in atoms or molecules usually neutralize each other in pairs has been confirmed by magnetochemical observations and by the analyses of spectra.^{2,3,4} No atom or molecule containing an odd number of electrons is known to be diamagnetic.⁵ However, there are numerous examples of paramagnetic atoms and molecules which contain an even number of electrons. Aside from the oxygen molecule, all such cases are to be found toward the centers of the long periods of the Periodic Table. The ions of vanadium investigated here occur in the first of these periods.

Hund's⁶ remarkable success in arriving at the magnetic moments of the ions of the rare earths in solution, from spectroscopic information alone, has raised the hope that the electronic configurations of all ions in solution might be determined and that an insight into their behavior might be obtained from spectroscopic data and the quantum theory.

A word should be said upon the relation of spectra to magnetic moments. In the evaluation of spectral lines it has been found possible to assign definite quantities of angular momentum to the electron (or electrons) in each orbit. The angular momentum of an electron is intimately related to its magnetic moment. More recently, the electron itself is pictured as spinning and the ratio in Bohr units of its magnetic moment to its mechanical moment is two. In general, the ratio between the magnetic moment and the resultant mechanical moment is some simple rational fraction, a value deduced in each case from observations on the anomalous Zeeman effect.

Hund⁶ supposed that the regularities found in the spectra of other ions existed in the spectra of the rare earths. This assumption led him to

assign in an unbroken sequence the character of the basic term of each ion, that is, the net angular momentum of the ion in its most stable state. Then, by applying the rules holding universally in the anomalous Zeeman effect, he calculated the magnetic moment of the ion in the gas. These values were almost identical with the values obtained from the crystals and from solution.⁷

Laporte and Sommerfeld⁸ have extended Hund's ideas to apply to the series of the elements from scandium to copper. Their predictions demand a knowledge of the energy intervals between the multiplet levels of the basic terms of the ions. Because of the complexity of these atoms such a knowledge will not be obtained for a considerable time. Moreover, the work to be herein described will show their conclusions to be highly improbable.

Magnetic Measurements in Solution

Magnetic susceptibilities of many substances have been measured but most of the results obtained have been vitiated by the magnetic impurities in the samples investigated. Recently some accurate work has been done.

Among the measurements that deserve the highest confidence are those of water and those of nickel chloride solutions—both of which were taken as standards for this investigation. The value adopted for the gram susceptibility of water at 20° was -0.720×10^{-6} , based upon the elaborate determination of Piccard and Devaud,⁹ who obtained -0.7199×10^{-6} with a probable relative error of 0.01%.¹⁰

The value 4383×10^{-6} was used for the molal susceptibility of NiCl_2 at 20.0°. This is the value obtained by Brant¹⁰ and was found to be constant over a 3000-fold change in concentration with a claimed accuracy of 0.1% in the portion of the range used here as standard.¹¹

Principle of Method

The method used was an adaptation of the Gouy method which depends upon having a cylinder with one end in a uniform field and the other end in a field of negligible intensity. The force on the cylinder depends upon the difference between the susceptibility per unit volume of the medium surrounding the cylinder and the susceptibility of the cylinder.

⁸ Laporte and Sommerfeld, *Z. Physik*, 40, 333 (1926).

⁹ Piccard and Devaud, *Arch. sci. phys. Nat.*, 5, 2 (1920).

¹⁰ Brant (*Phys. Rev.*, 17, 678 (1921)), whose values for nickel chloride were used here, by assuming the above value for water, checked the susceptibility of air obtained by Soné (*Phil. Mag.*, March, 1920, p. 345) within 0.1%. Seves' (*Ann. chim. phys.*, [8] 27, 189, 425 (1912)) value for water was -0.720×10^{-6} . Weiss and Piccard (*Compt. rend.*, 155, 1234 (1912)) obtained -0.7193×10^{-6} .

¹¹ The results obtained by Miss Brant checked well with those of Cabrera, Moles and Guzman (*Arch. Sci. Phys. Nat.*, 37, 325 (1914)) and those of Weiss and Bruins (*Proc. Acad. Sci. Amsterdam*, 18, 346 (1915)), whose accuracy was probably within 1%.

A null method utilizing this fact was suggested by Professor G. N. Lewis. Cylinders of various susceptibilities were balanced horizontally against liquids of known susceptibility. These cylinders were then used to determine the unknown susceptibilities of the solutions under investigation.

Various devices were tried out to realize the advantages of such a null method. In the earlier experimentation on the method the writer had the benefit of the coöperation of Dr. S. S. Shaffer.

Apparatus

EW is a Pyrex glass tube, 11 mm. in diameter at E and about 1 mm. at W. It is filled with nickel chloride solution and sealed at O where it is fastened by means of a strip of compressed paper and screws to a brass rod Y grooved to give the rod lightness and rigidity. The latter is fastened above to an angled brass frame which has an agate knife-edge H. The knife-edge rests on a polished horizontal agate plate fastened to a heavy brass bar. The latter is screwed to 4" X 4" uprights which are in turn bolted to the iron base of a powerful electromagnet. ZZ are nuts with which the center of gravity of the swinging system can be adjusted for its optimum sensitivity.

The "bath" in which the tube E is immersed is shown with its top view at A. The tube N about 12 mm. in diameter permits the circulation and mixing of the solution, which is done by a stirrer (not drawn) in the extreme right end of the bath, above the tube N. The portion EK' fits between the pole pieces of the magnet. The latter is of the Weiss type. It produces a field of about 19,000 gauss in a pole gap 2 cm. in diameter and 2 cm. long.

Fig. 1.

Materials

All the vanadium salts used were made from the same sample of hydrated vanadium pentoxide. The latter and the nickel chloride used for standardization were analyzed

by the systematic analytical procedure of Noyes and Bray¹² and of Noyes, Bray and Spear¹³ for the common and rarer elements. The sensitive color reactions for Fe, Co, Mn, Cr, Ni, Mo and Ti were taken advantage of and comparison was made with color standards in water or ether or, in the case of vanadium, in the vanadium solutions themselves, so as to eliminate any influence of the dissolved substances upon the sensitivity of the tests.

Sodium chloride was tested only for iron before its diamagnetic measurements. Perchloric acid and sulfuric acid were analyzed only for the commoner substances.

¹² Noyes and Bray, *THIS JOURNAL*, 29, 137 (1907).

¹³ Noyes, Bray and Spear, *ibid.*, 30, 481 (1908).

The hydrated vanadium pentoxide was found to contain 0.35 mole of sodium in the form of vanadate and 0.015 mole of acetate for every mole of vanadium in the sample. The amounts of potassium permanganate used to oxidize the same sample of vanadium pentoxide twice in succession after it had been reduced with sulfur dioxide were practically identical.

Because of its diamagnetism the effect of the acetate upon the results was neglected.

Analysis

The quantitative analysis of vanadium in its different valence states was made by titrating with standard potassium permanganate solution, which oxidized all of the vanadium to the quinivalent condition. Then through the resulting solution sulfur dioxide gas from a cylinder was passed which reduced all of the vanadium to the quadrivalent state. By reoxidizing this quadrivalent vanadium with the standard potassium permanganate solution the total vanadium was found. These two titrations were sufficient to determine the concentrations of vanadium of two different valences. It was assumed that not more than two can coexist in the solution because of their extreme reactivity.

Rutter¹⁴ has reported the rapidity with which these ions interact.

The reduction of vanadium by sulfur dioxide for its quantitative determination was highly recommended by Treadwell and Hall,¹⁵ Hillebrand¹⁶ and Lundell and Knowles,¹⁷ whose precautions were strictly followed.

The sulfate present in solutions containing quadrivalent vanadium (VO^{++}) was found to be quantitatively precipitated by barium chloride solution. In the analyses for sulfate, the trivalent and bivalent vanadium solutions were left exposed to the air to be oxidized to the quadrivalent state before the sulfate analyses were made.

Mode of Operation and Standardization of Tubes

Five tubes such as EW were filled with different concentrations of nickel chloride solution and sealed at O. Each tube was standardized by filling the bath in which the tube was immersed with pure nickel chloride solution and by adjusting its concentration until the tube would swing neither in one direction nor in the other when the magnetic field was on. After the balance had been reached in a field of about 19,000 gauss, samples were taken out of the bath and analyzed. The density of the solution was taken and also its temperature.

In the case of unstable substances, calibrated pipets were "washed" with carbon dioxide until they touched the bath. The pipet filled with the solution was allowed to drain to the mark and then into a flask filled with carbon dioxide and containing sulfuric acid solution and a known amount of potassium permanganate. As the pipet was being drained into the flask, a stream of carbon dioxide was passed just over the top of the pipet.

During the standardization of the tubes the effect of one drop of water in 175 cc. of solution in the bath could be detected when the more concentrated solutions (about 0.20 molal nickel chloride) were being measured.

In the following table are the concentrations of nickel chloride which balanced each tube and the corresponding susceptibilities per unit volume. These values were

¹⁴ Rutter, *Z. anorg. Chem.*, **52**, 368 (1907).

¹⁷ Lundell and Knowles, *THIS JOURNAL*, **43**, 1560 (1921).

computed by taking -0.720×10^{-6} as the susceptibility of a gram of water and 4383×10^{-6} as the susceptibility of a mole of nickel chloride at 20° .

A variation of 3° had no measurable effect upon the concentration necessary to balance each tube.

Independent magnetic measurements of the same tube gave identical results as far as analyses could disclose, that is, within 0.2%.

TABLE I
STANDARDIZATION OF TUBES

Tube	Molal concn., NiCl_2	Density	G. H_2O cc. soln.	$\chi_{\text{cc}}^{20^\circ} \times 10^6$
1	0.2766	1.0310	0.9951	+0.4958
2	.2191	1.0242	.9958	+ .2433
3	.1618	1.0176	.9966	- .0083
4	.1119	1.0115	.9970	- .2275
5	.07927	1.0076	.9973	- .3707

^a $\chi_{\text{cc}}^{20^\circ}$ is the susceptibility per cc. at 20° .

Diamagnetic Measurements

All of the constituents of the solution have associated with them definite amounts of diamagnetism. The diamagnetism of the magnetic ions will be discussed later. The diamagnetism of all the other ions was determined by the Gouy method described by Shaffer and Taylor.¹⁸

Wiedemann's law of the additivity of ionic susceptibilities was used in these evaluations as well as in the paramagnetic ones. To determine the susceptibilities of single ions the diamagnetism of one of the ions had to be known from some other source. The value -20×10^{-6} was taken for the atomic susceptibility of Cl^- . This value is in accord with the theoretical considerations on diamagnetism of Joos,¹⁹ who obtained -19.5×10^{-6} , and the experimental work of Pascal,²⁰ who obtained -20×10^{-6} from his magnetic work on organic compounds and on chlorine gas.

The following table gives the diamagnetic susceptibilities. They are the mean of a number of measurements and are good to about 5%.

TABLE II
DIAMAGNETIC MEASUREMENTS

From Table II the following values were adopted, $\chi_{\text{ClO}_4^-}^{20^\circ} = -28 \times 10^{-6}$; $\chi_{\text{SO}_4^{--}} = -37 \times 10^{-6}$; $\chi_{\text{Na}^+} = -12 \times 10^{-6}$.

Quadrivalent Vanadium Ion

The basic idea which was constantly kept in mind was to introduce a minimum of foreign matter into the solutions so as to keep the corrections as small as possible. All solutions were prepared at room temperature or below to avoid hydrolysis and other complications that might accompany higher temperatures. It appears that if cobalt chloride solution be warmed its molal susceptibility thereafter varies with the concentration but it remains constant if not warmed.

To minimize the danger of the formation of complex ions Professor G. N. Lewis suggested that the perchlorates should be used whenever feasible.

Preparation of Solution.— $\text{VO}(\text{ClO}_4)_2$ solution was prepared by suspending the hydrated vanadium pentoxide in a solution of perchloric acid containing a known amount of the acid. Hydrogen sulfide gas made by dilute sulfuric acid reacting with iron sulfide was washed in water and then conducted slowly into the solution. The liberated sulfur was filtered off through a Jena porous-glass filter and then the excess of hydrogen sulfide was pumped off at room temperature with a Nelson vacuum pump. Some of the blue $\text{VO}(\text{ClO}_4)_2$ solution was taken and carbon dioxide was passed through it and then into very dilute potassium permanganate solution for five minutes without decolorizing the pink solution.

As some authors claim that vanadium pentoxide reduced with hydrogen sulfide requires a little more potassium permanganate for its reoxidation than vanadium pentoxide reduced with sulfur dioxide, the $\text{VO}(\text{ClO}_4)_2$ solution freed from hydrogen sulfide was shaken with solid vanadium pentoxide and then filtered. Upon titrating the resulting solution with potassium permanganate solution, reducing with sulfur dioxide and titrating again, about 0.5% of quinquivalent vanadium was found in the solution. The amount of the latter increased to 0.9–1.0% by the time the last of the magnetic measurements on quadrivalent vanadium were finished.

The effect of so small an amount of diamagnetic²¹ substance was negligible.

The solution was diluted to a definite volume before any had been removed for detecting unevaporated hydrogen sulfide in order to fix the concentration of ClO_4^- . The concentration of total vanadium was determined in this volume and since the total number of moles of perchloric acid was known, a definite ratio of the concentrations of total vanadium to total perchlorate was fixed. This ratio remained unaltered

²¹ Ref. 20 a, p. 565.

throughout the various magnetic runs as it obviated the repeated analyses for ClO_4^- . The concentration of total vanadium in any solution automatically gave the concentration of total perchlorate.

Magnetic Measurements.—The data obtained on quadrivalent vanadium ion are given in the preceding table.

Trivalent Vanadium Ion

Preparation of Solution.—Rutter's¹⁴ suggestion that platinized platinum serve as the cathode in the electrolytic reduction of quadrivalent vanadium to trivalent vanadium was adopted.

As perchlorate ion is reduced by trivalent vanadium ion, the sulfate was used.

Vanadyl sulfate, prepared as described in the preceding section, was reduced in an electrolytic cell of about 200 cc. capacity. The latter consisted of a cathode of platinized platinum and of an anode of platinum wire. The latter was dipped into a dilute sulfuric acid solution in an aluminum thimble. Carbon dioxide at least 99% pure, which was passed through potassium permanganate solution and then through distilled water, was bubbled through the electrolyte.

The color changed gradually from a bright blue to a greenish-brown. This brown solution was filtered in an atmosphere of carbon dioxide through a Jena porous-glass filter.

Magnetic Measurements.—The data of the magnetic measurements are given in the following table.

TABLE IV

VII	.1076	.0073	.15	.0402	.264	.994	1.0261	— .3707	3216

^a If an attempt were made to calculate the susceptibility on the basis of V^{3+} , that is, disregarding the contradiction of inequality of positive and negative constituents, all values of magnetic moments would be about 0.3% higher.

^b The deficiency in sulfate to form just a neutral solution if V^{3+} were assumed is: I, 0.053 molal; II, 0.046 molal; III, 0.050 molal; IV, 0.019 molal. (The greater the deficiency, the less the H^+ concentration.)

A few remarks are necessary here. The brown solution of the preceding paragraph was measured magnetically and then analyzed. It was found to be a mixture of trivalent and quadrivalent vanadium; but the amount of sulfate present, known to within 1%, did not agree with the formula

V^{+++} for trivalent vanadium but accorded well with the assumption that the trivalent vanadium was present chiefly as VO^+ .

In the literature trivalent vanadium is described as green and its formula is usually given as V^{+++} . Indeed, the crystals of $V_2(SO_4)_3$ have been isolated out of a solution containing six-molal sulfuric acid.

A little more sulfuric acid was added in the next electrolytic reduction and the color of the final product was pure green as was expected.

The first four solutions tabulated were prepared independently; the green solutions were dilutions from one electrolytic reduction. An attempt to make the electrolyte even less acid than in I, II and III resulted in the gradual settling out of a greenish-gray precipitate.

The brown variety oxidized in the bath rapidly, although there was a heavy stream of carbon dioxide constantly entering the paraffin pocket.

In II an innovation was introduced. Xylene was put over the solution in the bath until it formed a layer 5 mm. thick. Moreover, the stream of carbon dioxide was not interrupted. Under these conditions, the deflection of the balance was the same before and after two minutes of rapid stirring, that is, the oxidation was sufficiently slow.

It should be observed that the results with xylene are the same as the one without xylene.

The Use of Xylene

Twenty cc. of xylene did not affect the color caused by one drop of 0.03 *N* potassium permanganate although the mixture was vigorously agitated. Ten cc. of xylene in contact with V^{++} for a day, as well as several cc. in contact with the trivalent for a week behaved similarly.

Benzene dissolves in water only to about 0.08% by volume. Toluic acid is given in the tables as less soluble in water than benzoic.²² Saturated aliphatic compounds are less soluble than aromatic. From the work of Conant and Cutter²³ on the action of bivalent vanadium on organic substances, it was concluded that its reduction of xylene was nil or negligible. Even if xylene were reduced, the product formed would be less soluble than xylene itself. Its diamagnetic effect could certainly be ignored, particularly as the difference in its diamagnetism from that of water would have to be considered. *Henceforth xylene was always used over the bath.*

The effect of carbon dioxide was also neglected. Its diamagnetism is quite high, -0.42×10^{-6} per gram according to Soné²⁴

The difference between this value and that of water is involved. A correction would amount to less than 0.1% in the magnetic moment.

Bivalent Vanadium

Preparation of Solution.—Bivalent vanadium was prepared from $VOSO_4$ in the same way as trivalent vanadium, except that a mercury cathode was used instead of a platinum one. The solution was surrounded with ice but in order to avoid local heating a low current density was used.

²² Hertz, *Ber.*, 31, 2671 (1898).

²³ Conant and Cutter, *THIS JOURNAL*, 48, 1016 (1926).

²⁴ Stoner, "Magnetism and Atomic Structure," Dutton and Co., New York, 1926, p. 268.

The color changed in some cases from the blue of the vanadyl to a brownish-green, then to a lavender, and in others from the blue to a deep brown with a greenish hue and then to lavender. The variation through the trivalent state depended upon the original acid concentration. The acid concentration was kept low and in every case a fine precipitate formed as the reduction passed through the trivalent state, a precipitate which did not redissolve.

The first attempt to prepare the bivalent vanadium resulted in a solution containing some of this precipitate and it catalyzed the decomposition of water to such an extent as to decompose 23 to cc. out of 150 cc. in fifteen minutes.

The tube through which the carbon dioxide was bubbled into the cell was later used to siphon the solution through a porous-glass filter into a filter flask connected to a vacuum pump. The filter was in a Gooch funnel which reached to the bottom of the filter flask, in which there were about 10 cc. of xylene. The system was filled with carbon dioxide before evacuation began. In its passage from the electrolytic cell, which was constantly in operation and evolving hydrogen, to the filter flask the bivalent vanadium did not come in contact with the atmosphere.

The concentration of the acid was reduced and a solution of bivalent vanadium was finally prepared which could be handled with comparative ease.

Magnetic Measurements.—The following table (V) gives the results. As will be observed, the bivalent vanadium was contaminated with a considerable amount of trivalent vanadium. If the trivalent had been assumed to be of the form V^{+++} , there would still have been a surplus of SO_4 to account for the H^+ tabulated. It was then obvious that the trivalent vanadium present was of the "green variety" considered under "Trivalent Vanadium."

For purposes of correction, the average of the three green solutions of trivalent vanadium was used, that is, 3228×10^{-6} as the molal susceptibility of V^{+++} at 20° .

* Preliminary run included to show that the peculiar increase in grams H_2O per cc. of solution was probably real. In the preliminary run, the solution was heated to evaporate the excess of sulfur dioxide gas in the reduced vanadium pentoxide solution. It was then cooled in ice and electrolyzed. The regular solutions were never heated.

In the calculations, the presence of carbon dioxide in the solution was ignored, as was done previously.

Aside from the experiments whose results have been tabulated, only one other complete magnetic run on the vanadium ions was made. This was rejected because of a poor check in the analyses.

Discussion of Errors

The cumulative effect upon the susceptibility of the quadrivalent vanadium ion of all the substances ignored in the calculations, such as dissolved air, carbon dioxide, etc., is probably not more than 0.3% (or 0.15% in the magnetic moment). The effect of each substance is in general to reduce the apparent susceptibility because of the very high diamagnetic susceptibility of one gram of water.²⁵

The errors in the analysis of quadrivalent vanadium are probably not greater than 0.2%, those of trivalent vanadium not greater than about 0.5% and those of the bivalent ion not greater than about 0.8%. In the two latter cases, the reflection of these analytical errors upon the susceptibilities is not as serious as it appears to be. The concentration of total vanadium even here was determined within about 0.3% and a decrease in the bivalent vanadium (if that be the ion under consideration) due to an analytical error would increase the trivalent ion impurity and so the resultant error would involve the differences in the susceptibilities of these two constituents and not one only.

More serious sources of error are the diamagnetic corrections and the correction for V^{+++} in V^{++} solutions.

The uncertainty in the value of e/m is of vital importance when the magnetic moments are considered, especially in the case of quadrivalent vanadium ion.

Discussion of Results

Change of susceptibility with change in acid concentration is common. It is usually attributed to the formation of complex ions. The latter probably result from the pairing of unbalanced electrons. It is not surprising then that the susceptibility of the trivalent ions should decrease with increasing H^+ concentration. The variation in susceptibility of the bivalent vanadium ions might be due almost entirely to the accompanying trivalent vanadium ions. As previously mentioned, it was the constant aim to have a minimum of acid present.

Langevin²⁶ arrived at the following formula connecting the susceptibility of a paramagnetic gas with its magnetic moment for ordinary field strengths and at room temperature

$$\chi T = \frac{M^2}{R} \overline{\cos^2 \Theta}$$

where M is the magnetic moment of a mole of the gas, R is the gas constant, T is the absolute temperature and $\overline{\cos^2 \Theta}$ is the mean of the square

²⁵ The content in water was determined by the difference between the calculated weight of the dissolved substances in 1 cc. listed in the tables and the specific gravity of the solutions.

²⁶ Langevin, *Ann. chim. phys.*, [8] 5, 70 (1905).

of the cosines of the angle which the axis of the electronic orbit makes with the direction of the magnetic field.

The magnetic moment considered above applies only to the paramagnetism of the gas and not to the diamagnetism induced by the field, which reacts upon the susceptibility actually measured. Corrections for this diamagnetism must be estimated. Its amount is small and the error introduced in the estimation is not serious. Thus, potassium ion has a molal susceptibility of -15×10^{-6} , whereas calcium being a bivalent ion²⁷ has a smaller susceptibility, in fact -6×10^{-6} . VO^{++} because of its oxygen content is probably a little more diamagnetic than the latter.²⁸ As a rough estimate -13×10^{-6} per mole was taken. In the same way, -20×10^{-6} was taken as the molal diamagnetic susceptibility for VO^+ . That of V^{+++} and V^{++} was neglected. If the VO^{++} had been considered to have zero for its diamagnetic susceptibility, the magnetic moments tabulated would have been lowered by 0.5%.

One-half of one per cent. is about the uncertainty in our knowledge of the exact value of e/m . The value of the latter as given by Sommerfeld is employed, that is, 1.769×10^7 . Consequently, the Bohr unit of magnetic moment

$$\frac{1}{4\pi} N h \frac{e}{m} = 5584 \text{ gauss cm. per mole}$$

From this value and the Langevin equation as modified by Sommerfeld's²⁹ application of the quantum theory, the following table was calculated.

According to the quantum theory only discrete orientations of the magnetic moments with respect to the field are permissible. If the lowest term of the ion is an S term, the orientations depend only upon the resultant mechanical moment of the ion.³⁰

TABLE VI		
Units of angular momentum	Bohr magnetic units	Average squared cosines
$1/2$	1	1
$2/2$	2	$2/3$
$3/2$	3	$6/5$

For all S terms, the ratio of the magnetic moment to the mechanical moment is exactly two. For basic levels other than S the ratio is in general non-integral. Using the $\overline{\cos^2\Theta}$ listed in each table, the following values were obtained for the magnetic moments.

²⁷ Ref. 24, p. 271.

²⁸ Pascal, ref. 20, found that O in organic compounds has the atomic susceptibility of -4.6×10^{-6} .

^a Refers to tables of susceptibilities.

From the measurements of Cabrera³¹ it appears that Cr^{+++} has 3 (within 1%) and Cr^{++} has 4 (within 2%) Bohr magnetons. The generalization of Kossel³² that the atomic moments of all ions having the same number of electrons are equal has been found to hold ($\text{V}^{++} - \text{Cr}^{+++}$).

The three ions of vanadium and the two of chromium form a remarkable series of integral values,³³ values which would never be expected from the theory of Laporte and Sommerfeld.⁸ The values anticipated by them would be non-integral and, *a fortiori*, not a regular sequence of integral values.

Sommerfeld's modification of Langevin's equation is based upon the anomalous Zeeman effect, as observed on *atoms* and atomic ions. Why the application of such an equation to *molecular* ions in solution such as VO^{++} and VO^+ should yield integral numbers of Bohr magnetons is not at all clear.

The striking resemblance in the character of electronic levels of molecules (and molecular ions) to that of electronic levels in atoms (and atomic ions) of the same number of "valence" electrons³⁴ has caused the electronic levels of molecules to be classified as S, P, D, etc., levels in analogy to the energy levels of atoms. To determine how strict this analogy is will require much further work in band spectra.

It is highly probable that even in the case of "simple" atomic ions, such as those discussed here, the ionic individuality includes the water

³¹ Cabrera, *Anales soc. españ. fis. quim.*, 15, 199 (1917), given by Weiss, *J. phys. radium*, 5, 141 (1924).

³² Kossel, *Ann. Physik*, 49, 229 (1916).

³³ Mn^{++} and Fe^{+++} also constitute members of this series as each of them appears to have five Bohr magnetons. (Ref. 29, p. 639.)

³⁴ (a) Mulliken, *Phys. Rev.*, 26, 561 (1925). (b) Mecke, *Naturwissenschaften*, 13, 698 (1925). (c) Birge, *Nature*, 117, 300 (1926).

molecules of coordination.³⁵ The atomic ions in long periods of the Periodic Table should then be considered as of the molecular type. Presumably magnetic influences on band spectra (Zeeman effect, Paschen-Back effect) should be invoked to study them and not the anomalous Zeeman effect on atomic ions as has been done heretofore.

The writer expresses with pleasure his deep obligation to Professor G. N. Lewis for his suggestions and interest in this research. He also wishes to thank Professor W. F. Giaque for his interest in this work.

Summary

1. A new method has been developed for measuring magnetic susceptibilities.

2. The magnetic susceptibilities of the positive quadrivalent, trivalent, and bivalent ions of vanadium have been measured.

3. It appears that: (a) the quadrivalent vanadium ion has 1 integral Bohr magneton; (b) the trivalent vanadium ion has 2 integral Bohr magnetons; (c) the bivalent vanadium ion has 3 integral Bohr magnetons.

4. The above results do not agree with any current theory based upon the quantum theory and anomalous Zeeman effect. A reason for this discordance is suggested.

5. Some measurements on diamagnetic substances are included.

STUDIES OF METHANOL CATALYSTS. I

BY HUGH STOTT TAYLOR AND GEORGE B. KISTIAKOWSKY¹

RECEIVED JULY 11, 1927

PUBLISHED OCTOBER 5, 1927

During the past few years the technique of hydrogenation catalysis in industry has undergone a revolutionary development. Until recently, hydrogenation catalysts were confined practically exclusively to a very restricted series of metals, among which platinum, nickel, copper and iron were the most important. With the industrial development of methanol synthesis, this series of catalysts has expanded fundamentally in that it has been shown that a variety of hydrogenation processes may be carried out in contact with various oxides or mixtures of the same. This extension

³⁵ Such a condition undoubtedly obtains among the ions having their outer electronic shells incompletely filled. On the other hand, among the ions of the rare earths the electrons responsible for the magnetic moments are far within the kernel and are surrounded by shells having their full complement of electrons. Under such conditions, the water molecules do not form an integral part of the ions and apparently their influence is slight, as is shown by the close agreement between the values calculated from spectroscopic studies and those observed in solution.

¹ International Research Fellow.

was an obvious development of the observations of Sabatier and succeeding workers on the activity of such oxides as dehydrogenating catalysts and on the conclusion from thermodynamic reasoning that a catalyst for a reaction in a given direction is a catalyst also for the reverse reaction.²

Thus far, the study of oxide catalysts for hydrogenation has been almost exclusively technical; little inquiry has been made into the fundamental aspects of the problem. The use of oxide catalysts for dehydrogenation processes has, on the other hand, been the object of a considerable amount of scientific study with a view to elucidating the mechanism of the catalytic action.³ As yet, however, the problem of mixed dehydrogenation and dehydration is still a matter for lively discussion. We have accordingly ventured to initiate a systematic study of oxide catalysts as hydrogenation agents, along the lines that have proved successful in this Laboratory when applied to metal catalysts. It was hoped that something could be learned, by such studies, concerning the properties of oxide catalysts in general. The reason for their superiority over metal catalysts for methanol synthesis might also be elucidated. The present paper records the results of adsorption studies with two typical methanol catalysts, zinc oxide and a mixture of zinc and chromium oxides.

The adsorption of gases by oxide catalysts has already been the subject of some little study. Benton⁴ measured the adsorptive capacity of various oxide oxidation catalysts for hydrogen and carbon monoxide. Lazier and Adkins⁵ attempted to correlate the dehydrogenation-dehydration ratio of zinc oxide with the adsorption of this oxide and other catalysts but concluded that there existed no simple relationship between the two factors. Hoover and Rideal⁶ studied the adsorptions of hydrogen and ethylene on thoria catalysts in order to learn something of the dehydrogenation-dehydration activity of thoria for ethanol. In our work, in ascertaining the adsorption of hydrogen and carbon monoxide on zinc oxide and on a mixture of zinc and chromium oxides, we were studying the capacity of a single oxide catalyst and of a well-known active methanol mixed oxide catalyst for the only two reactants of the methanol synthesis. We have also measured, in one case, the adsorption of carbon dioxide. Our results have abundantly justified the effort.

Experimental Procedure

Apparatus.—The apparatus was essentially that used in the earlier experimental studies of adsorption on metal catalysts.⁷ A vessel containing the catalyst was connected through three-way stopcocks with a manometer, gas buret and pump system for evacuation purposes. In the present experiments the latter consisted of two mercury vapor pumps in series with a high-vacuum oil pump as fore-vacuum. The free space in the catalyst vessel was determined by a series of measurements of volume and pressure of a non-adsorbed gas, for example, nitrogen, at a controlled temperature. From the volumes of hydrogen or carbon monoxide required to fill the vessel to a given pressure at the same temperature, the extent of adsorption at this pressure could be determined.

Catalysts Employed.—Three samples of a single preparation of zinc oxide and one of a mixed zinc oxide-chromium oxide were studied. The zinc oxide was prepared by ignition at 450°, special precautions being taken to ensure that the catalyst was entirely free even from traces of alkaline or acid ions, since these may both materially alter the characteristic of the catalyst.^{3c,d} The mixed zinc oxide-chromium oxide was of the type described in patents of the Badische Company,⁸ obtained by precipitating zinc chromate from a solution of the nitrate, thoroughly washing the precipitate, drying and igniting at 450°. It contained approximately two moles of ZnO to one mole of Cr₂O₃. With both these catalysts methanol can be readily made from mixtures of hydrogen and carbon monoxide; it is well known, however, that the mixed catalyst is far superior to the single oxide.⁹ The zinc oxide samples were, respectively, 39, 39 and 32 g. The zinc oxide-chromium oxide sample weighed 25 g.

Experimental Results.—Our early experiments showed that the adsorptive capacity of a sample of the oxide was very sensitive to the cleanness of the surface. It was soon found that both zinc oxide and the mixed oxide catalyst showed no adsorption for either hydrogen or carbon monoxide even after evacuation for one hour at 300° in the high-vacuum system already described. Between 300 and 400°, however, a rapid evolution of adsorbed *water vapor* and *carbon dioxide* occurred, after which the surface of the catalyst immediately revealed pronounced adsorptive capacity for both gases.

Fig. 1 shows graphically the increase in adsorptive capacity for carbon monoxide of zinc oxide, No. 1, consequent on the increasing cleanliness of the surface, due to better evacuation. The curves 1a and 1b, etc., are corresponding runs at 100 and 0°. The initial runs with this gas,

⁷ See, for example, Pease, *THIS JOURNAL*, **45**, 1196 (1923).

⁸ Brit. pat. 227,147; U. S. pat. 1,558,559.

⁹ Patart, International Conference on Bituminous Coal, Carnegie Inst. Tech., 1926, p. 141.

after pumping off at 200°, showed identical values for nitrogen and carbon monoxide, indicating zero adsorption of the latter. The succeeding results, recorded in the order of their performance, show the progressive increase in the adsorptive capacity of the catalyst. Curves 3a and 3b were obtained after evacuation for three hours at 510°. One result with hydrogen, 4a and 4b, is also included for comparative purposes. We have found that portions of both gases are adsorbed very tenaciously and are only removed from the surface in the oxidized condition either as carbon dioxide or water vapor, partial reduction of the catalyst to a corresponding amount occurring. At first we were inclined to ascribe all of the increase in adsorptive capacity to this reduction process but we now have full evidence that even unreduced but clean surfaces of these catalysts show large adsorptive capacity for the two gases.

Fig 1

The reduction produces gray spots in the otherwise white zinc oxide. The reduction process is very probably an interface reaction as with copper oxide¹⁰ since the gray spots grow with increased treatment. At first we considered the possibility that the dark spots might be due to catalytic decomposition of carbon monoxide by the reaction, $2\text{CO} = \text{CO}_2 + \text{C}$, carbon being deposited in the oxide. Our experiments on zinc oxide No. 2, carried out exclusively with hydrogen, disposed of this possibility since here again the gray specks formed. The adsorption of hydrogen on this catalyst is shown in Fig. 2, Curve I, after evacuation at 450°. Since we found that a treatment at 500° with oxygen partially destroyed the adsorptive capacity (Curve II) and since oxygen was partially consumed in the process, we assumed this to be evidence in favor of adsorption

¹⁰ Pease and Taylor, *THIS JOURNAL*, 43, 2179 (1921).

by reduced zinc nuclei in the mass. An extended treatment with oxygen for 18 hours, followed by evacuation at 500° , gave a surface which subsequently showed (Curve III) high adsorption for hydrogen, thus discrediting the theory that adsorption is due *solely* to metal atoms.

Fig. 2.

We disposed of this metal theory of adsorption by evacuating zinc oxide No. 3 thoroughly at 500° before bringing the sample into contact with any reducing gas. Curve I in Fig. 3 shows the high adsorptive capacity attained. With this catalyst we also showed the adverse effect of too

Fig. 3.

high a temperature, since Curve II shows the diminished adsorption after evacuation at 600° . This sample was very dark in color after this treatment.

In order to compare adsorptions on zinc oxide and on the mixed oxides we next made measurements on the zinc oxide-chromium oxide sample.

This adsorbed neither gas after evacuation at 200 or 300°. After half an hour of evacuation at 400°, Curve I, Fig. 4, with hydrogen was obtained. A further half hour of evacuation at 400° gave with hydrogen the results in Curve II. Curve III records results with carbon monoxide

Fig. 4.

after a further half hour of evacuation at 400°. Curve IV gave hydrogen adsorption after one further evacuation for half an hour at 400°. It is very definitely established from these results that the hydrogen adsorption is more marked than that of carbon monoxide on the mixed oxide catalyst, while the reverse is true on the single zinc oxide (Fig. 1).

Fig. 5.

Fig. 5 shows the extraordinary adsorption of carbon dioxide by the zinc oxide catalyst. Thus the admission of 21.70 cc. of this gas to the catalyst at 100° produced a pressure of only 5 mm., and this pressure may be due in part to impurities, since tank carbon dioxide only was used; in the preceding runs with hydrogen and carbon monoxide the same amount of these gases had produced pressures of approximately 250 mm. This experiment confirms our observation in the evacuation process of the tenacity with which both carbon dioxide and water are adsorbed.

Discussion of Results

The experimental results demonstrate conclusively that zinc oxide and zinc oxide-chromium oxide catalysts show the same type of adsorption for the reactants of the methanol synthesis that is shown by metal catalysts in hydrogenation reactions. The type of adsorption isotherm is exactly the same in the two cases. There is strong adsorption at low pressures with relative saturation of the surface at these low pressures and little increase in adsorption with a many fold increase in pressure. This latter is readily appreciated by observing the nearly horizontal portions of the curves in the several diagrams.

The astonishing feature of the studies is, however, the extraordinary capacity of the catalysts for adsorption of the gases in question. They show many times the adsorptive capacity of the metal catalysts under the same conditions. This is readily seen from the appended Table I, which gives a few selected data of maximum adsorptions found in the earlier studies at Princeton on metal catalysts, under a variety of conditions, as well as some typical results from the present research.

TABLE I

Catalyst	ADSORPTIONS PER 100 G. OF CATALYST			Author
	Cc H ₂ adsorbed	Temp, °C.	Press., mm.	
Reduced copper	13.4	110	760	Taylor and Dew
Reduced copper	45	0	760	Taylor and Beebe
Reduced nickel	130	0	760	Taylor and Beebe
ZnO-Cr ₂ O ₃	184	100	1	Taylor and Kistiakowsky
ZnO	50	0	20	Taylor and Kistiakowsky

The table shows that at 100° and 1 mm. pressure a zinc oxide-chromium oxide catalyst has a greater adsorptive capacity for hydrogen than the best nickel catalyst we have ever prepared possesses at 0° and 760 mm., and a 13-fold better adsorptive capacity than a very active sample of reduced copper at 110° and 760 mm. pressure. The extremely high adsorptive capacity at low pressures thus revealed implies a very considerable amount of active catalytic surface per unit weight of material. This implies a corresponding insensitiveness to poisons and foreign materials in the gas mixture for such oxide catalysts. It may be concluded that such catalysts will tolerate concentrations of reversible poisons many fold greater than those which, with metal catalysts, produce a given diminution in catalytic activity. This is a very important industrial consideration.

Both the curves and the table show that the active surface in a mixed zinc oxide-chromium oxide catalyst is far greater than that of a corresponding weight of zinc oxide catalyst. There is, therefore, no element of surprise in the statements in both patent and technical literature that such mixed oxide catalysts are preferable to the single zinc oxide. Whether

the change in ratio of adsorption α_{H_2}/α_{CO} , with change from a single to a mixed oxide catalyst is significant in the synthesis of methanol cannot be deduced from these experiments. It will be noted that the ratio α_{H_2}/α_{CO} changes from approximately unity to approximately 0.5 at, for example, 100 mm. pressure. Whether this ratio change is significant may possibly be revealed by kinetic studies of the methanol process which are now in progress.

The very pronounced adsorption of carbon dioxide shown in Fig. 5, and the observation that both water vapor and carbon dioxide are so strongly retained by these catalysts that no measurable adsorptions were shown by samples evacuated at or below 300°, indicate that both gases are temporary poisons for these catalysts in methanol synthesis. It is significant that the activity of these methanol catalysts begins in the temperature range in which free evaporation of carbon dioxide and water vapor occur.

The rapid saturation of the surface at low pressures or the small change in total adsorption at higher pressures is characteristic of adsorptions involving high heats of adsorption. Rough calculations from the adsorption isotherms at 0 and 100° confirm this conclusion and indicate heats of adsorption of the same order of magnitude as are involved in adsorption of the gases on metal catalysts and considerably greater than the heats of liquefaction of the gases. We are attempting to measure these heats of adsorption directly to ascertain their precise magnitude and to discover whether they indicate special processes of activation.

The experiments recorded here are in complete harmony with the known activity of zinc oxide and zinc oxide-chromium oxide catalysts as agents for the synthesis of methanol. They suggest, however, a whole series of further investigations designed to ascertain why other oxides, for example magnesium oxide, cannot be utilized for such purposes with efficiency. The answer to such problems should promote a fuller understanding of the general problem of contact catalytic action. With some of these questions we are now engaged.

Summary

1. Adsorptions of hydrogen, carbon monoxide and carbon dioxide on two methanol catalysts, zinc oxide and zinc oxide-chromium oxide, have been measured at 0 and 100°.
2. It has been shown that, to obtain such measurements, the catalyst surface must be cleaned of adsorbed water vapor and carbon dioxide by evacuation at 400°.
3. It has been shown that both catalysts have adsorptive capacities per unit weight considerably greater than those of most metal catalysts.
4. The adsorption of both hydrogen and carbon monoxide is pro-

nounced at very low pressures and rapidly reaches saturation capacity independent of further pressure increase.

5. The experiments indicate that the heat of adsorption is considerably greater than the heat of liquefaction and attains values characteristic of heats of adsorption on metal catalysts.

6. The mixed oxide catalyst shows greater adsorptive capacity than the zinc oxide in harmony with its higher order of catalytic activity.

7. The experimental results generally are shown to be in agreement with the known facts concerning methanol synthesis on these catalysts.

PRINCETON, NEW JERSEY

THE STANDARDIZATION OF PROFESSOR T. W. RICHARDS'S THERMOCHEMICAL DATA

BY WOJCIECH SWIETOSLAWSKI AND J. BOBINSKA

RECEIVED JULY 20, 1927

PUBLISHED OCTOBER 5, 1927

Professor T. W. Richards has authorized one of us to recalculate the values of the heats of combustion of organic compounds as examined by him, in order to standardize them and make them comparable with the standard unit now accepted in thermochemistry. As benzoic acid is established as this unit, the base for that comparison is the heat of combustion of 1 g. of benzoic acid weighed in a vacuum, 6319 cal. _{15°}, or 1 g. of this acid weighed in air, 6324 cal. _{15°}.

Discussing this question personally with Professor Richards, we accepted that, in the first column of each table containing the standardized thermochemical data, there must be cited the unchanged values, as given by the author in his original publication. Naturally, these values must be expressed in the same units used by the author. Therefore, we give in our two tables the values expressed in 18° calories or in kilojoules, respectively.

According to the different dates of publication, the measurements of Professor Richards are divided into two groups. The first series contains the determinations made with R. H. Jesse in 1910; the second one contains the rest, carried out after 1915, that is to say, after the appearance of Dickinson's investigations which established with great accuracy the heats of combustion of benzoic acid, cane sugar and naphthalene. This division is connected with the manner of determination of the heat capacity of the calorimetric system. In 1910, Professor Richards and R. H. Jesse carried out this determination using cane sugar as a standard substance. They accepted for the heat of combustion of this compound the value 16,545 kilojoules, proposed in 1909 by E. Fischer and Wrede. In the other papers, published after 1915, Professor Richards accepted the figures given by Dickinson.

The standardization of the data published after 1915 did not present any difficulty. In fact, Dickinson's values for the heats of combustion of benzoic acid, cane sugar and naphthalene had been accepted by the International Committee on Thermochemical Standards as the base for the establishment of the heat of combustion of benzoic acid. Therefore, the standardization in this case is a matter of expressing Professor Richards's data in terms of 15° calories instead of 18° calories or kilojoules, as was done in the original papers.

The coefficient rendering this recalculation possible is equal to 0.99942. It is calculated by using the following values of the mechanical equivalent of heat, determined by transforming electrical energy into heat at different temperatures.

Temp., °C.	Mech. equiv. of heat	Temp., °C.	Mech. equiv. of heat
15	4.1843	18	4.1819
16	4.1835	19	4.1812
17	4.1827	20	4.1805

The corresponding coefficient enabling us to standardize the data published in Professor Richards's first paper (1910) has been determined by comparing the values given by Fischer and Wrede for the heats of combustion of cane sugar and naphthalene with the figures established lately with great precision by several authors (Dickinson, Verkade, Swietoslawski and Starczewska and Schläpfer).

It has been shown by Swietoslawski,¹ in several papers concerning the establishment of a thermochemical standard unit, that the above-mentioned data of Fischer and Wrede are too high by +0.3%. The following comparison gives directly the value of the coefficient which ought to be accepted for the recalculation of the Richards data published in 1910.

Compound	Formula	Fischer and Wrede [KJ]	Standardized data [KJ]	Stand. data
				Fischer and Wrede
Naphthalene	C ₁₀ H ₈	40,314 ^a	40,179	0.9967
Cane sugar	C ₁₂ H ₂₂ O ₁₁	16,545 ^b	16,501	0.9973
				Average value 0.9970

^a Wrede

^b Fischer and Wrede (2).

When the above-mentioned values have been expressed in kilojoules, the coefficient 0.9970 must be multiplied by 1000 and divided by 4,1843; $\alpha = (0.9970 \times 1000)/4.1843 = 238.27$.

In the two tables the first column contains the name of the substance with reference to original publication; the second, the formula; the third, the molecular weight *M*; the fourth, the heat of combustion of 1 g.

IGNITION OF NATURAL GAS-AIR MIXTURES BY HEATED METAL BARS¹

BY H. F. COWARD² AND P. G. GUEST³

RECEIVED JULY 30, 1927

PUBLISHED OCTOBER 5, 1927

This communication records certain observations, of general scientific interest, concerning the influence of catalytically active surfaces on the ignition temperature of gas mixtures. The work is preliminary to a technical study of the possibilities that heated metal may directly or indirectly initiate gas explosions in coal mines.

The experimental work was conducted by the junior writer in the Electrical Section of the Pittsburgh Experiment Station of the Bureau of Mines at the instigation and under the general supervision of L. C. Ilsley, electrical engineer.

Influence of Solids on the Ignition of Gases

It was long ago observed that the apparent ignition temperature of an explosive gas mixture was raised by increase of the area of a solid body exposed to it, as, for example, by packing the containing vessel with fragments of glazed porcelain.⁴ This was ascribed to the retardation which the solid exerts on the self-heating of the gas mixture; for if the vessel and its contents are at the same temperature, self-heating of the gas by its own combustion is more difficult the more there is of solid material exposed to absorb the thermal energy of the combustion.

When, however, the solid has a marked catalytic action, this might be expected to reduce the ignition temperature; the ignition of a jet of cold hydrogen when it has streamed for a few moments over platinized asbestos apparently confirms this expectation. On the other hand, the experiments reported herein show that a powerfully catalytic surface has to be far hotter to ignite an explosive mixture of natural gas and air than has a surface of equal dimensions but of small catalytic action. Furthermore, those mixtures of natural gas and air which are most violently explosive require the highest temperatures for ignition by a heated bar of catalytically active metal (platinum).

The new observations are not in conflict with that of the ignition of hydrogen by platinized asbestos, for this solid has relatively little mass, in comparison with its surface area, and becomes red- or white-hot before

⁴ Hélier, *Ann. chim. phys.*, [7] 10, 521 (1897).

the gas in its interstices ignites. The metal bars used in the present experiments have so great a heat capacity that their temperature is but little affected by combustion around them. They behave rather as thermostats, whereas the platinized asbestos rapidly rises in temperature, accumulating heat from the gas first burning by slow combustion and thereby increasing the rate of burning of gas arriving subsequently.

Experimental

Strips of metal were heated electrically in the center of a gas-tight, rectangular gallery of about 4.5 cu. ft. capacity. The dimensions of the metal strips or bars were varied in some of the tests, but for comparison between different metals a standard size of 4.25 inches long (between the terminal clamps), 0.50 inch wide and 0.040 inch thick was chosen. At the high temperatures required for ignition, a length of about an inch at the center of the bar was found to be uniformly heated. Its temperature was observed by means of a thermocouple peened into the bar, and careful tests showed that when the couple was properly inserted the alternating current used in heating the bar did not interfere with the thermocouple current.

The gallery was fitted with a large release valve of waxed paper which burst when an explosive mixture was ignited. It also contained a large fan, used to ensure homogeneity of the gas mixture, and a smaller fan which was used in some experiments on the influence of turbulence on ignition.

The explosive gas mixtures used were composed of natural gas and air. The composition of the former was fairly constant during the series of experiments and averaged 93.2% CH_4 , 3.3% C_2H_6 , 1.5% C_3H_8 , 0.5% C_4H_{10} , etc., and 1.5% N_2 . The gas admitted to the gallery was measured approximately by means of a standard wet-type gas meter. When the gas and air had been well mixed by the fan, a sample was withdrawn and analyzed by the thermal conductivity method. Either gas or air was then admitted as required until the desired mixture was obtained. Occasional checks on the accuracy of the gas analysis, by comparing the thermal conductivity results with those obtained by a combustion analysis, were satisfactory.

When the atmosphere in the gallery had been prepared, the bar was rapidly heated to a few degrees short of the temperature at which, according to previous trials, ignition might be expected. The rate of rise of temperature was then somewhat retarded and the potentiometer used in connection with the thermocouple was adjusted continuously for zero galvanometer reading until ignition took place. Practice enabled the investigator to raise the temperature of the bar to the ignition point with sufficient rapidity to avoid any sensible change in the composition of the

gas mixture in the gallery, and yet not too rapidly for the temperature of ignition to be noted accurately. The gallery was large enough to provide latitude in the duration of the heating period, and constant results were obtained within a wide range of variation of rate of heating.

The choice of metals suitable for experiment is limited; the metal must have a high melting point and must not oxidize too rapidly at temperatures well above 1000° . On account of rapid oxidation and irregular scaling, iron failed to give reproducible results, although samples from several sources were tried. Certain steels, copper and Monel metal were more regular but melted at temperatures which restricted their utility. Stainless steel and a British steel of special composition, which resists oxidation at high temperatures, gave reproducible results. Platinum and nickel were found to be the most satisfactory materials for use in a long series of tests, and the latter was adopted as a standard of comparison.

Fig. 1.—Ignition of natural gas and air mixtures by heated nickel bars.

The range in composition of the mixtures which are reported as "ignited" lies between 2.4 and 16% of natural gas. Ignition of mixtures near to the two limits was indicated by the sudden appearance of a cap of flame above the bar and an increase of pressure as shown on a manometer. It was only between the limits of 5.5 and 13.5% natural gas that the inflammation spread from the bar through most or all of the gas mixture.

Results of Experiments

1. Nickel Bars: Effect of Change of Bar Dimensions.—Nickel bars of various widths⁵ were placed in the terminal clamps within the gallery in such a manner that their axes of length and thickness were horizontal, that is, they were on edge and the vertical dimension was varied. Fig. 1 shows the minimum temperatures at which the various bars ignited the

⁵ These were cut from the same sheet of commercial nickel.

whole series of natural gas-air mixtures. The solid-line curves represent the results obtained when there was no mass movement of the gas other than that caused by convection currents about the heated bar. The broken curves represent results obtained in gas agitated by the rapid revolution of the small fan mounted several inches above the bar.

It is clear that the temperature necessary to ignite these mixtures by nickel bars increases with increase in natural-gas content of the mixture. No certain explanation for this is at present available.⁶ The wider bars ignite the various mixtures more readily than the narrower bars; for the streaming gas is exposed for a longer period to the source of heat when in contact with the wider bars. Such turbulence as was imparted by the fan served to reduce the temperature necessary for ignition; but experiments now in progress show that when the turbulence is sufficiently great the opposite effect is produced.

Fig. 2.—Ignition of natural gas mixtures by heated bars of various metals.

The limits of temperature at which ignition occurred with bars ranging between 0.25 and 1.5 inches in width, mixture composition between 2.5 and 14%, with and without turbulence, were 940 and 1180°. This range is widened by more extreme variations in the experimental conditions. For example, a thin nickel bar bent into the form of a slotted tube gave a value as low as 724°. The figures must, therefore, be regarded as relative, rather than absolute.

A few tests made with methane for comparative purposes showed that

⁶ For a suggestion, made in connection with somewhat similar results observed in quartz vessels, see S. C. Lind, *J. Chem. Soc.*, 125, 1867 (1924).

this gas, in contact with nickel, ignites at temperatures about 30° higher throughout the range of mixtures.

2. Effect of Different Metals on Ignition Temperatures.—Fig. 2 shows the minimum temperatures at which bars of various metals ignited the series of natural gas-air mixtures. As already stated, all the bars were of the same dimensions and were mounted as described in (1).

It appears (see also Fig. 3) that the various steels, copper, Monel metal and gold do not differ nearly so much in their ability to ignite the gas as the catalytically active metals platinum and palladium differ from nickel;

Fig. 3.—Ignition of natural gas-air mixtures by heated platinum and palladium surfaces. (The broken line in this figure represents the corresponding observations with a nickel bar.)

and three samples of platinum differed widely from one another. The abnormal character of the molybdenum curve is doubtless associated with the rapid burning of the metal; dense clouds of oxide were formed in all experiments. Tungsten did not give rise to an oxide cloud until raised to temperatures higher than any required for ignition of the gas mixtures.

Fig. 3 shows that while platinum sample No. 1 had to be much hotter than nickel in order to ignite the gas, the two curves are of similar type. Samples⁷ No. 2 and 3, however, showed a remarkable peak in the neigh-

⁷ We are indebted to the American Platinum Company for the following analysis of platinum bar No. 3: Pt, 99.51%; Ir, nil; Pd, 0.32%; Rh, 0.11%; Au, nil. The first bar had been remelted with other scrap metal before the desirability of an analysis was recognized.

borhood of the most violently explosive mixtures of gas and air, namely, those which contain just over 9% of natural gas.⁸ Wüllner and Lehmann⁹ record a similar result with a platinum wire of 0.5 mm. diameter suspended in methane-air mixtures. A stouter wire, also a platinum gauze, failed to show a maximum temperature for ignition in their other series of experiments.

Further experiments with platinum bar No. 2 showed that this effect could be increased by electrolytically depositing finely divided platinum or palladium upon the surface of the bar, and thereafter could be decreased somewhat by treating the bar with such catalytic poisons as arsenic and sulfur. These poisons burned off, however, after the first few ignitions and the characteristics previously showed by the bar were restored.

That the most explosive mixture should require the highest temperature for ignition by these two bars is evidence that the specific action of platinum is to be ascribed to its high catalytic activity in comparison with the weaker action of nickel and the other metals tested. In support of this contention is the variability of platinum bar No. 2 with chemical treatment and the dissimilarity of the curve for platinum bar No. 1. The consistency of the nickel results, in conjunction with the variability of the platinum results (as between the three samples), is what would be expected if platinum were the material subject to the vagaries of a catalyst and nickel were little more (in the case of natural gas and air) than a source of heat without much catalytic effect.

Further evidence in support of this view is also shown in Fig. 3. Two nickel bars were used, one coated with platinum and the other with palladium. Observations were made with increasing amounts of natural gas, and the upper parts of the two curves were obtained. In each case, after the observation with the 11% gas mixture, the subsequent figures (plotted in the lower part of the curve) followed closely the nickel curve. Doubtless the rare metal had dissolved and passed into the mass of the nickel when this occurred.

If it is correct to ascribe the high ignition temperature obtained with platinum to its high catalytic activity, direct evidence should be obtainable from an examination of the gases exposed to the hot metals. Parallel experiments were therefore made in which nickel and platinum bars were separately placed in mixtures containing 9% of natural gas and carefully maintained at 1050° for periods of 8 and 20 minutes. The results of the analyses of samples then taken after thoroughly mixing the gallery atmosphere with the fan were as follows.

⁸ The "theoretical" mixture of natural gas and air, which has just sufficient oxygen to burn the gas completely, contains 9.09% of natural gas. Flame is propagated most rapidly in mixtures which are slightly richer than this. See ref. 11.

⁹ Wüllner and Lehmann, "Anlagen zum Hauptbericht der Preussischen Schlagwetter Commission," 1886, p. 219.

COMBUSTION OF GASES DURING PRE-FLAME PERIOD		
Gas present	With platinum bar, %	With nickel bar, %
Natural gas, at start	9.1	8.99
CO ₂ , after 8 minutes	1.01	0.05
CO, after 8 minutes	0.72	.50
Natural gas, at start	8.75	8.77
CO ₂ , after 20 minutes	1.96	0.07
CO, after 20 minutes	0.22	.36

It will be seen that more than 20 times as much carbon dioxide was formed with the platinum bar as was formed with the nickel at the same temperature.

In all the higher percentage mixtures employed, when the mixture was not inflamed, quiet combustion around the platinum maintained its temperature above red heat for several minutes after the heating current had been shut off. This was not observed at any time with the nickel bar and is further evidence, if any were needed, of the superior catalytic action of platinum at high temperatures on natural gas-air mixtures.

3. Comparative Experiments with Nickel and Quartz.---It is generally accepted that fused quartz has relatively little catalytic action on the combustion of the paraffin hydrocarbons.¹⁰ If, then, nickel and fused quartz should give similar results in similar circumstances, it might be concluded that nickel also had little catalytic action on the combustion of natural gas. As it was not possible to heat a quartz bar by the same means as the metal bars had been heated, a comparison of the ignition temperatures in tubes was adopted. The ignition temperature of natural gas in a certain quartz tube was about 620° and varied but little over the whole range of inflammable mixture.¹¹

Tubular vessels of length and diameter equal to the quartz tube were made from two samples of nickel sheet and were heated by the same means as had been used for the metal bars in the same chamber. A narrow slit was left along the bottom of each tube and when ignition occurred within, flame was seen to be projected through the slit and to ignite the main mass of gas outside. In these circumstances the range of ignition temperatures for mixtures containing from 4 to 12% of natural gas was 832 to 878° in one tube, 724 to 800° in another. It had been expected that much lower ignition temperatures would be obtained for the nickel tubes than for the nickel bars, for Mallard and Le Chatelier¹² had found that methane was ignited by a heated iron crucible at a much lower temperature when the gas was allowed to stream up into the in-

¹⁰ See, for example, H. B. Dixon and H. F. Coward, *J. Chem. Soc.*, 95, 514 (1909). W. Mason and R. V. Wheeler, *ibid.*, 121, 2079 (1922); 125, 1869 (1924).

¹¹ Coward, Jones, Dunkle and Hess, *Bull. 30, Carnegie Inst. of Tech.*, "The Explosibility of Methane and Natural Gas," 1926, 42 pp.

¹² Mallard and Le Chatelier, *Ann. des Mines*, [8] 4, 274 (1883).

verted crucible than when the gas streamed up around the outer surface of the crucible in its normal position. This they explained on the basis of the effect of convection currents in removing hot gases before the end of the "time lag" prior to inflammation. The figures obtained with the two tubes used in the present experiments differed somewhat widely; the difference may be due to some difference in shape or in material, although bars cut from the two samples of nickel sheet gave almost identical figures. However that may be, it is clear that in a comparison between quartz and nickel surfaces, the quartz surface of small catalytic action gives the lower ignition temperature. In view of this, and in the light of the conclusions drawn regarding the high catalytic action of platinum, it must be concluded that nickel itself has a significant catalytic action on the combustion of natural gas.

The most probable explanation of the apparent paradox (that catalytic action of a solid surface tends to raise the ignition temperature of a gaseous mixture) can hardly be given better than in the words of Mason and Wheeler.¹⁰

"The mixture immediately surrounding the heated surface may be consumed so rapidly as to become incapable of propagating flame, the reaction continuing to take place only at or near the heated surface even though its temperature there may rise far above the true ignition temperature of the mixture."

The effect of moderate turbulence must be to bring inflammable gas into the zone of burnt-out mixture, and thus to raise its temperature, perhaps to the ignition point, when it is near but not on the heated surface.

Summary

Measurements of the temperatures at which metal bars ignite mixtures of natural gas and air show that:

1. In parallel experiments the metals of greater catalytic effect must be hotter to cause ignition than metals or other substances of smaller catalytic effect. The difference may be several hundred degrees.

2. The temperature necessary to ignite these mixtures by bars of nickel, tungsten and several special steels increased regularly with increase in natural gas content throughout the whole range of inflammable mixtures.

3. With two of the three platinum bars tested, a much higher temperature was required to ignite the most violently explosive mixtures than was required to ignite mixtures of less explosibility.

A record is also given of the effect of variations in dimensions of the heated bar and of the effect of moderate turbulence on the ignition of these gaseous mixtures.

TERNARY SYSTEMS. VI. SODIUM CARBONATE, SODIUM BICARBONATE AND WATER

BY ARTHUR E. HILL AND LESLIE R. BACON¹

RECEIVED JULY 30, 1927

PUBLISHED OCTOBER 5, 1927

It has been known for a very long time that solutions of carbonate and bicarbonate of sodium may precipitate the double salt Trona as well as the two simple salts. The concentrations and temperatures at which these compounds separate have not, however, been investigated except in a single instance; McCoy and Test² have studied the three-component isotherm at 25°, giving the results in terms of volume concentration. We have here studied the system at the temperatures 25, 30 and 50°, determining the composition of the saturated solutions by weight and their density.

Experimental Methods.—The sodium carbonate and bicarbonate used were Kahlbaum's "zur Analyse" preparations; the former was found to be 100% in purity, and was kept constantly in an electric oven at 100° until removed for use. The samples of bicarbonate were found to contain from 1.30 to 3.16% of normal carbonate and from 0.33 to 0.70% of water. Because the conditions for keeping the bicarbonate from change are not known, the samples were used without removing the carbonate, making proper corrections for their actual composition in the various experiments.

Solubilities were obtained in thermostats, using 50 cc. glass-stoppered Pyrex tubes, the stoppers being wired in to prevent loss of carbon dioxide during stirring. Rotation was continued until equilibrium was obtained, the usual period being about fifteen hours. Samples for analysis were removed with a pipet fitted with a filter, and weighed to give a fairly accurate density determination. The loss of carbon dioxide, which Dibbitts³ points out as considerable for solutions saturated with sodium bicarbonate, is very little in the presence of even small amounts of the normal carbonate; no especial precautions were necessary on this account. One sample of filtrate was titrated with 0.5 *N* hydrochloric acid, using methyl orange as indicator, to determine the total base; a second sample was analyzed for carbon dioxide content by absorption in soda lime in a Morgan bottle, thus permitting calculation of the concentration of both normal salt and acid salt. The thermometers were compared with a standard thermometer.

¹ The material of this paper is part of a thesis presented by Leslie R. Bacon in partial fulfilment of the requirements for the degree of Doctor of Philosophy, at New York University.

³ Dibbitts, *J. prakt. Chem.*, **10**, 417 (1874).

The Binary Systems.—For the two binary systems, only the eutectics were determined, as the solubility data in the literature appear to be accurate. In the case of the bicarbonate, the usual method of lengthy stirring in open vessels was found to result in considerable loss of carbon dioxide and the formation of normal carbonate. To avoid this error, washed carbon dioxide was passed into the solution during the determination of the eutectic in the Beckmann apparatus; the correction for freezing-point depression caused by saturation with the gas is only a few hundredths of a degree. The results are given in the following table.

TABLE I
BINARY EUTECTICS FOR Na_2CO_3 AND NaHCO_3 WITH H_2O

Point in Fig. 4	Eutectic temp.	Solution		Density	Solid phases
		Wt. %, Na_2CO_3	Wt. %, NaHCO_3		
B	-2.05	5.71	..	1.056	$\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O} + \text{ice}$
M	-2.33	..	6.26	1.046	$\text{NaHCO}_3 + \text{ice}$

The eutectic for the bicarbonate we have not found in the earlier literature. That determined by us for the normal carbonate is slightly lower in temperature and concentration than that given by Guthrie⁴ (-2.0° and 5.97%) and is higher in concentration than the value given by de Coppet⁵ (-2.1° and 5.03%); it is much closer to the extrapolated solubility curve than either of these earlier results.

The Ternary Isotherms.—In Tables II, III and IV are given the data for the ternary system at 24.87, 30.0 and 50.0°. The water in the saturated solutions may be calculated by subtracting the sum of Cols.

2 and 3 from 100%. As abbreviations for the compositions of the solid phases given in the last column, N_{10} , N_7 and N_1 are used for the decahydrated, heptahydrated and monohydrated sodium carbonate, respectively, N_{bi} for the bicarbonate and T for the double salt, Trona, $\text{NaHCO}_3 \cdot \text{Na}_2\text{CO}_3 \cdot 2\text{H}_2\text{O}$. Figs. 1, 2 and 3 represent the results graphically.

Lines drawn through the two points representing the saturated solution and the original complex can be extrapolated to pass through the point representing the saturating solid phase with sufficient accuracy.

From the foregoing data, it can be shown that the solubility of the normal carbonate is increased slightly by the addition of bicarbonate, if calculated as referred to a constant amount of water; this is the case for the course of the short solubility curve DC. The solubility of the bicarbonate, however, as indicated by the curve AK, shows the more usual behavior of a marked decrease in solubility upon the addition of the carbonate. The solubility of the pure bicarbonate, given at A in the three isotherms,

satisfied ourselves as to the correctness of this formula by two independent methods. The first consisted in a slow isothermal evaporation over sulfuric acid at about 30° , using a solution represented by a point on the solubility curve CK, discontinuing before the total composition of the system had moved outside the triangle TCK; the slow procedure gave relatively distinct crystals (although we have not been able to obtain them of any large dimensions) which could be well centrifuged. Analysis of three samples gave the water content 1.43% too great, the bicarbonate 1.05% too small and the carbonate 0.38% too small for the above formula. The second method consisted in preparing two saturated solutions, to one of which the three components were added in the molecular ratio

Fig. 2.—Isotherm for $\text{Na}_2\text{CO}_3\text{--NaHCO}_3\text{--H}_2\text{O}$ at 30° .

$\text{NaHCO}_3 + \text{Na}_2\text{CO}_3 + 3\text{H}_2\text{O}$ and to the second in the ratio $\text{NaHCO}_3 + \text{Na}_2\text{CO}_3 + \text{H}_2\text{O}$; in the first experiment the composition of the saturated solution moved in the direction toward K, and in the second toward C, indicating that the first addition contained water in excess and the second in deficit.

The range of concentrations within which Trona is stable varies widely with the temperature. At 25° the triangle TKC is quite narrow, indicating that the compound is here but slightly above its temperature of formation; the determination of that temperature is given later in the paper. The points C and K agree with those of McCoy and Test² within less than 0.2%, the comparison being made possible by the density data contained in our tables. At 30° the triangle TKC has extended considerably, and at 50° is still larger. It seems probable, therefore, that Trona

may be stable up to considerably higher temperatures, provided the pressure is kept high enough to prevent the loss of carbon dioxide. The salt shows incongruent solubility throughout the temperature range studied; but it should be observed that with increasing temperature there is a continuous movement of the point K toward A, and it is not by any means excluded that at sufficiently high temperature and pressure it may move far enough to bring the salt into congruent saturation, so that it might be recrystallized from water.

The point C represents solutions isothermally saturated with Trona and with sodium carbonate decahydrate in Tables II and III, and with Trona

Fig. 3.—Isotherm for $\text{Na}_2\text{CO}_3\text{--NaHCO}_3\text{--H}_2\text{O}$ at 50° .

and sodium carbonate monohydrate in Table IV; at temperatures between 31.98 and 35.27° , as shown later in this paper, the two salts will be Trona and sodium carbonate heptahydrate. In every case the point is close to the $\text{H}_2\text{O--Na}_2\text{CO}_3$ axis, its farthest removal being 3.74% at 21.26° and its closest approach being 0.16% at 31.98° . It is apparent from these figures that a comparatively small addition of bicarbonate to normal carbonate will result in the precipitation of Trona, and that pure carbonate cannot be prepared by recrystallization if the excess of carbon dioxide is more than a very small amount.

The Invariant Points (Quintuple Points).—With the number of possible solid phases at moderate temperatures so large ($\text{Na}_2\text{CO}_3\text{--H}_2\text{O}$, $\text{Na}_2\text{CO}_3\text{--}7\text{H}_2\text{O}$, $\text{Na}_2\text{CO}_3\text{--}10\text{H}_2\text{O}$, NaHCO_3 , Trona and ice) it is obvious that several invariant (quintuple) points might be expected. Investigation from the temperature of the ternary eutectic up to 50° has given four such

invariant points, the data for which are in Table V. L stands for the saturated liquid phase. The phase reaction, read from left to right, represents the change occurring upon addition of heat.

TABLE V
INVARIANT POINTS IN THE SYSTEM $\text{Na}_2\text{CO}_3\text{-NaHCO}_3\text{-H}_2\text{O}$

Point in Fig. 4	Temp., °C.	Liquid phase		Density	Phase reaction
		Wt. %, Na_2CO_3	Wt. %, NaHCO_3		
E	-3.32 ± 0.05	4.41	4.64	1.078	$\text{N}_{10} + \text{N}_{bi} + \text{ice} \rightleftharpoons \text{L}$
H	$+21.26 \pm .10$	18.15	3.74	1.220	$\text{N}_{10} + \text{N}_{bi} \rightleftharpoons \text{T} + \text{L}$
N	$31.98 \pm .05$	31.32	0.16	1.334	$\text{N}_{10} + \text{T} \rightleftharpoons \text{N}_7 + \text{L}$
O	$35.17 \pm .05$	33.08	.19	1.350	$\text{N}_7 + \text{T} \rightleftharpoons \text{N}_1 + \text{L}$

The invariant temperature of Line 1 was determined with the usual Beckmann apparatus; the heat of the reaction is large and if vigorous stirring and a slow drop of temperature are maintained, the transition temperature is reproducible with satisfactory accuracy. In the other experiments, however, each of which involves the formation or decomposition of Trona, special precautions were necessary to avoid considerable variations in the transition temperature. This was especially true of the experiment of Line 2, which is the temperature of formation of Trona from its components previously referred to, and found to be at 21.26° . The temperature found is in agreement with the finding of McCoy and Test² that Trona is a stable phase at 25° , and with that of Applebey and Lane³ that the compound is non-existent at 18° . The use of the ordinary Beckmann apparatus, however, gave no satisfactory determination of the temperature; cooling curves and heating curves showed arrests differing a degree or more from each other, and yielding no truly invariant temperature, from which it may be deduced that the heat of the reaction is small or that the rate of formation and decomposition of the double salt is slow, or possibly that both statements may be true. In order to obtain a satisfactory curve, it was necessary to carry on the experiments in a small Dewar flask, surrounded by water at a temperature only a degree or two above the invariant temperature, and to carry on mechanical stirring over a period approximating a day, seeding the mixture with the necessary salts. With the exceedingly slow change in temperature thus produced, a constant temperature was obtained over a period of several hours; the average of four such determinations is given. The determinations of Lines 3 and 4 were somewhat less troublesome but the use of the Dewar flask as a container was found necessary. Since in these two latter cases the concentration of bicarbonate in the solution is very small, it is clear that the transition points can vary only slightly from the two-component transition temperatures of the heptahydrated and decahydrated carbonates. These two-component temperatures were therefore redetermined by us so that

³ Applebey and Lane, *J. Chem. Soc.*, 113, 609 (1918).

our three-component temperatures should express a difference brought about by the presence of the bicarbonate rather than a variation between the work of different investigators. By our experiment the transition temperature of sodium carbonate decahydrate was found to be 32.08° ,⁹ making the depression by the bicarbonate 0.1° , and that of the heptahydrate was found at 35.27° , making the depression by the bicarbonate again 0.1° .

From the solubility data and the invariant points it is possible to construct a space model showing relationships in the ternary system from -3.32° to $+50^\circ$. This is shown in perspective in Fig. 4, which is drawn

Fig. 4.—Space model of the system Na_2CO_3 - $\text{NaHCO}_3\cdot\text{H}_2\text{O}$.

M are the binary eutectics of Table I. The dotted lines $GA''K''C''D''$ and $FA'K'C'D'$ represent the temperatures of the isotherms at 25 and 30° , and the upper surface of the figure represents the isotherm at 50° .

Summary

1. Isotherms of the system: Na_2CO_3 - NaHCO_3 - H_2O at 25, 30 and 50° have been studied.

2. The double salt Trona, $\text{NaHCO}_3\cdot\text{NaCO}_3\cdot 2\text{H}_2\text{O}$, is stable in contact with saturated solutions from 21.26° , the temperature of its formation, up to at least 50° . It shows incongruent solubility throughout this entire range of temperatures. The range of concentrations within which it may be prepared increases gradually with increase in temperature. The salt forms a stable phase from solutions containing as little as 0.16%

⁹ Wells and McAdam (THIS JOURNAL, 29, 721 (1907)) found 32.00° at 31.34% and 35.37° at 33.19% as the two transition temperatures and concentrations.

of bicarbonate at 31.98° , and nowhere requires for its formation more than 3.74% of bicarbonate in the solution.

3. Four invariant temperatures for the ternary system have been found between the temperature of the ternary eutectic at -3.32 and 35.27° .

PHOTOCHEMICAL STUDIES. V. THE PHOTOCHEMICAL DECOMPOSITION OF AMMONIA BY RELATIVELY SHORT WAVE LENGTHS

BY LOUIS S. KASSEL AND W. ALBERT NOYES, JR.

RECEIVED AUGUST 4, 1927

PUBLISHED OCTOBER 5, 1927

Very few photochemical studies in the far ultraviolet have been carried out. In a previous paper¹ a report was made of a study of the photochemical decomposition of anhydrous oxalic acid in the far ultraviolet. It was found, qualitatively, that the decomposition proceeded more rapidly with light transmitted by fluorite than with light transmitted by quartz.

The present work was undertaken with the object of determining the quantum efficiency of the decomposition of ammonia in the region of wave lengths below that transmitted by quartz.

I. Experimental Method and Results

It is possible to use fluorite windows for studies of the effects of radiations of slightly shorter wave lengths than those transmitted by quartz. Quartz may be said to transmit, under ideal conditions and in thin layers, as far as $185m\mu$. Fluorite is considerably more variable in its characteristics and the data on its transmission do not agree among themselves. Fluorite transmits relatively well to about $150m\mu$ and some authors report transmission as far as $100m\mu$.

Many authors have made spectroscopic investigations in the far ultraviolet. Methods of detection of the radiation were available which were far more sensitive than the ordinary methods which may be used in photochemical studies.

In the case of gas reactions, the rate of reaction can be determined by measurements of the pressure change. It is far more difficult to find a suitable light source, since the sources of light used by spectroscopists for studies in this region are usually too feeble to produce measurable photochemical effects unless the quantum efficiency of the reaction is high. In the present work two sources of light were tried. The first was a discharge tube of the type described by Hopfield.² This tube was used with both nitrogen and hydrogen, but the light emitted was found to be too feeble to produce

¹ Noyes and Kouperman, *THIS JOURNAL*, **45**, 1398 (1923).

² Hopfield, *Phys. Rev.*, **20**, 573 (1922).

measurable decomposition of the ammonia. The second type was a condensed discharge through hydrogen. The spark gap was of tungsten and the hydrogen was passed through in a continuous stream. The spark was brought about by means of a $\frac{1}{4}$ kilowatt transformer with a secondary voltage of approximately 8000 volts. A capacity of approximately 0.003 microfarad was used. The tube was cooled by a rapid stream of water and the sputtering was greatly reduced by the rapid flow of hydrogen.

In the preliminary experiments an attempt was made to measure the ammonia decomposition directly with a McLeod gage. This was found not to be feasible.

The procedure finally adopted was to freeze out the ammonia with liquid air and measure the residual pressure with a McLeod gage.³ The reaction chamber was 9 cm. in length and 2 cm. in diameter. The fluorite window was sealed on with a special vacuum wax and the bulb containing the spark gap was sealed directly to the other side of the window. There was, therefore, no air gap between the source of light and the reaction vessel.

The ammonia used in these experiments was a commercial product. On issuing from the cylinder it passed over sodium hydroxide and then over calcium oxide in order to remove most of the moisture. It was next condensed in a bulb surrounded by carbon dioxide snow and ether. After an appreciable amount had condensed, ammonia was drawn out of the system by a water pump until about 25% of it had disappeared. The system was then shut off from the water pump and the carbon dioxide snow and ether placed around a second bulb containing metallic sodium. After the ammonia had distilled over to the sodium the system was evacuated for a few minutes and the ammonia distilled onto a second quantity of sodium contained in a third bulb. The sodium dissolved in the ammonia to give a deep blue solution which was permanent until the ammonia was distilled off. The ammonia was finally distilled onto ammonium nitrate which had been dried for a period of several hours at a high vacuum and a temperature of 105°. The ammonia from this solution was used as needed.

In order to obtain the effect of radiation transmitted by fluorite but not by quartz, a quartz window was used in part of the experiments. The window was of clear crystalline quartz with a thickness of about 3 mm.

TABLE I
RATE OF DECOMPOSITION OF AMMONIA (WITH QUARTZ WINDOW)

240	1.423	8.208	406	0.01669
150	0.146	1.778	79	.02066
250	0.821	5.700	271	.01800
Average				.01845

Since the volume of the entire apparatus was 670 cc. and since one mole of ammonia gives two moles of decomposition products, the rate of decomposition of ammonia when quartz windows are used is found to be ($T = 25^\circ$) 3.32×10^{-10} moles per minute.

In order to calculate the quantum efficiency it is necessary next to determine the light intensity. Since the pressures used were relatively low and the fraction of the total intensity absorbed was small, it would be difficult to use the ordinary methods of determining light intensities.

³ The vapor pressure of solid ammonia has been measured by Karwat, *Z. physik. Chem.*, 112, 486 (1924). Extrapolation by means of his equation shows that at liquid-air temperatures the vapor pressure is less than 10^{-6} mm.

Average				.03591

^a In this experiment a quantity of air was purposely admitted. It seems to show that neither oxygen, nitrogen nor water vapor affects the decomposition markedly. Kuhn⁴ had previously shown that nitrogen and water vapor are without effect.

From the above data it is found that 6.470×10^{-10} moles of ammonia are decomposed per minute when fluorite windows are used.

Accordingly, a photochemical method was finally adopted. Warburg⁵ has determined the quantum efficiency for the formation of ozone from oxygen. Since oxygen absorbs in the same region as ammonia, it should be possible to obtain a good measure of the light intensity by means of this reaction.

Warburg⁵ finds that two molecules of ozone are formed per quantum absorbed. His values never quite attain this figure, but he used relatively high pressures and the quantum efficiency would approach two molecules per quantum at atmospheric pressure. From theoretical considerations, also, this value is probable.⁶ The mechanism may be pictured as a direct dissociation of oxygen with subsequent addition of the two atoms formed to normal molecules.

A calculation based on the data of Landsberg and Predwoditileff⁷ shows that for all wave lengths less than $214m\mu$ the absorption by ammonia is practically complete under the conditions of the experiments described. Few accurate quantitative data on the absorption of radiation by oxygen in this spectral region are available. Kreusler⁸ has determined the absorption coefficient of oxygen at two different wave lengths, $186m\mu$ and $193m\mu$. Bloch and Bloch⁹ have measured the wave lengths of many absorption lines of oxygen with a quartz spectrograph from 195.75 to $186.48m\mu$. Warburg⁵ at high pressures has obtained ozone at a wave length of $253m\mu$.

Recently, Hopfield and Leifson¹⁰ have studied the absorption spectrum of oxygen, using a layer 2.5 cm. in thickness at atmospheric pressure and the continuous spectrum of hydrogen as a background. They find sixteen clearly-resolved bands between 195 and 176m μ and a great absorption band from 175 to 130m μ . The conclusion may be drawn from the various lines of evidence mentioned that the absorption by oxygen under the conditions of these experiments would be very nearly complete for wave lengths below those transmitted by quartz and down to the limit of fluorite.

It would be possible, therefore, to determine the number of quanta emitted per second in this region of the spectrum by the source of light used in these experiments if oxygen could be passed through the reaction vessel and the amount of ozone formed determined. A similar calculation could not be made for the range of wave lengths transmitted by quartz, since the absorption bands of ammonia and of oxygen do not coincide.

Hydrogen shows only a faint continuous spectrum between 240 and 168m μ , since there is no many-lined spectrum in this region.¹¹ Since hydrogen at a pressure of one atmosphere begins to absorb strongly at 160m μ ,¹² the wave lengths transmitted by fluorite and not by quartz in these experiments lie mainly in the region between 190 and 160m μ . In addition, fluorite transmits slightly better than quartz for the wave lengths slightly longer than 190m μ . The effect of this on the results will be discussed later.

In order to determine the intensity of the light, an exit tube was sealed to the reaction chamber as close to the window as possible. Dry oxygen was streamed through the tube, entering at the back and leaving at the end near the light source.

The quantity of ozone produced by the action of the light used was very small, so that it became necessary to devise a sensitive method for the determination of ozone. A colorimetric method was finally adopted. The oxygen issuing from the reaction vessel was led into a tube in such a manner that it came into contact with a piece of filter paper moistened with a solution of starch and potassium iodide. After the oxygen had streamed for a few minutes with the light on, the paper was observed to have become colored. The color, however, was brown instead of the blue usually associated with the starch-iodine complex. Several experiments were carried out with various oxidizing agents and it was finally found that solutions of hydrogen peroxide produced the same brown color. The equations for these reactions are as follows.¹³

¹⁰ Hopfield and Leifson, *Phys. Rev.*, 25, 716 (1925).

¹¹ Lyman, "The Spectroscopy of the Extreme Ultraviolet," Longmans, Green and Co., London, 1914, p. 75.

¹² Ref. 11, p. 71.

¹³ Mellor, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry," Longmans, Green and Co., London, 1922, Vol. I, p. 904, 940.

A number of starch-potassium iodide papers were prepared. To some of them a drop (weighed to within about 2%) of very dilute hydrogen peroxide was added. These served as standards. Others were exposed to the oxygen-ozone stream and the time which they required to develop a color that matched that of the standards was determined. Several sources of error might be mentioned. 1. The ozone formed might not be completely absorbed by the starch-potassium iodide papers. 2. The ozone might be partially decomposed by the ultraviolet light. The second of these errors is not serious.¹¹ However, both of these errors would produce an effect in the same direction, namely, the time of formation of the proper brown color would be increased. An idea of the error could be obtained by a variation of the rate of flow of the oxygen. Increase in the rate of flow produced no regular variation in the time required for a given darkening. The maximum variation was not over 20%, while the rate of flow was nearly tripled in some instances. In addition, two different concentrations of hydrogen peroxide were used, one three times the other, and the ratio of the average times for darkening is nearly the same as the reciprocal of the ratio of the concentrations.

The hydrogen peroxide solutions were made by diluting ordinary hydrogen peroxide to about 0.1 *N* and titrating with permanganate. This solution was subsequently diluted to 0.001591 *N* or 0.000530 *N*. In all of this work conductivity water was used. A fresh solution of hydrogen peroxide was prepared each day, although it was found that the solution could be kept fairly well in the dark. The oxygen was dried by phosphorus pentoxide before exposure to the light.

The weight of solution used was always 0.048 g., within about 2%. When the 0.001591 *N* solution was used with the fluorite window the average time for equivalent darkening was 30.10 minutes with a maximum deviation of 9.7%. With the 0.000530 *N* solution and fluorite window the average time was 10.07 minutes with a maximum deviation of 14.3%. With the 0.000530 *N* solution and the quartz window the average time was 36.21 minutes with a maximum deviation of 9.6%.

The ratio of the two concentrations used is 1:3.002, whereas the ratio of the average times is 2.989:1. One drop of the 0.000530 *N* solution is equivalent to 1.272×10^{-8} mole of ozone. The above figures give as a result, therefore, the production of 1.263×10^{-9} mole of ozone per minute when fluorite windows are used. A similar calculation with the more concentrated solution gives 1.268×10^{-9} mole per minute. For the quartz window it is found that 0.352×10^{-9} mole of ozone is formed per minute. The difference, or 9.14×10^{-10} , is the number of moles of ozone formed per minute by radiation transmitted by fluorite but not

by quartz. If the assumption is now made⁵ that two molecules of ozone are formed per quantum absorbed, it is found that 2.77×10^{14} quanta per minute are transmitted by fluorite in the region in which quartz does not transmit. Returning now to the photochemical decomposition of ammonia, it is found that 3.15×10^{-10} mole of ammonia is decomposed per minute by the radiation transmitted by fluorite but not by quartz. Multiplication by Avogadro's number (6.06×10^{23}) gives 1.91×10^{14} molecules of ammonia decomposed per minute. It is found, therefore, that on the average 0.690 molecule of ammonia is decomposed per quantum absorbed or, in other words, that 1.45 quanta are required on the average to decompose one molecule.

It is difficult to estimate the accuracy of this figure for the quantum efficiency. The determination of the quantity of ozone should not be in doubt by more than 10%. The values for the rate of decomposition of ammonia show good agreement with one exception. The actual numerical value may probably be written as 1.45 ± 0.50 quanta per molecule if the assumptions made in this work are justified. The assumption that both oxygen and ammonia absorb completely in the region between 190 and 160m μ seems to be justified on the basis of the best data available. The effect of the slightly better transmission of fluorite in the region between 190 and 220m μ would be to make the number of quanta absorbed per molecule too high rather than too low in the region under consideration.

II. Discussion of Results

The calculations made above are based on the assumption that the photochemical decomposition of ammonia proceeds according to the equation

This reaction has apparently been assumed by Warburg¹⁴ and by Kuhn.⁴ The former found that four quanta are absorbed per molecule decomposed in the spectral region 214–202.5m μ . The latter for the same spectral region found that 2.2 quanta are absorbed per molecule decomposed but that as the light became more nearly monochromatic (210–206.3m μ), about ten quanta were required on the average to make one molecule decompose.

More recently, Dickinson and Mitchell¹⁵ and Taylor and Bates¹⁶ have studied both the direct photochemical decomposition of ammonia and the decomposition sensitized by mercury vapor. No measurements of the quantum efficiency were made by either of these authors. There are some slight disagreements between the researches of these authors, but both are in agreement that more hydrogen is obtained in the non-condensable gases during the direct (unsensitized) photochemical de-

¹⁴ Warburg, *Sitzb. preuss. Akad. Wiss.*, 1911, 746; 1912, 216.

¹⁵ Dickinson and Mitchell, *Proc. Nat. Acad. Sci.*, 12, 692 (1926); Mitchell and Dickinson, *THIS JOURNAL*, 49, 1478 (1927).

¹⁶ Taylor and Bates, *Proc. Nat. Acad. Sci.*, 12, 714 (1926).

composition than would be obtained if equation (1) were obeyed. This may indicate, perhaps, the formation of hydrazine. Taylor and Bates report that the non-condensable gases contain 96% of hydrogen, while Dickinson and Mitchell report 87% of hydrogen. Since Taylor and Bates used a dynamic method, while Dickinson and Mitchell used a static method, the discrepancy may be due to subsequent photochemical decomposition of hydrazine if it is left exposed to radiation. Since a static method was used in the experiments herein reported, and, in addition, a shorter wave length than that used by the other authors, the decomposition to nitrogen and hydrogen probably represents the majority of the reaction. In case hydrazine were formed, the number of molecules decomposed per quantum would be larger than that given above.

We may state, however, with a good deal of assurance that the quantum efficiency for the decomposition of ammonia is higher in the region 190–160m μ than it is in the region of the spectrum employed by Warburg¹⁴ and by Kuhn.⁴ Kuhn also reports that the quantum efficiency increases with the temperature and that at 500° only 0.3 quantum is absorbed per molecule decomposed. On the basis of the following heats of reaction

Kuhn has calculated that the dissociation

involves the absorption of about 124,000 calories. This corresponds to light of about 230m μ in wave length. Kuhn proposes a mechanism to account for the various observed facts. The criticism to which this mechanism is open is that the heats of dissociation used are probably too small. Witmer¹⁷ gives 100,000 calories per mole as the heat of dissociation of hydrogen obtained from an analysis of band spectra. Birge and Sponer⁶ give about 260,000 for nitrogen. While little confidence can be placed in mechanisms based on the sort of calculation referred to, it may be of interest to list those reactions which are possible and those which are not possible, using as a basis these more recent values for the heats of dissociation of hydrogen and of nitrogen. For a wave length of 208m μ , corresponding to 137,000 calories per mole, it is found that the following reactions are possible

¹⁷ Witmer, *Phys. Rev.*, **28**, 1221 (1926).

The following reactions are found to be impossible:

Any mechanism based on these figures would be somewhat different from that given by Kuhn. If there were no dissipation of energy, the resulting quantum efficiency would be 2, but this would not be expected in any actual case. Equation (6) is similar to that offered by Dickinson and Mitchell to explain the inhibiting effect of hydrogen on the sensitized decomposition of ammonia. Equation (9) would explain, similarly, the lack of effect of nitrogen. Kuhn offers similar explanations.

It may be of interest to point out the relation of the decomposition of ammonia to the ideas expressed by Franck.⁶ Ammonia in the gaseous state is doubtless made up almost entirely of non-polar molecules and the electron orbits of the molecule probably have little similarity to the electron orbits of nitrogen or hydrogen atoms. The heat of dissociation, as in the case of oxygen, would be high. Dissociation, as in oxygen, can follow the absorption of radiation only through the agency of collisions. In this case the probability of dissociation after collision would be a function of the electron energy levels at the time of collision, and the potential energy of the nuclear system would not vary greatly. Thus, we can see qualitatively that the shorter the wave length used, the greater the chance of dissociation. The apparent deviation from the Einstein Law of Photochemical Equivalence may be satisfactorily explained in this manner. One would expect that the quantum efficiency would approach unity at the point where continuous absorption begins. In line with the results herein reported, the quantum efficiency increases for short wave lengths and may be unity for the short wave lengths of the region studied.¹⁸

With regard to the nature of the particular dissociation process involved, we may offer only speculations since the band spectrum of ammonia has never been thoroughly analyzed. If the process involves the removal of one hydrogen, then two NH_2 groups might add to each other with the production of hydrazine. This would seem to be a most unlikely occurrence with low light intensities. If hydrazine is formed it would be more reasonable to explain it as a result of a collision of one NH_2 group with a normal ammonia with the resultant production of monatomic hydrogen and hydrazine. It seems somewhat more reasonable to expect that the collision between an excited ammonia molecule and a normal molecule would lead to a more profound decomposition with production of nitrogen and hydrogen.

¹⁸ See "Molecular Spectra in Gases," by Kemble, Birge, Colby, Loomis and Page, *Bull. Nat. Res. Council*, Vol. XI, Part 3, No. 57 (1926), for a full discussion of the relation of band spectra to dissociation.

Summary

1. The photochemical decomposition of ammonia by relatively short wave lengths has been studied. It is found that for the approximate region of the spectrum between 190 and 160 μ , 1.4 quanta are absorbed per molecule decomposed. This is based on the assumption that two molecules of ozone are produced from oxygen per quantum absorbed. The quantum efficiency is higher in this region of the spectrum than that found by other authors in the neighborhood of 210 μ .

2. A short theoretical discussion is given. It does not seem possible to give a mechanism for the reaction which is free from all criticism, but with the use of thermal data it is possible to indicate which reactions might be possible. The increase in quantum efficiency with increase in frequency of radiation receives a reasonable qualitative explanation on the basis of recent theories of band spectra.

THE CATALYTIC COMBINATION OF ETHYLENE AND HYDROGEN IN THE PRESENCE OF METALLIC COPPER IV. KINETICS AT 100 AND 220°, THE TEMPERATURE COEFFICIENT BETWEEN 0 AND 220°, AND SUMMARY

BY ROBERT N. PEASE AND CARL A. HARRIS

RECEIVED AUGUST 20, 1927

PUBLISHED OCTOBER 5, 1927

Previous work¹ on the hydrogenation of ethylene in the presence of copper has shown that at 0° the rate is increased by excess of hydrogen but decreased by excess of ethylene, while at 200° the rate indicates an approximation to a bimolecular reaction, in which case proportionate increases in rate are caused by excess of either hydrogen or ethylene. Obviously, at some intermediate temperature the reaction rate should be independent of the ethylene concentration and proportional to the hydrogen concentration alone. We have thought it worth while to investigate this case and at the same time to obtain additional data on the higher temperatures. Further, we have taken occasion to measure rates at a series of temperatures between 0 and 200° in order to obtain the conventional heat of activation of this reaction.

The apparatus and general method of procedure have been fully described in previous papers.^{1b} Suitable gas mixtures were made up in a calibrated gas buret and run into the evacuated catalyst chamber. The rate of reaction was then followed by the pressure decrease at constant volume.

¹ (a) Grassi, *Nuovo Cimento*, [6] 11, 147 (1916); (b) Pease, *THIS JOURNAL*, 45, 1198, 2235 (1923).

Two catalysts were used, one of which was partially deactivated by heating in order to carry out the measurements at intermediate temperatures. One of these catalysts consisted of approximately 10% by weight of copper on broken diatomite brick (kindly furnished by the Armstrong Cork Co.). The brick was sized to 4-10 mesh, thoroughly washed with nitric acid, dried and impregnated uniformly with the proper amount of copper nitrate solution. This solution was made up to such a concentration that its weight was approximately that of the brick, since the latter will take up its own weight of water without becoming distinctly wet. After slow drying, the catalyst was reduced in hydrogen at 200°. Sixty cc. of catalyst was used. The second catalyst was prepared by coating glass beads with metallic copper, precipitated from a warm alkaline solution of cuprous hydroxide with phenylhydrazine. The method is due to Chattaway,² and gives a uniform bright copper coating; 575 glass beads of average diameter 0.486 cm., possessing a total surface of 426 sq. cm., carried 0.409 g. of copper. The purpose of this type of catalyst was to get away from possible solution effects.

The brick-supported catalyst used in the present work did not prove as active as the bulk catalyst used earlier,³ and a comprehensive series of measurements at 0° was not attempted. The first such measurements were at 50°. As the disturbing effect of ethylene still persisted, the catalyst was partially deactivated by heating to 500° for eight hours in a vacuum. This treatment gave a catalyst of moderate activity at 100°.

Experiments at 100°.—The results of thirteen experiments at 100° are summarized in Table I. The initial rates were obtained by extra-

² Chattaway, *Chem. News*, 96, 85 (1907).

³ This is due, perhaps, to a smaller surface area.

polarization, and are compared with the initial partial pressures. The latter are calculated from the composition of the mixture and the initial pressure. The adsorptions of ethylene and hydrogen on this catalyst were not determined at 100°. At 50°, before deactivation, 0.15 cc. of hydrogen and 3.10 cc. of ethylene were adsorbed at 1 atm. and 0.15 cc. of hydrogen and 2.35 cc. of ethylene at $\frac{1}{2}$ atm. It is to be presumed that the deactivated catalyst would have adsorbed a negligible amount of hydrogen and something less than 1 cc. of ethylene at 100° and 1 atm. If adsorption were taken into account, the partial pressure of hydrogen would be increased and that of ethylene decreased slightly.

It is clear that over the range investigated the reaction rate is proportional to the hydrogen concentration alone, and the reaction is, therefore, monomolecular with respect to hydrogen and of zero order with respect to ethylene. This represents the transition from the behavior at low temperatures, when ethylene inhibits the reaction, to higher temperatures, when the reaction rate increases in proportion to the ethylene partial pressure.

Experiments at 220°.—In the original work at higher temperatures, the bulk copper catalyst was found to adsorb hydrogen very slowly. As it was thought that this might have interfered somewhat with the pressure measurements, new experiments have been carried out using as catalyst a film of copper deposited on glass beads. It was found that individual experiments gave very good bimolecular constants. Excess of ethylene, however, leads to an appreciably lower constant, as was found in the earlier work. Thus, the reaction is nearly but not quite normally bimolecular even at 220°. The average values of $K = (dp/dt)(1/p_{H_2} \cdot p_{C_2H_4})$ are given below; p is in millimeters of mercury, t is in minutes.

TABLE II
AVERAGE BIMOLECULAR CONSTANTS AT 220°

atm. H_2	Initial mixture atm. C_2H_4	$K \times 10^4$
$\frac{1}{2}$	$\frac{1}{2}$	1.8
$\frac{2}{3}$	$\frac{1}{3}$	2.0
$\frac{1}{3}$	$\frac{2}{3}$	1.75
$\frac{1}{4}$	$\frac{1}{4}$	1.9

The results are much the same as those previously obtained. The catalyst is about as active as a bulk copper catalyst deactivated at 500°.

Temperature Coefficient.—Runs were carried out with a 50% mixture, initially at 1 atmosphere, between 0 and 220°. From 0 to 60° the brick-supported catalyst before heat treatment was used; from 60 to 100° the brick-supported catalyst after heat treatment; from 194 to 220° the catalyst consisted of copper deposited on glass beads.

The question arises as to the basis upon which to compare rates at different temperatures, since the reaction kinetics change as the temper-

ature rises. A complete expression for the latter would take account of this. Full data on the rate at each temperature and on the small adsorptions would be required, however, and we have not thought it worth while to obtain these. Instead, we compare rates at equal pressures ($1/2$ atmosphere of each gas) and obtain therefrom the conventional heat of activation. The difference between this and the true heat of activation involves terms for the heats of adsorption.

The reaction velocity curves have been extrapolated back to 1 atmosphere initial pressure and the tangent taken at this point. The latter are taken as the velocity constants at each temperature. They are given in Table III along with values of A , the conventional heat of activation calculated from $\log \frac{k_2}{k_1} = \frac{A}{4.58} \left(\frac{T_2 - T_1}{T_1 T_2} \right)$.

TABLE III		
HEATS OF ACTIVATION		
Brick-supported catalyst before deactivation		
Temp., °C.	dp/dt (1 atm.) = " k " (mm. per min.)	A , cal.
0	0.358	13,350
10	0.853	
20	2.32	
30	4.62	
40	9.21	
50	16.27	11,450
60	31.0	13,800
		Av. 13,400
Brick-supported catalyst after deactivation		
60	4.06	14,050

		Av. 13,200
Copper film on glass beads		
194	14.6	6000
220	20.5	

It is clear that the conventional expression for temperature coefficient applies from 0 to 100°, and that deactivation of the brick-supported catalyst does not change the heat of activation. The lower value in the

194–220° range is characteristic of the reaction, not of the unusual catalyst. The data of Grassi^{1a} and of Pease^{1b} lead to the same result. Thus, Pease calculated the heat of activation to be 7000 cal. between 200 and 250°. Between 150 and 200° it was 10,800 cal. These values were obtained on the same sample of bulk copper catalyst in the same state of activation. Grassi's data give 12,000 cal. between 150 and 200°, and only 1300 cal. between 200 and 250°. Between 250 and 275° he found the temperature coefficient to be zero. A similar decrease in temperature coefficient is noticeable in the results of Morris and Reyerson on the hydrogenation of ethylene in presence of copper, platinum and palladium deposited on silica gel.⁴

Theoretical Interpretation.—In concluding for the present this work on the hydrogenation of ethylene in the presence of copper, it may be of interest to summarize it briefly and supply the interpretation based on Langmuir's theory of adsorption and surface catalysis.⁵

The Langmuir theory assumes that reaction takes place on the catalyst surface in a layer of adsorbed gas not more than one molecule deep. The reaction kinetics, therefore, depend on the adsorptions as these are affected by pressure and temperature changes.

Assuming, with Langmuir, the monomolecular film, assuming that every molecule striking bare surface condenses and that the amount adsorbed depends chiefly on the rate of evaporation, one obtains for the fraction, x , of surface covered: $x = k_1 p / (k_2 + k_1 p)$, where p is the pressure, k_1 is the rate of condensation on a free surface (and is practically equal to the number of impacts) and k_2 is the rate of evaporation from the completely covered surface. With small adsorptions, x is proportional to the pressure; with a nearly covered surface, x slowly approaches unity, and the fraction $(1 - x)$ of surface free of gas varies inversely as the pressure $(1 - x)p = k_2/k_1$. The adsorption changes with temperature on account of the variation of k_2 , the unit rate of evaporation, chiefly. The function is doubtless of the "vapor pressure" type, so that $d \ln k_2 / dt = Q/RT^2$, where Q is approximately the heat of adsorption.

Assuming k_1 independent of temperature (the square root of temperature is involved), this results, in the case that the adsorption is small ($x = k_1 p / k_2$), in x decreasing with the temperature in the same way that k_2 increases, pressure being constant. When the adsorption is large, so that $-(1 - x)p = k_2/k_1$, the fraction $(1 - x)$ of surface bare of gas increases with the temperature in the same way as k_2 increases, pressure being constant.

The above are the relations which we shall apply to the ethylene-hydrogen reaction. It is to be remembered that the fundamental equation

⁴ Morris and Reyerson, *J. Phys. Chem.*, **31**, 1224 (1927).

⁵ Langmuir, *THIS JOURNAL*, **38**, 2221 (1916).

expresses a limiting law. In particular, it assumes a uniform surface. Poisoning experiments with carbon monoxide,⁶ and other data indicate that this condition is very far from applying. Nevertheless, the "active" surface may be considered to be meant in this case.

We consider first the low temperature experiments. At 0° both ethylene and hydrogen are strongly adsorbed, the ethylene adsorption being the higher of the two. Ethane is loosely adsorbed only. The rate is approximately proportional to the hydrogen concentration and inversely as a fractional power of the ethylene concentration. We suppose that molecules of the two gases must be in favorable juxtaposition on the catalyst surface for reaction to occur, and that in view of the stronger adsorption of ethylene, the surface is largely covered with this gas. Then the fraction $(1 - x)$ of surface free of ethylene, and available for condensation of hydrogen, would be inversely proportional to the ethylene partial pressure. At a given partial pressure of ethylene, the chance that a hydrogen molecule will strike a vacant spot on the surface is proportional to its pressure. The resulting reaction would then take place at a rate proportional to the hydrogen pressure and inversely proportional to the ethylene partial pressure. The experimental results approximate to this sufficiently closely to warrant the conclusion that this expresses fairly accurately the actual condition. If reaction followed immediately on condensation of hydrogen on a vacant spot, the above relations should hold somewhat better. Actually there is probably some lag, so that at any moment there are both hydrogen and ethylene molecules on the surface, the effect being to complicate somewhat the relations of adsorptions to pressures.

In the simple case, the effect of temperature would be to increase the fraction $(1 - x)$ of surface free of ethylene, and to increase the rate in proportion to $(1 - x)$. The temperature coefficient of reaction would then be equal to that of k_2 , the unit rate of evaporation of ethylene from the surface. This assumes that the temperature coefficient of the surface reaction is zero, which is probably not the case. Actually the temperature coefficient probably includes as well a term for the surface reaction. In either case the rate should increase exponentially with temperature, as is found between 0 and 100°.

The preceding discussion covers one limiting case. At the other extreme, namely, at high temperatures with a very inactive catalyst and small adsorptions, there is to be expected a bimolecular reaction with a negative temperature coefficient. This follows from the conclusion that with small adsorptions the amount adsorbed (fraction of surface covered) will be proportional to the pressure ($x = k_1 p / k_2$). The chance that molecules of ethylene and hydrogen will be favorably situated for

⁶ Pease and Stewart, *THIS JOURNAL*, 47, 1235 (1925)

reaction is then proportional to the product of the pressures. With varying temperature and constant pressure, x will vary inversely as k_2 (the unit rate of evaporation) for each gas. Since k_2 increases with the temperature, x will decrease. At the highest temperatures, the surface reaction rate will become infinite, so that every time molecules of the two gases are suitably disposed on the catalyst surface, reaction will occur. The temperature coefficient of reaction will then be the product of the temperature coefficients of the unit rates of evaporation, and will be negative.

It was found that at 200 and 220° the reaction is in fact nearly bimolecular, and the temperature coefficient undoubtedly will be negative at about 300° and higher. At 250° it is practically zero. At 200° ethylene is still somewhat inhibiting the reaction, however, and this, together with a probable increase in the surface reaction rate with temperature in this range, accounts for the temperature coefficients being still positive.

The conditions at 100° correspond to a transition from low temperatures and large adsorptions, when ethylene inhibits, to high temperatures and small adsorptions, when ethylene behaves normally. Large ethylene adsorptions interfere with reaction by preventing condensation of hydrogen. Smaller ethylene adsorptions allow more hydrogen molecules to condense, but increase the possibility of a condensing hydrogen molecule finding no ethylene in proximity with which to react. The two effects seem to neutralize each other at 100° over the pressure range studied.

The characteristics of the ethylene-hydrogen reaction in the presence of copper closely duplicate those of the hydrogen-oxygen reaction in the presence of platinum, which has been thoroughly investigated by Langmuir.⁷ In the latter hydrogen inhibits the reaction at low temperatures and the temperature coefficient is positive. Stoichiometric relations and a negative temperature coefficient are observed at high temperatures. The kinetics are, therefore, much the same in the two cases.

Summary

1. It has been found that at 100° the hydrogenation of ethylene in the presence of copper takes place at a rate proportional to the hydrogen concentration and independent of the ethylene concentration over partial-pressure ranges of $1/8$ to $3/4$ atmospheres.
2. It has been shown that at 220° the reaction is nearly but not quite bimolecular.
3. Rates have been measured between 0 and 220° and heats of activation calculated. The normal expression has been shown to apply between 0 and 100°. At higher temperatures there is a marked decrease in temperature coefficient and in heat activation.

⁷ Langmuir, *Trans. Faraday Soc.*, 17, 621 (1922).

4. The results of these and earlier experiments on this reaction are summarized and interpreted.

UNIVERSITY, VIRGINIA

NOTE

Note on a Light Source for Continuous Spectrum.—Since the introduction of the photometric methods for the determination of the quantitative absorption of light by solutions, much difficulty has been experienced in finding a suitable light source. A Tesla spark under water fulfils most nearly the requirements but previous designs¹ of such lamps have not been satisfactory for general or continuous use.

Fig. 1.—Continuous spectrum light source.

Fig. 2.—Continuous spectrum light source, detail of window clamp.

The accompanying cuts show the details of the completed lamp. Some points about its construction ought, however, to be mentioned. The glass sleeves carrying the brass rods are fire-polished until the inside diameter is slightly less than the diameter of the brass rod. The split end of the brass rod is then compressed and used to grind one end of the glass sleeve until the rod passes through to the other end where the grinding is continued. The two ground ends hold the brass rod rigidly in position.

¹ The most recent of these is described in the Bureau of Standards Scientific Papers, No. 440.

These prepared glass sleeves are placed on a 20-inch piece of the same brass rod and the whole is placed through the glass jacket of the lamp where the parts are held in position by a rubber stopper at each end. The plaster of Paris is then poured into the ends. After the plaster has set the long brass rod is replaced by the two split-end rods into which have been inserted the wires employed as electrodes. No. 16 drawn brass wire gave the best results.

Fig. 3.—Continuous spectrum light source, detail of top end.

Earlier models of the lamp were made without a side tube, but without this cushion the bulb was frequently broken or the quartz window loosened. A lamp of this type has been in use in this Laboratory for three years.

GERMANIUM. XVIII. FURTHER ORGANIC COMPOUNDS OF GERMANIUM¹

BY W. R. ORNDORFF, D. L. TABERN AND L. M. DENNIS

RECEIVED MARCH 25, 1927

PUBLISHED OCTOBER 5, 1927

Introduction

In previous papers² the authors have described the synthesis of some organic compounds of germanium. The study of these substances was undertaken not only to add to our knowledge of the rare element germanium, but also in the hope of being able to prepare organic compounds of either divalent or tetravalent germanium which would be soluble in water and which might be suitable for the treatment of pernicious anemia. It has been stated that an aqueous solution of germanium dioxide stimulates red cell formation³ but the value of the substance for this purpose appears to have been disproved by Bodansky.⁴

The present investigation was not carried as far as had been contemplated but, because of the withdrawal of two of us (W. R. O. and D. L. T.) from the field, it seems desirable to place on record such results as were obtained.

Experimental

Triphenyl Germanium Bromide, $(C_6H_5)_3GeBr$.—This compound was first prepared by Morgan and Drew⁵ by means of the Grignard reaction. Kraus and Foster⁶ describe the preparation of this substance by the bromination of tetraphenyl germanium by boiling a solution of the latter substance and bromine in carbon tetrachloride for several hours. Before their article appeared we had found that when ethylene dibromide is employed as a solvent only a few minutes' warming is required and that a perfectly pure product results after removal of the solvent and a single recrystallization from petroleum ether containing hydrogen bromide. The melting point of the substances was found to be 134° , a somewhat lower value than reported in the two papers mentioned above.

Anal. Subs., 0.2774, 0.2882. $AgBr$, 0.1352, 0.1410. Calcd. for $C_{18}H_{15}GeBr$: Br , 20.8. Found: 20.8, 20.8.

¹ The investigation upon which this article is based was supported by a grant from the Heckscher Foundation for the Advancement of Research, established by August Heckscher at Cornell University.

Kraus and Foster, *THIS JOURNAL*, **49**, 457 (1927).

Treatment of an alcoholic solution of the bromide with silver nitrate, filtration and dilution of the filtrate with water yielded triphenyl germanium oxide reported by Morgan and Drew.

Triphenyl Germanium Chloride, $(C_6H_5)_3GeCl$.—When triphenyl germanium oxide is dissolved in dry petroleum ether and the solution is saturated with hydrogen chloride, triphenyl germanium chloride separates in large, colorless crystals resembling the corresponding bromide. It may also be made by saturating a solution of triphenyl germanium bromide with hydrogen chloride and cooling. A third method consists in dissolving triphenyl germanium oxide in boiling alcohol and adding concentrated hydrochloric acid. The products prepared by each of these methods were recrystallized from petroleum ether and were found to melt sharply at 117–118°.

Anal. Subs., 0.1830: $AgCl$, 0.0765. Calcd. for $C_{18}H_{15}GeCl$: Cl , 10.5. Found: 10.3.

The Action of Two Moles of Bromine on Tetraphenyl Germanium.—The removal of two phenyl groups from tetraphenyl germanium was found to proceed much less smoothly than the removal of one, the evolution of some hydrogen bromide indicating the existence of side reactions. Since the direct isolation of diphenyl germanium dibromide was not found possible, subsequent reaction products were hydrolyzed directly. In addition to some triphenyl germanium oxide, two substances melting at 147 and 210° were formed. In all probability these were the complex dehydration products of diphenyl germanic acid previously reported by Morgan and Drew. As this reaction did not seem to offer a satisfactory way of preparing diphenyl germanium dibromide, it was not investigated further.

Unsymmetrical Aryl and Alkyl Germanes

Triphenyl *p*-Tolyl Germanium, $(C_6H_5)_3GeC_6H_4CH_3$.—Triphenyl *p*-tolyl germanium was prepared by the action of a large excess of *p*-tolyl magnesium bromide upon triphenyl germanium bromide. To insure the completion of the reaction, the ether was replaced by dry benzene, and the flask was heated to boiling for eight hours. The reaction mass was decomposed by a dilute aqueous solution of ammonium chloride and was subjected to prolonged steam distillation to remove all ditolyl. The product is best recrystallized from petroleum ether and alcohol or from glacial acetic acid; *m. p.* 123–124°.

Anal. Subs., 0.2238, 0.1781: CO_2 , 0.6209, 0.4960; H_2O , 0.1173, 0.0921. Subs., 0.2052, 0.2402: GeO_2 , 0.0553, 0.0650. Calcd. for $C_{24}H_{21}Ge$: C , 76.02; H , 5.62; Ge , 18.36. Found. C , 75.69, 75.98; H , 5.87, 5.75; Ge , 18.70, 18.78.

Triphenylanisyl Germanium, $CH_3OC_6H_4Ge(C_6H_5)_3$.—When treated in the same way, anisyl magnesium bromide (but not the iodide) and triphenyl germanium bromide yielded triphenylanisyl germanium. The product was finally recrystallized twice from alcohol and four times from glacial acetic acid, in both of which it is fairly insoluble in the cold. It melts at 158–159° (uncorr.).

Anal. Subs., 0.1758, 0.1845: CO_2 , 0.4720, 0.4945; H_2O , 0.0888, 0.0933. Subs., 0.2150, 0.1973: GeO_2 , 0.0543, 0.0505. Calcd. for $C_{24}H_{21}OGe$: C , 73.02; H , 5.40; Ge , 17.68. Found: C , 73.24, 73.12; H , 5.65, 5.66; Ge , 17.53, 17.77.

Triphenylethyl Germanium, $(C_6H_5)_3GeC_2H_5$.—Triphenylethyl germanium was prepared, in good yield, in essentially the same manner from triphenyl germanium bromide and ethyl magnesium bromide; m. p. 75–76°.

Anal. Subs., 0.2254, 0.2130: CO_2 , 0.5938, 0.5612; H_2O , 0.1239, 0.1122. Subs., 0.1812, 0.3982, 0.1493; GeO_2 , 0.0571, 0.1251, 0.0465. Calcd. for $C_{20}H_{20}Ge$: C, 72.12; H, 6.06; Ge, 21.82. Found: C, 71.87, 71.86, H, 6.15, 5.89; Ge, 21.86, 21.81, 21.62.

Triphenyldimethylanilino Germanium, $(CH_3)_2NC_6H_4Ge(C_6H_5)_3$.—Specimens of triphenyl germanium bromide were refluxed with an excess of dry dimethylaniline under varying conditions but no interaction took place.

One mole of triphenyl germanium bromide and two moles of *p*-bromodimethylaniline were dissolved in xylene and the liquid was refluxed with an excess of sodium. Sodium bromide separated and after an hour the metal retained its fresh surface. The solvent was decanted and as much of it as possible removed under moderate diminished pressure. The addition of alcohol resulted in the separation of slightly brownish, crystalline nodules. After recrystallization from hot petroleum ether and alcohol the product melted at 138–140°. Purified through the hydrochloride, it melted at 140–141° and still retained a brownish tinge.

Anal. Subs., 0.2004, 0.1891: CO_2 , 0.5423, 0.5117; H_2O , 0.1074, 0.1037. Subs., 0.2137, 0.2136: GeO_2 , 0.0527, 0.0525. Calcd. for $C_{28}H_{28}NGe$: C, 73.64; H, 5.95; Ge, 17.11. Found: C, 73.82, 73.82; H, 5.997, 6.137; Ge, 17.12, 17.06.

Passage of hydrogen chloride through an ethereal solution of triphenyldimethylanilino germanium yields at once the solid, crystalline hydrochloride, which may be separated either by evaporation of the ether or by decantation. It is insoluble in water and in hydrochloric acid, but dissolves readily in absolute alcohol, from which it is precipitated by the addition of water. It melts with decomposition between 105 and 110°. From it pure triphenyldimethylanilino germanium may be secured by treatment with alkali.

Tetrabenzyl Germanium and Its Tetrasulfonic Acid

Tetrabenzyl Germanium, $(C_6H_5CH_2)_4Ge$.—Nine g. of magnesium turnings was suspended in ether and the formation of the Grignard reagent was initiated by the addition of about 5 g. of benzyl chloride. A mixture of 40 g. of benzyl chloride, 10 g. of germanium tetrachloride and five volumes of dry xylene was then added drop by drop with good mechanical stirring and gentle refluxing. Finally, sufficient xylene was added to form a thin paste and the ether was distilled off on a steam-bath. Heating on the steam-bath was continued for some hours and the mixture was allowed to stand for two days. On working it up in the usual manner, taking care to subject the organic product to a vigorous and prolonged steam distillation to insure the removal of all dibenzyl, a nearly quantitative yield of tetrabenzyl germanium was secured. The first product melted at 106–107°, and at 107–108° after repeated crystallization from several solvents, including alcohol and petroleum ether.

Anal. Subs., 0.2116, 0.2000: CO_2 , 0.5991, 0.5660; H_2O , 0.1236, 0.1182. Subs., 0.2007, 0.1923: GeO_2 , 0.0481, 0.0466. Calcd. for $C_{24}H_{20}Ge$: C, 76.92; H, 6.46; Ge, 16.62. Found: C, 77.24, 77.10; H, 6.54, 6.61; Ge, 16.64, 16.82.

Tetrabenzyl Germanium Tetrasulfonic Acid, $(SO_3HC_6H_4CH_2)_4Ge$.—The above germane is preferably sulfonated by slowly dissolving it in an excess of 25% fuming sulfuric acid, keeping the temperature below 35°. Rapid agitation is essential. After standing for half an hour at room temperature, the reaction mixture was poured upon ice and the excess of sulfuric acid was removed by barium carbonate. When alcohol was added to the decolorized and strongly concentrated filtrate, the barium salt separated as an oil which changed to a white, crystalline solid on the addition of more al-

cohol. The solid was ground in a mortar with anhydrous acetone and was dried, first at room temperature and then at 110°. This substance, the normal barium salt of tetrabenzyl germanium tetrasulfonic acid, dissolves readily and completely in cold water, but is insoluble in acetone, alcohol or ether.

For analysis for either barium or sulfur alone the sample was decomposed by fusion in a nickel crucible with a mixture of potassium hydroxide and potassium nitrate. Germanium was determined in other samples by dissolving them in boiling water and precipitating the barium by the addition of an excess of sulfuric acid. The filtrate was concentrated and finally heated to 120° in a platinum crucible. Fuming nitric acid was added and the determination of germanium was carried out as described by Tabern, Orndorff and Dennis.^{2a}

Anal. Subs., 0.3615, 0.3730: BaSO₄, 0.1640, 0.1690. Subs., 0.2899, 0.3874: BaSO₄, 0.2618, 0.3442. Calcd. for C₂₀H₂₄Si₄O₁₂Ba₂Ge: Ba, 26.75; S, 12.46; Ge, 7.06. Found: Ba, 26.62, 26.66; S, 12.40, 12.20.

Anal. Subs., 0.5433, 0.6897: BaSO₄, 0.2505, 0.3156; GeO₂, 0.0562, 0.0706. Found: Ba, 27.15, 26.92; Ge, 7.18, 7.10.

Simple and Substituted Germanic Acid Anhydrides

Phenyl Germanic Acid Anhydride, (C₆H₅GeO)₂O.—One mole (3.6 g.) of mercury diphenyl and one mole (2.1 g.) of germanium tetrachloride were dissolved in dry xylene and heated at 140° in a sealed Pyrex bulb for two days. The contents of the bulb was diluted with absolute ether and filtered. The solid residue was pure phenyl mercuric chloride. The filtrate was further diluted with benzene and was treated with water containing a few drops of ammonium hydroxide. On standing, a granular precipitate separated at the liquid interface. This was filtered off and dried at 115°. Although quite pure, the substance was dissolved in dilute sodium hydroxide and was precipitated hot by neutralization of the solution with acetic acid.

Anal. Subs., (A) 0.2149, (B) 0.1885: GeO₂, 0.1302, 0.1140. Calcd. for C₆H₅-GeOOH: Ge, 39.7; for C₁₂H₁₀O₂Ge₂: Ge, 41.8. Found: 41.9, 41.9.

These analytical results indicate that the product in hand approached quite closely to the anhydride in composition, though Morgan and Drew concluded that the acid secured by them in small amount as the end fraction from a Grignard reaction was the fully hydrated form.

The anhydride of phenyl germanic acid is a white, fluffy, amorphous solid, insoluble in water and organic solvents, but soluble in excess of alkali; from such solution it is precipitated in lustrous flakes by carbon dioxide. It has no definite melting point.

***p*-Tolyl Germanic Acid Anhydride, (CH₃C₆H₄GeO)₂O.**—Mercury ditolyl and germanium tetrachloride when heated at 160–190° in xylene yielded *p*-tolyl germanic acid anhydride. The method of isolation was essentially the same as in the preceding instance.

Anal. Subs., 0.2100, 0.2309: GeO₂, 0.1175, 0.1285. Calcd. for C₇H₇GeOOH: Ge, 36.9; for C₁₄H₁₄O₂Ge₂: Ge, 38.65. Found: Ge, 38.9, 38.6.

Benzyl Germanic Acid Anhydride, (C₆H₅CH₂GeO)₂O.—Equimolecular quantities of mercury dibenzyl and germanium tetrachloride (4.2 g.) were dissolved in xylene and heated in a closed tube between 115 and 120° for two days. A higher temperature results in the decomposition of the mercury dibenzyl. The isolation of the benzyl germanic acid anhydride was carried out as in the case of the phenyl analog except that

here, because of the marked solubility of the benzyl mercuric chloride, water was added directly to the xylene solution without filtration.

Benzyl germanic acid anhydride is a colorless, granular precipitate, soluble in alkalies, fairly soluble in boiling water and in pyridine, but insoluble in organic solvents.

Anal. Subs., 0.1958, 0.1269: GeO_2 , 0.1074, 0.0690. Calcd. for $\text{C}_7\text{H}_7\text{GeOOH}$: Ge, 36.9; for $\text{C}_{14}\text{H}_{14}\text{Ge}_2\text{O}_4$: Ge, 38.65. Found: Ge, 38.1, 37.7.

Dimethylaminophenyl Germanic Acid Anhydride, $[(\text{CH}_3)_2\text{NC}_6\text{H}_4\text{GeO}]_2\text{O}$.—Ten grams of germanium tetrachloride and an excess of dry dimethylaniline were placed in a flask which was then sealed and heated to 100 – 110° for two days. The strongly fluorescent gelatinous product was made alkaline and was subjected to steam distillation. After filtration carbon dioxide was passed into the resultant clear solution until the acid anhydride was completely precipitated. Re-solution and reprecipitation were repeated until the filtrate contained no germanium dioxide. The product may also be purified by dissolving it in acid and precipitating it with dilute ammonium hydroxide.

Dimethylaminophenyl germanic acid anhydride is a pearly white, fluffy powder, soluble in very dilute mineral acids, and also in an excess of alkali. Like the preceding anhydrides it does not have a definite melting point.

Anal. Subs., 0.1896, 0.2581: CO_2 , 0.3043, 0.4174; H_2O , 0.0825, 0.1134. Subs., 0.2068, 0.1985: GeO_2 , 0.1006, 0.0955. Calcd. for $\text{C}_8\text{H}_{11}\text{O}_2\text{NGe}$: C, 42.53; H, 4.9; Ge, 32.17. Calcd. for $\text{C}_{16}\text{H}_{20}\text{O}_4\text{N}_2\text{Ge}_2$: C, 44.30; H, 4.65; Ge, 33.50. Found: C, 43.78, 44.12; H, 4.88, 4.92; Ge, 33.76, 33.40.

When a thin layer of the above anhydride is kept for some time in an atmosphere of dry hydrogen chloride, it is converted entirely into the hydrochloride of dimethylanilino germanium trichloride; $[(\text{CH}_3)_2\text{NC}_6\text{H}_4\text{GeO}]_2\text{O} + 8\text{HCl} = 2\text{HCl}(\text{CH}_3)_2\text{NC}_6\text{H}_4\text{GeCl}_3 + 3\text{H}_2\text{O}$. The above hydrochloride melts with decomposition near 110° . It is readily and completely soluble in water and from such a solution ammonium hydroxide precipitates dimethylaminophenyl germanic acid anhydride.

Tetra-*n*-butyl Germanium, $(\text{C}_4\text{H}_9)_4\text{Ge}$.—Germanium tetrachloride was added to a large excess of butyl magnesium bromide, the reaction being carried out essentially in the manner described in a previous paper for the propyl analog. The desired product was thus secured in good yield as an almost odorless, oily liquid boiling between 178 and 180° at 733 mm. Unlike its lower homologs, it is ignited only with difficulty.

Anal. Subs., 0.2648, 0.1986: CO_2 , 0.6178, 0.4590; H_2O , 0.2855, 0.2081. Subs., 0.2384, 0.2415: GeO_2 , 0.0826, 0.0829. Calcd. for $\text{C}_{16}\text{H}_{36}\text{Ge}$: C, 63.81; H, 12.06; Ge, 24.13. Found: C, 63.65, 63.03; H, 12.07, 11.72; Ge, 24.05, 23.83.

Summary

A further study of the organic compounds of germanium—especially those containing potential solubilizing groups—has led to the synthesis and study of the following types of substances: (1) triphenyl germanium halides; (2) mixed aryl and alkyl derivatives, with and without a salt-forming group; (3) tetrabenzyl germanium and its tetrasulfonic acid; (4) simple and substituted phenyl germanic acid anhydrides; (5) tetra-*n*-butyl germanium.

AFFINITY, REACTIVITY AND STRUCTURE IN ACETAL FORMATION. II

BY WALTER H. HARTUNG AND HOMER ADKINS

RECEIVED APRIL 14, 1927

PUBLISHED OCTOBER 5, 1927

The investigation of the relationship between the structure of various alcohols and aldehydes and the rate and extent of the reversible reaction $RCHO + 2R'OH \rightleftharpoons RCH(OR')_2 + H_2O$ has been continued.¹ It has been often assumed that the effect of a given substituent upon the equilibrium point was qualitatively if not quantitatively constant. There would then be certain groups that might be described as "positive" and others as "negative." It has now become evident that this is by no means true. A methyl group, for example, may in one case increase affinity and in another decrease the affinity for the same type of reaction. A methyl group may be more "negative" than a phenyl, a bromine more "positive" than a hydrogen and an hydroxyl more "negative" than a bromine.

This is a result to be expected if the effect of a group in lowering or increasing affinity is considered to be the result of a shift of the electronic structure. The shift resulting from the introduction of a substituent into a compound will depend not only on the character of the substituent but upon the character of the substituted compound, that is, upon the particular electronic system that is acted upon. The *effect* of the shift upon affinity will be dependent upon a third factor, that is, upon whether the shift has produced an electronic configuration which requires *more or less* energy to get the electrons (that is, their orbits) into a position where a new linkage may be formed with the particular reactant involved. It appears that a given substituent does not bring about simply a dislocation of electron pairs towards or away from the reactive end of the molecule but that it modifies the whole electronic architecture of the molecule. It is evident that the positivity or negativity of a group may not be defined except for the reactions of specific compounds.

The experimental results are summarized in Table I. For the sake of convenience the aldehydes are regarded as beta substitution products of acetaldehyde, a quantitative measure of the effect of the substituent being given in the third column of the table under $-RT \ln K_e$. The value of the expression $-RT \ln K$ would be that of the decrease in free energy ΔF if the activities of the reactants were equivalent to the analytically determined concentrations. Since for the present the activities are not known, it seems preferable not to consider the decrease in free energy to be equal to the values of $-RT \ln K$ but to refer to them as "affinity

¹ Adkins and Adams, *THIS JOURNAL*, 47, 1368 (1925).

values." It is possible that the absolute values of $-RT \ln K$ are of little significance,² and that even the relative values vary in different solvents.

The equilibrium point was approached from both sides in the case of aldehydes 4, 5, 7, 8, 12 and 15. The data for aldehydes 1, 2, 3, 6, 10, 11, 12 and 15 have not been previously published. Data on aldehydes 4, 5, 7, 8 and 14 were published by Adams and Adkins but the experimental work has been repeated and corrected values are given here. The new values are of the same order as those previously published except in the case of heptaldehyde. The equilibrium constants for aldehydes 9 and 13 were recalculated from Adams' data and are given here for the sake of ready comparison. Aldehydes 1, 2, 3, 6, 10 and 11 have never been prepared in a state of purity so that the equilibrium could not be obtained from the synthetic side.

TABLE I

EFFECT OF BETA SUBSTITUTION IN ACETALDEHYDE UPON AFFINITY IN ACETAL FORMATION

No.	Aldehyde	β -substituent	K	$-RT \ln K$
1.	Amino-acetaldehyde	$\text{NH}_2\text{HCl}-$	0.1340	1190 \pm 200
2.	Bromo-acetaldehyde	$\text{Br}-$.1121	1300 \pm 200
3.	Cyano-acetaldehyde	$\text{CN}-$.1070	1320 \pm 200
4.	Heptaldehyde	$\text{C}_6\text{H}_{11}-$.0970	1380 \pm 30
5.	Propionaldehyde	CH_3-	.0782	1510 \pm 30
6.	Imino-acetaldehyde	$-\text{NH}(\text{HCl})-$.0770 ^a	1520 \pm 200
7.	Acetaldehyde	$\text{H}-$.0744 ^b	1540 \pm 30
8.	Butyraldehyde	C_2H_5-	.0691	1580 \pm 30
9.	<i>iso</i> Butyraldehyde	$(\text{CH}_3)_2$.0355	1980 \pm 30
10.	β -Chloropropion-aldehyde	$\text{CH}_2\text{Cl}-$.0294	2090 \pm 200
11.	Glycolic aldehyde	$\text{HO}-$.0202	2300 \pm 200
12.	Acrolein	$\text{CH}_2=$.00455	3270 \pm 30
13.	Benzaldehyde00163	3810 \pm 30
14.	Cinnamaldehyde	$\text{C}_6\text{H}_5\text{CH}=$.00089	4160 \pm 30
15.	Crotonaldehyde	$\text{CH}_3\text{CH}=$.00063	4360 \pm 30

^a The calculations are based on the assumption of the hydrolysis of both acetal groups.

^b The authors are indebted to A. E. Broderick for the value for diethyl acetal and for other valuable assistance.

The equilibrium points for these six aldehydes were determined by the colorimetric method so that the values for $RT \ln K$ should be read ≈ 200 . The analytical method used for the determination of the other aldehydes should give a value accurate to within ≈ 30 units.

From an inspection of the table it becomes evident that the normal chain aliphatic aldehydes (Nos. 4, 5, 7 and 8) occupy, within a relatively narrow range, nearly the same position and are very high in the scale, whereas *isobutyraldehyde* (No. 9), with a branched chain, is decidedly lower. The hydrochloride of amino-acetaldehyde shows a high affinity

² See Conant, *THIS JOURNAL*, 49, 293 (1927).

value, as would be expected from the positive nature of the amino group. Bromo-acetaldehyde and cyano-acetaldehyde are practically alike as one would expect but that both should show a slightly greater affinity than acetaldehyde is indeed striking, for both the bromo and cyano groups are commonly considered negative and one would, therefore, expect them to have a marked depressing effect. Glycolic aldehyde, on the other hand, shows a marked lowering of affinity as compared with acetaldehyde. While a halogen on the alpha carbon of acetaldehyde is "positive" in its effect, the same is not true of beta-halogenated propionaldehyde, for β -chloropropionaldehyde is decidedly lower in affinity than is propionaldehyde. These results seem to conflict with those obtained by Wegscheider³ and Derick⁴ who studied the effect of halogen substitution on the dissociation constants of saturated aliphatic acids.

In 2,3 unsaturated aldehydes the affinity is much lower than in the saturated aldehydes. Acrolein drops almost to the level of benzaldehyde, and if a methyl or phenyl group is substituted for hydrogen on the beta carbon of acrolein a further lowering in affinity is observed, the alkyl having an even greater effect than the aryl group. That the phenyl group should exercise such influence is not surprising when one compares the relative positions of acetaldehyde and benzaldehyde; but the affinity value for crotonaldehyde indicates that the effect of a methyl in an unsaturated aldehyde is very different from that in a saturated one.

Experimental Method

In general the procedure of Adams was followed, known amounts of reactants being mixed in a dry Pyrex test-tube of suitable size and the tube closed with a stopper bearing a sampling device. The latter was made by sealing a 5cc. pipet to the single arm of a three-way stopcock. One of the double arms was extended to reach the bottom of the reaction tube while the other was lengthened and bent to permit exactly 5 cc. of the solution to be delivered into a suitable receiver. The concentration of the catalyst in the synthetic reactions was usually that used by Adams, while in the slower hydrolytic reactions the concentration was five or ten times as great. The reactions were allowed to proceed at 25°. In those cases where the aldehyde was available both the synthetic and hydrolytic reaction were carried out. In the other cases the hydrolysis was carried out at two different concentrations.

Preparation and Purification of Materials

Ethyl alcohol, acetaldehyde and ethyl acetal were purified as described in previous papers.⁵ The ethyl acetals of propionaldehyde, butyraldehyde and heptaldehyde were

³ Wegscheider, *Monatsh.*, **23**, 289 (1902).

⁴ Derick, *THIS JOURNAL*, **33**, 1152 (1911).

⁵ (a) Child and Adkins, *ibid.*, **45**, 3013 (1922). (b) Adkins and Nissen, *ibid.*, **44**, 2749 (1922).

prepared by Nissen's method. The diethylpropional had a density (referred to water at 4°) of 0.8232, and the diethylbutyral, of 0.8417 at 25°. Butyraldehyde was purified through the bisulfite compound, the vapors being dried over calcium chloride as in the purification of acetaldehyde and finally fractionated under reduced pressure. It boiled below 12.5° at 60 to 80 mm. Its density at 25° was 0.7988 and its refractive index (Abbé) at 25° was 1.3750. The propionaldehyde boiled 46.5 to 47.4° at 740 mm. The cinnamic aldehyde boiled at 108–109° at 35 mm. Its density at 25° was 1.045. Heptaldehyde was purified through the bisulfite addition compound and by the hydrolysis of diethylheptal. The final step in purification was a distillation carried out so slowly at 30–34° at 4 mm. that there was no noticeable ebullition. The density at 25° was 0.815 and the refractive index (Abbé) at 25° was 1.4077.

The Diethyl Acetal of Bromo-acetaldehyde was prepared by a modification of the method of Pinner⁶ and Fischer.⁷ One mole of bromine was added from a dropping funnel, during 30 to 45 minutes, to a well agitated mixture of one mole of diethyl acetal and 55 g. of precipitated calcium carbonate. The reaction mixture was kept in an ice-bath but the bromination proceeded best if the temperature was allowed to rise as much as possible without allowing the loss of the acetal, namely, to about 10°. The mixture was allowed to stand for 8 to 24 hours and enough steam introduced to dissolve the salts. The crude oil was then separated and placed over potassium carbonate. The aqueous layers from several brominations were steam distilled and the acetal so obtained was added to the crude oil, which was then washed with potassium carbonate solution until free from acid and dried for at least 12 hours over fresh potassium carbonate. The product was then fractionated. From 246 to 332 g. of the bromo-acetal boiling at 167–170° was obtained from 472 g. (4 moles) of acetal. This slightly colored product may be purified by distilling at 3 mm. pressure, shaking for 45 minutes with granular potassium carbonate and distilling at 48–49° (3 mm.). The density at 25° is 1.28. The pure acetal after a few hours becomes colored, and black after several days. The crude acetal, that is, the material boiling at 167–170°, was kept for months with little loss. It is a powerful lachrymator.

The Cyano-acetal was prepared by a modification of the method of Wohl.⁸ One hundred and thirty-two g. of bromo-acetal, 86.5 g. of potassium cyanide, 11 g. of potassium iodide, 300 cc. of alcohol and 150 cc. of water were gently refluxed for 72 hours in an oil-bath. The reaction mixture was steam distilled, the first portions of the distillate being diluted with water to throw out the acetal. After drying over granular potassium carbonate the crude product was fractionated at 5 mm. pressure, the compound boiling at 52–54°. At 15 mm. the boiling point is 55–57°; higher pressures result in considerable decomposition. The water-white acetal, density 1.255 at 24°, remains colorless if sealed in glass but becomes colored if allowed to stand in air. Such colored acetal should be allowed to stand with potassium hydroxide for an hour and be re-distilled at 5 mm. pressure.

The Acetal of Glycolic Aldehyde was prepared by a modification of the method of Pinner.⁶ A mixture of 66 g. of bromo-acetal, 37 g. of potassium hydroxide and 300 cc. of 95% alcohol was gently refluxed for 72 hours. The alcohol was distilled and the residue shaken with water. The oily layer was separated and the water layer extracted with ether. The oily layer was added to the ether and the whole dried over potassium hydroxide for 12 hours. The product was fractionated, that portion boiling at 163–167° being the desired product. This was fractionated at 8 mm., boiling at 57–58°; or 49–51° at 3–4 mm. The yields were from 40 to 60% and the density at 24° was 0.888.

⁶ Pinner, *Ber.*, 5, 149 (1872).

⁷ Fischer, *Ber.*, 25, 2551 (1892).

⁸ Wohl, *Ber.*, 39, 1952 (1906).

Acetal Amine (Amino Acetal) and Diacetal Amine were obtained by a modification of the method of Wohl⁹ and Wolff.¹⁰ Absolute ethanol was saturated at 0° with anhydrous ammonia and for each 7 g. of alcoholic ammonia 1 g. of bromo-acetal was used. The mixture was then sealed in tubes and heated at the temperature of boiling toluene for 18-24 hours. Any solid that may have formed was filtered off and the alcohol distilled from the filtrate. The residue from the distillation and the solid first obtained were combined, taken up in water and treated with alkali, whereupon an insoluble layer collected on the surface of the liquid. This was drawn off, the aqueous layer extracted several times with ether, the ethereal extract and the product first obtained were combined and dried over solid potassium hydroxide for at least 12 hours. The ether was distilled off and the residue repeatedly fractionated under reduced pressures. Fractions boiling at 52-53° at 2 mm. and at 127-130° at 3 mm. were obtained. The compound of lower boiling point had a density at 25° of 0.9161 and a refractive index (Abbé) of 1.4120. Analysis for nitrogen by combustion showed:

Anal. Calcd. for $\text{H}_2\text{NCH}_2\text{CH}(\text{OC}_2\text{H}_5)_2$: N, 10.52. Found: 10.88.

The compound of higher boiling point had a density of 0.9541 at 25° and a refractive index of 1.4210.

Anal. Calcd. for $\text{HN}(\text{CH}_2\text{CH}(\text{OC}_2\text{H}_5)_2)_2$: N, 5.62. Found: 5.96.

Crotonic Aldehyde was prepared from aldol by slowly distilling it at ordinary pressures through a 30cm. Vigreux fractionating column. The unsaturated aldehyde was obtained from the distillate by salting out with calcium chloride, drying and redistilling at ordinary pressures; b. p., 101-104°.

Acrolein.—The method used for the preparation of acrolein has been described by us in "Organic Syntheses."¹¹ The product boiled at 52.5 to 53.5° and had a density at 0° of 0.859 and at 25° of 0.8377.

The Acetals of Acrolein and Crotonic Aldehyde and the Acetal of β -Chloropropionaldehyde were prepared by the method of Witzemann¹² and of Evans and Hass.¹³ The acetal of β -chloropropionaldehyde, having a boiling point at 3-4 mm. of 47-50° and a density of 0.983 at 25°, was obtained in a yield of 41%. The β -chlorobutyraldehyde acetal used as an intermediate in the preparation of the acetal of crotonic aldehyde boiled at 70-90° at 40-45 mm. pressure. The acetal of crotonic aldehyde boiled at 146-148° at 740 mm. and at 33-34° at 2.5 mm. The yields of the acetal on the basis of crotonaldehyde used were only 4-7%. The density of crotonic aldehyde acetal at 25° was 0.846.

Analytical Determination of the Concentration of Reactants at the Equilibrium Point.—The concentrations at equilibrium of acetaldehyde, heptaldehyde, butyraldehyde, propionaldehyde, cinnamic aldehyde and crotonic aldehyde were determined by the modified Seyewitz-Bardin method as described in previous papers. Numerous titrations of weighed amounts of the purified aldehydes showed that under the conditions present in the titrations one mole of butyraldehyde reacted with 0.95 mole of bisulfite, one mole of heptaldehyde with 0.90 mole of bisulfite, one mole of crotonic aldehyde with 1.85 moles of bisulfite and one mole of cinnamic aldehyde

hyde with 1.84 moles of bisulfite. It was demonstrated that the alkene linkage, in the acetals of the two last-mentioned aldehydes, did not react with the sulfite under the conditions of titration. The above values were used in calculating from the titration values the amounts of the aldehydes present.

The Seyewitz-Bardin method apparently cannot be used for the determination of acrolein, glycolic aldehyde, cyano-acetaldehyde, bromo-acetaldehyde, β -chloropropionaldehyde, amino- and imino-acetaldehydes. A long and fruitless search was made for a method whereby these aldehydes could be determined in the presence of their acetals. Finally it was found necessary to determine the extent of the reaction by determining the amount of water present in the equilibrium mixture. This was done by using cobaltous chloride in a colorimetric method. An accuracy better than 5% cannot be claimed for this method. Results obtained in this way agreed with the sulfite titration method when the latter could be used, as with acetaldehyde and heptaldehyde.

The pink crystals of cobaltous chloride were dehydrated by heating over a gas flame. A saturated solution of the dried salt was made in absolute alcohol, and three to five drops of this solution (depending on the amount of water present) was used as an indicator for each 5 cc. of solution. It was found that the color of the cobaltous chloride was a function not only of the amount of water but also of the amount of acetal present, but the color was not influenced by the free aldehyde, as with acetaldehyde, heptaldehyde and acrolein.

The amount of water at equilibrium was determined by comparing a 5cc. sample of the reaction mixture containing indicator with a set of standards which were prepared in the following way.

In a series of test-tubes previously cleaned and dried were put equimolecular amounts of water and of the acetal under investigation; the volume of each standard was made up to 5 cc. with absolute alcohol and the cobalt chloride indicator added. By comparing the color of the sample with that of the standards the amount of water in the equilibrium mixture could be determined. Since the amounts of acetal and water for each standard were small, separate solutions containing a known weight of acetal in absolute alcohol (Solution I) and a known weight of water in absolute alcohol (Solution II) were made up in volumetric flasks, and from these the necessary amounts of each were used and absolute alcohol then added to each tube to make the total contents equal to 5 cc.

To illustrate the use of this method an actual case will be given in detail.

In a reaction tube were placed

7.255 g.	Chloropropylal	0.0435 mole	7.36 cc.
0.785 g.	Water	.0436 mole	0.79 cc.
23.04 g.	Ethanol-catalyst (HCl)	.479 mole	<u>28.10 cc.</u>
			36.25 cc.

Several days later standards were prepared by using ordinary test-tubes, previously thoroughly cleaned and dried, and putting into them the indicated amounts of Solutions I and II. Solution I contained 10.014 g. of β -chloropropionaldehyde acetal and was made up to 25 cc. with absolute alcohol; Solution II contained 4.346 g. of water and was diluted with absolute alcohol to 50 cc.

No.	G., water	Cc., soln. II	G., acetal	Cc., sol. I	Cc., abs. alc.
1	0.0870	1.00	0.885	2.01	1.96
2	.0521	0.60	.488	1.20	3.20
3	.0261	.30	.242	0.64	4.06
4	.0191	.22	.177	.44	4.34
5	.0174	.20	.161	.40	4.40

A 5cc. sample was withdrawn from the reaction tube and to each of the standards and sample 3 drops of the cobalt chloride indicator was added. A color comparison of the sample with the standards showed it to be like 1. The next day a new set of standards in the vicinity of 1 was made but with less water variation, and in this way it was found that the acetal-equilibrium mixture corresponded to the standard containing 0.0912 g. of water per 5 cc. Thus the amount of unhydrolyzed acetal was found to be 84%.

Calculation of Equilibrium Constants and Affinity Values

The values for K_e listed in Table I are mean values and the manner in which they were obtained, especially where the equilibrium point was determined colorimetrically, is illustrated in the case of glycolic aldehyde. The extreme values of K_e for this aldehyde were found to be 0.0150 and 0.0272, giving for $-RT \ln K$ 2480 units and 2140 units, respectively, of which the average is 2310 units, corresponding to $K_e = 0.0202$; and $-RT \ln K$ becomes 2300 ± 180 units. K_e and $-RT \ln K$ were obtained in a similar manner for other aldehydes.

$$-RT \ln K = 1.9885 \times 298 \times 2.3026 \times \log_{10} k$$

Summary

The equilibrium constants for the reaction of ethanol with amino-acetaldehyde, bromo-acetaldehyde, cyano-acetaldehyde, imino-acetaldehyde, β -chloropropionaldehyde, glycolic aldehyde, acrolein and crotonic aldehyde, heptaldehyde, propionaldehyde, acetaldehyde, butyraldehyde and cinnamaldehyde have been given.

The values of $-RT \ln K$ have been calculated and used as the basis for a comparison of the relative affinity manifested by the various aldehydes in the acetal reaction.

It has been noted that the effect of a given substituent upon affinity in the acetal reaction is neither quantitatively nor qualitatively constant. The same substituent in some cases increases and in others decreases affinity.

Methods for synthesis of several acetals are given and some of their physical constants have been determined.

MADISON, WISCONSIN

THE OSMOMETRIC METHOD OF DETERMINING THE MOLECULAR WEIGHTS OF PROTEINS

BY GILBERT ADAIR¹

RECEIVED APRIL 27, 1927

PUBLISHED OCTOBER 5, 1927

In a recent paper Svedberg and Nichols² state that the osmotic pressure method of measuring the molecular weights of proteins is rendered quite uncertain by the Donnan equilibrium. Svedberg and Fåhræus³ stated that conflicting results, obtained by different investigators of the molecular weight of hemoglobin, were partly due to the difficulty of measuring osmotic pressures against semipermeable membranes and partly due to the Donnan effect.

An explanation of these difficulties has been suggested.⁴ The conflicting results referred to by Svedberg had been obtained with hemoglobin equilibrated with water of unknown hydrogen-ion concentration. New measurements⁴ showed that deviations from the isoelectric point led to abnormally high osmotic pressures on account of the excess of ions inside the membrane.

Unfortunately, Svedberg and Fåhræus did not refer to any of the papers on the osmotic pressure of hemoglobin published in 1924 and 1925, which showed that the membranes gave true equilibria,^{4,5,6} and the molecular weights corrected for the ion distribution effects were the same as the figure they obtained by the ultra-centrifugal method, namely, 62,000–71,000 for purified horse hemoglobin.

The osmometric data for the hemoglobins of various species have been given in the papers referred to as follows: hemoglobin of man, the horse and the sheep (solvent *N*/10 NaCl, etc.);⁴ hemoglobin of man and the ox (solvent salts of red corpuscle);⁶ hemoglobin of the horse and the sheep (solvent, distilled water).⁴ All the molecular weights agreed to within 10% of 66,800, which is four times the equivalent calculated from iron analyses.

The agreement of the results with different salt solutions affords a check on the accuracy of the membrane equilibrium corrections in the case of hemoglobin. The empirical correction formula⁵ which was pro-

³ Svedberg and Fåhræus, *ibid.*, **48**, 430 (1926).

⁴ Adair, *Proc. Roy. Soc. (London)*, **109A**, 292 (1925).

⁵ Adair, *Proc. Camb. Phil. Soc. (Biol.)*, **1**, 75 (1924).

⁶ Adair, *Proc. Roy. Soc. (London)*, **108A**, 627 (1925).

visionally suggested (because Donnan's assumptions concerning osmotic pressures apply only to ideal solutions) can be now withdrawn in favor of methods based on a new theoretical treatment of membrane equilibria.⁷

The corrections for hemoglobin were fairly accurate, but I had made no experiments on other proteins and the available data were difficult to interpret. Later work has shown that some of the provisional estimates⁵ require revision. The average mass of the protein particles in serum must be raised from 80,000 to about 100,000.

The data for egg albumin in concentrated ammonium sulfate solutions cannot yet be interpreted with confidence, but it is probable that 43,000 is nearer the truth than the earlier figure 66,000 which is now withdrawn.

Sørensen, on the basis of certain assumptions concerning the ionization of ammonium albuminate, formerly considered doubtful, deduced that the molecular weight of salt-free egg albumin would be about 34,000, an estimate recently confirmed by the centrifugal experiments of Svedberg and Nichols. Critics of the osmometric method might object that the influence of traces of alkali dissolved from the glass, and the hydrogen ions given off by the protein, might increase the osmotic pressure and the free energy of the protein and diminish the apparent molecular weight, but even in the case of acidic proteins like egg albumin, dissolved in distilled water, the hydrogen ions are unlikely to cause errors exceeding 20%, and it seems reasonable to claim that the agreement of the results obtained by different methods supports the view that the osmometer gives at least approximately correct results under suitable conditions.

Although the unequal distribution of ions is often advanced as a theoretical objection to the osmometric method, it is advantageous from the practical point of view because it facilitates the study of the activity coefficients of diffusible ions in the presence of proteins, an important point when the protein systems are studied as a whole.

THE SOLUBILITY OF NON-RADIATED CHOLESTEROL IN LIQUID AMMONIA

BY REUBEN G. GUSTAVSON AND JOHN B. GOODMAN

RECEIVED APRIL 27, 1927

PUBLISHED OCTOBER 5, 1927

Franklin and Kraus have pointed out the marked similarity of water and liquid ammonia as solvents, and determined the solubility in liquid ammonia—generally at atmospheric pressure (-33.35°)—of about two hundred inorganic and two hundred and fifty organic compounds.¹

This work was a continuation of the work of Gore.²

The work reported was largely qualitative. Franklin and Kraus report cholesterol as insoluble in liquid ammonia.³

Liquid ammonia has recently been used in this Laboratory to separate the female sex hormone from cholesterol.⁴

Advantage was taken of the insolubility of cholesterol in liquid ammonia by Koch, Cahan and Gustavson in the concentration of the antirachitic factor in irradiated cholesterol.⁵

The above work has made a quantitative study of the solubility of cholesterol in liquid ammonia highly desirable.

Method of Procedure

The cholesterol used was purified by several crystallizations from acetone and melted sharply at 147° . After preparation, the cholesterol was shielded from all light rays to preclude the possibility of radiating any considerable portion of it. The reaction tubes used in the experiments were of "T" shape, very similar to the type used by Franklin in his earlier experiments. Their use and manipulation can be best shown by the description of a typical determination.

A weighed amount of cholesterol was placed in a small filter paper. The whole was rolled up in the form of a small capsule and tied with cotton thread. Both thread and filter paper were previously extracted with liquid ammonia in a closed Soxhlet system. The capsule was placed in one leg of the reaction tube and covered with 3–5 cc. of anhydrous liquid ammonia. The tube was then sealed off. The study of the temperature effect on solubility was accomplished by immersing the "T" tube in a water thermostat accurately maintained at the required temperature. The tube was frequently shaken to facilitate the dispersion of the solute throughout the solvent. Tubes were allowed to remain in the thermostat for 3,

¹ Franklin and Kraus, *Amer. Chem. J.*, **20**, 820 (1898).

² Gore, *Proc. Roy. Soc. (London)*, **20**, 441 (1872).

³ Ref. 1, p. 834.

⁴ Frank and Gustavson, *J. Am. Med. Assoc.*, **84**, 1715 (1925).

⁵ Koch, Cahan and Gustavson, *J. Biol. Chem.*, **67**, No. 2, lii (1926).

4, 5, 6 and 7-day periods. No increase in the quantity of cholesterol dissolved was found after 72 hours, showing that equilibrium had been established. The temperature at -38° was maintained by immersing the tube in liquid ammonia contained in a Dewar flask open to the atmosphere (630 mm. barometric pressure). The cholesterol-saturated liquid ammonia was poured over into the other leg of the tube and the volume of the solution taken at 20° . The ammonia was then distilled back by carefully warming the solution and cooling the tube containing the capsule. Care had to be exercised at this point to avoid an error due to foaming. Since the quantity of cholesterol soluble in 3-5 cc. of liquid ammonia at low temperatures is small, the error introduced in weighing would be correspondingly larger.

The solubility at -38° was checked by the following method, which insured obtaining a saturated solution.

A "I" tube was prepared with a constriction in the side arm and a piece of cotton was placed in this constricted portion of the tube. A capsule containing cholesterol was placed in the other leg of the tube, covered with liquid ammonia and sealed off in the usual manner. The tube was placed in a water-bath at 45° and shaken frequently. On cooling to room temperature the liquid became turbid due to precipitation of the cholesterol. The tube was then placed in a Dewar flask containing liquid ammonia and allowed to stand for 24 hours.

The ammonia with some suspended cholesterol was filtered through the cotton into the other leg of the tube. The whole tube was immersed in liquid ammonia during this part of the operation. The ammonia was then distilled back in the usual manner. No weighable residue remained. The Liebermann-Burchardt test was negative.

The temperature range above 49° was not investigated because of the high pressures developed in the tubes at elevated temperatures.

The results in Fig. 1 are shown in milligrams of cholesterol per 100 cc. of liquid ammonia. The results in each case are the average of four determinations. The tabulation below gives the average weight of chole-

Fig. 1.

terol extracted, the average volume of liquid ammonia and the average solubility of the cholesterol in milligrams per 100 cc. of liquid ammonia.

TABLE I
THE SOLUBILITY OF NON-RADIATED CHOLESTEROL IN LIQUID AMMONIA

Temperature, °C.	Av. vol. of ammonia, Cc.	Av. wt., mg.	Av. solubility, mg. per 100 cc.
-38	4.00	0.00	0.00
0	4.05	0.25	6.16
7	4.13	0.83	20.2
14	4.05	1.10	27.2
21	3.30	2.40	72.6
28	3.20	3.75	117.2
35	3.70	8.60	232.2
42	3.25	9.80	301.2
49	3.95	21.55	545.0

The assistance of a grant from the National Research Council for the study of the isolation and purification of the female sex hormone is gratefully acknowledged.

Summary

1. The solubility of cholesterol in liquid ammonia at temperatures ranging from -38 to $+49^{\circ}$ has been determined.
2. The solubility at -38° is beyond the sensitiveness of the Liebermann-Burchardt test.
3. Liquid ammonia can be used to separate certain preparations from cholesterol.

THE REARRANGEMENT OF ACID AZIDES AND HYDROXAMIC ACIDS OF GEOMETRICAL ISOMERS

BY LAUDER W. JONES AND J. PHILIP MASON¹

RECEIVED MAY 4, 1927

PUBLISHED OCTOBER 5, 1927

In an article by Jones and Wallis² an account of the rearrangements of compounds with optically active radicals was presented. It was shown that *d*-benzylmethylacetazide, dissolved in benzene, rearranged at room temperatures ($10-35^{\circ}$) and that an optically active product, *d*-benzylmethyl methyl isocyanate, $(C_7H_7)(CH_3)CH.N=C=O$, and nitrogen (97%) were formed. These results suggested the experiments described in the following article.

¹ This paper is based upon a thesis submitted by J. Philip Mason to the Faculty of the Graduate School of Princeton University in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

² Jones and Wallis, *THIS JOURNAL*, **48**, 169 (1926).

The problem may be stated as follows. If geometrical isomers in which the radicals of *cis* and *trans* configurations are directly attached to the group —CO.Nxy in such derivations as hydroxamic acids or acid azides undergo rearrangement, will the *cis* and *trans* configurations of their radicals be retained in the organic products of rearrangement?

Two pairs of *cis-trans* isomers, namely, cinnamic acid and allocinnamic acid, and crotonic and isocrotonic acids, were chosen for investigation. It was found that the azides offered less experimental difficulty than the hydroxamic acids. The two space isomers are represented by the formulas

If these pairs of isomers, in which R stands for C_6H_5 or CH_3 , rearrange and the configurations of the styryl and *iso*-allyl radicals persist, then two different isocyanates should result in each case

Furthermore, addition of ammonia to these isocyanates should yield *two pairs of space isomeric monosubstituted ureas*, for example,

But if the styryl and *iso*-allyl radicals change and the "labile" configuration gives place to the "stable" configuration, only one isocyanate would result in each case and consequently *only one urea* would be formed from each pair of isomeric azides.

Results of the Study of Azides

The azides of the four different acids were prepared by the action of powdered sodium azide upon the acid chlorides dissolved in absolute ether or in benzene. The azide of cinnamic acid has been described by Forster.³ It is a solid which melts at 86° , accompanied by decomposition. A solution of this azide in benzene did not evolve nitrogen until a temperature between 75 and 80° was reached. In contrast to this behavior, the azide of allocinnamic acid, during its preparation by the action of sodium azide upon the acid chloride dissolved in ether, lost nitrogen at room temperature continuously; about 100 cc. of nitrogen was collected during the course of the reaction (six–seven hours). The azide of cinnamic acid may be crystallized from boiling ether without suffering any decomposition. No attempt was made to isolate the azide of allocinnamic acid, because every precaution was being taken to prevent a change to the more stable cinnamic form, and at the temperature necessary to cause

³ Forster, *J. Chem. Soc.*, 95, 437 (1909).

sodium azide and the acid chloride to react decomposition was unavoidable and a mixture of azide and isocyanate was always obtained.

The behavior of ether solutions of the azides described above seems to justify the conclusion that the azide of allocinnamic acid existed in solution and decomposed to give nitrogen and an isocyanate at a temperature appreciably lower than that required to affect the azide of cinnamic acid.

The azides obtained from crotonic and isocrotonic acids did not show so pronounced a difference in reactivity.

The conversion of the isocyanates into monosubstituted ureas, a reaction carried out by passing the calculated amount of ammonia gas into cold ether solutions of the isocyanates, seemed to offer the best chemical method of determining whether or not the radicals in the isocyanates had retained their original configurations. When these experiments were performed, only *one monostyryl urea*, $C_6H_5CH=CH-NH-CO-NH_2$ (m. p. 142–143°), was obtained and, similarly, from crotonic and isocrotonic azides only *one mono-iso-allyl urea*, $CH_3-CH=CH-NH-CO.NH_2$ (m. p., 122°), resulted.

These observations lead to the conclusion that during rearrangement the labile radicals assume the more stable configurations; for it is not likely that the action of ammonia at 0° upon the isocyanates would cause the radicals to change their configurations from *cis* to *trans*.

Results of the Study of Hydroxamic Acids

Mention has been made of complications encountered in experiments with hydroxamic acids. Cinnamhydroxamic acid has been studied by several investigators.⁴ The potassium salt of the benzoyl ester of this hydroxamic acid, $C_6H_5CH=CH-CO.NKO.CO.C_6H_5$, was prepared and a solution of it in water was heated to cause rearrangement. In reactions of this kind, the isocyanates first produced are usually hydrolyzed and *sym.*-disubstituted ureas are obtained as the chief product of the reaction. It was hoped that these ureas might be employed to answer the question concerning the behavior of the radicals discussed above.

When the experiment was performed, no *sym.*-distyryl urea, $(C_6H_5CH=CH-NH)_2CO$, could be isolated. However, when the azide of cinnamic acid was heated with water, it behaved normally; the chief product of the reaction was *sym.*-distyryl urea.

Thiele and Pickard⁵ stated that the potassium salt of this benzoyl ester of cinnamhydroxamic acid heated with water gave "no definable transformation product." We have isolated a perfectly definite compound, a colorless solid which melted at 152°. It was not the disubstituted urea. The nitrogen content was almost exactly that required for cinnamhydrox-

⁴ Rostolski, *Ann.*, **178**, 214 (1875). Thiele and Pickard, *Ann.*, **309**, 189 (1899). Velardi, *Gazz. chim. ital.* [2] **34**, 66 (1904).

⁵ Thiele and Pickard, *Ann.*, **309**, 189 (1899).

amic acid, but the properties of the two compounds were totally different. At first it was thought that it might be γ -phenyl- α -isoxazolone, which melts at 152°.

The percentage of nitrogen in the compound was found to be almost exactly that required by this isoxazolone. But it is difficult to see how this particular isoxazolone could be formed in the reaction. It is evident that by intramolecular addition cinnamhydroxamic acid might yield α -phenyl- γ -dihydro-isoxazolone; but the isoxazolones possess very pro-

nounced acid properties and are readily soluble in solutions of the alkalis in the cold, whereas our compound was not soluble even in boiling alkalis. We hope to be able to identify the substance later.

In this connection, it is interesting to note that the potassium salt of the benzoyl ester of cinnamhydroxamic acid dissolved in boiling absolute alcohol shows a normal behavior; styryl urethan is formed by addition of alcohol to the isocyanate. This observation was also made by Thiele and Pickard.

Experimental Part

I. Rearrangement of the Azide of Cinnamic Acid

Preparation of the Azide.—The method employed was similar to the one used by Forster.⁶

Sodium azide (Kahlbaum) was purified by dissolving it in the minimum amount of water and reprecipitating it by the addition of acetone. Then, 20 g. of dry, finely-powdered azide (60% excess) was suspended in 120 cc. of absolute ether and 20 g. of cinnamyl chloride was added. This mixture was stirred for eight or ten hours at room temperature. The solid material was collected on a filter and washed with water to remove sodium chloride and sodium azide, and the azide was purified by crystallization from ligroin (b. p. 60–80°). Evaporation of the ether filtrate to one-half its original volume gave additional crystals of the azide. In all about 2.5 g. of pure azide (m. p. 86°) was obtained.

Preparation of Styryl Isocyanate: $\text{C}_6\text{H}_5\text{CH=CH-N=C=O}$.—A solution of 5 g. of cinnamic acid azide in 25 cc. of benzene dried over sodium was placed in a flask connected with a reflux condenser protected at the top by a calcium chloride tube. The

⁶ Forster, *J. Chem. Soc.*, 95, 437 (1909).

solution was heated to a temperature just below the boiling point until no more nitrogen was evolved. After removing the benzene, the isocyanate was distilled under diminished pressure (12 mm.). It boiled at 107°. About 3 g. of pure isocyanate was obtained.

sym.-Distyryl Urea: $(C_6H_5CH=CH-NH)_2C=O$. *Action of Water upon the Isocyanate.*—Several grams of styryl isocyanate was suspended in water heated to 50°. The isocyanate was decomposed slowly. A white solid was formed which, after crystallization several times from dil. alcohol, melted at 214°. It was soluble in alcohol and in ethyl acetate and insoluble in ether and ligroin.

Anal. Subs., 0.3723 g.: N, 35.5 cc. (29°, 758 mm.). 50% KOH used. Calcd.: N, 10.6. Found: 10.7.

Rearrangement of Cinnamic Acid Azide in the Presence of Water.—A suspension of 3 g. of the azide in 75 cc. of water was heated nearly to boiling for half an hour. A yellow solid was formed and the solution became turbid. The solid weighed 2.2 g. Treatment of it with ether removed the yellow color and recrystallization from dil. alcohol gave *sym.*-distyryl urea; m. p., 214°.

The turbid solution filtered from the solid was extracted with ether and the ether evaporated. This gave a yellow, gummy product which possessed the peculiar aldehyde odor noticed in the rearrangement of the benzoyl ester of cinnamhydroxamic acid described in the latter part of this article. The yellow material finally became solid. It was treated with a small amount of benzene to remove the yellow color and recrystallized from dil. alcohol. This gave distyryl urea; m. p., 213°.

The rearrangement of the azide in water was also carried out in an atmosphere of carbon dioxide in order to measure the nitrogen evolved. Bubbles of nitrogen were not observed until the temperature of the water reached 75 to 80°. Thus, 0.3135 g. of the azide gave 42.8 cc. of nitrogen at 22° and 743 mm. over 50% potassium hydroxide. This corresponds to 94.8% of the nitrogen required for complete decomposition according to the equation.

Monostyryl Urea: $C_6H_5CH=CH-NH-CO-NH_2$.—A solution of 1.6 g. of the azide of cinnamic acid in 10 cc. of dry benzene was heated to bring about the rearrangement of the azide. The benzene was removed and the isocyanate dissolved in 10–15 cc. of dry ether. The flask containing the solution was cooled by ice water, and dry ammonia gas passed into the ether. A pale yellow precipitate formed; wt., 1.1 g.; m. p., 140–143°. Recrystallization of it from dil. alcohol gave a colorless solid which melted at 143°. It was soluble in acetone, in alcohol and in ethyl acetate, and insoluble in water and in ether.

Anal. Subs., 0.2815: N, 41.5 cc. (21°, 757.5 mm.). 50% KOH used. Calcd.: N, 17.3. Found: 16.9.

II. Rearrangement of the Azide of Allocinnamic Acid

Preparation of Allocinnamic Acid.—Allocinnamic acid was prepared according to the method of Liebermann and Scholz⁷ and of Michael⁸ by the reduction of α -bromo-allocinnamic acid. The starting material in the preparation was cinnamic acid. The yield of allocinnamic acid (m. p. 67°) was small; not more than 7 g. of pure substance was obtained from 100 g. of cinnamic acid in any of our experiments.

Preparation of Allocinnamic Acid Azide.—The chloride of allocinnamic acid was made by treating the acid (3.3 g.) dissolved in a small amount of ether with an excess of thionyl chloride at 0°. The mixture stood for half an hour in an ice-bath. Ether and excess of thionyl chloride were removed by evaporation in a vacuum desiccator.

⁷ Liebermann and Scholz, *Ber.*, 25, 950 (1892).

⁸ Michael, *Ber.*, 34, 3648 (1901).

The acid chloride could not be distilled without being converted into the more stable chloride of cinnamic acid, so it was used directly. Finely powdered sodium azide (5 g.) was suspended in absolute ether contained in a 3-necked flask, which was connected with a carbon dioxide generator and also with an azotometer charged with a 50% solution of potassium hydroxide. After the system was thoroughly filled with carbon dioxide, an ether solution of the acid chloride (3.5 g.) was introduced through a dropping funnel.

This mixture was stirred for six or seven hours. During this time about 100 cc. of nitrogen gas collected in the azotometer. This implied that the azide of allocinnamic acid had formed and suffered decomposition and rearrangement at room temperature; the azide of cinnamic acid did not yield nitrogen under these conditions.

The Monostyryl Urea.—The ether solution which contained the isocyanate was filtered from the solids. It was cooled and treated with ammonia gas. A white precipitate weighing about 0.3 g. was collected and washed with water to remove any ammonium chloride. After crystallization from dil. alcohol it melted at 142°.

It is probable that the decomposition of the azide was not complete. The evolution of nitrogen took place slowly at room temperature. It did not seem desirable to hasten decomposition by increasing the temperature since this might cause a conversion of the allocinnamic form.

These results show that the same monosubstituted urea was obtained in the two experiments. It seems probable, therefore, that the isocyanates were identical.

III. Rearrangement of the Azide of Crotonic Acid

Preparation of the Azide: $\text{CH}_3\text{CH}=\text{CH}-\text{CO}-\text{N}_3$.—Crotonyl chloride was made by the action of thionyl chloride upon an excess of crotonic acid, first at room temperature and finally at 50–60°. It was separated by fractional distillation (b. p., 124°).

An ether solution of 21 g. of crotonyl chloride in which 23 g. of sodium azide was suspended was stirred mechanically for two days. An azotometer was connected with the flask containing the mixture. No nitrogen was evolved during the reaction. The ether solution was filtered and evaporated in a current of dry air. This gave 14 g. of the azide. It was a clear liquid possessing a sharp odor.

A sample of it was placed in a melting-point tube and, after inserting a glass thread, was heated slowly. At 30–40° an occasional bubble of gas was given off; at 75–85°, the evolution of nitrogen became very rapid.

To test the purity of the liquid, a weighed sample dissolved in benzene was decomposed in an apparatus from which air had been displaced by carbon dioxide, and the nitrogen was collected in an azotometer over a solution of potassium hydroxide. A correction was made for the vapor pressure of benzene.

Anal. Subs., 0.2470: N, 44.3 cc. (18°, 745 mm.). Vapor pressure of benzene at 18°, 68.9 mm. Calcd.: N, 49.8 cc. Found: 37 cc.; 74.2% azide in liquid.

Mono-*iso*-allyl Urea, $\text{CH}_3-\text{CH}=\text{CH}-\text{NH}-\text{CO}-\text{NH}_2$.—Seven g. of the impure liquid azide was placed in a clean, dry flask, attached to a reflux condenser, and heated on a water-bath until no more nitrogen was evolved. The liquid, chiefly *iso*-allyl isocyanate, possessed a very acrid and suffocating odor. Absolute ether was added to the residue and a current of dry ammonia gas was then passed through the solution as long as a precipitate was obtained. The white precipitate, collected on a filter and dried, weighed 2 g. Recrystallized from a mixture of hot ethyl acetate and chloroform by the addition of ligroin, it formed pure white crystals which melted at 122°.

It is very soluble in alcohol and in acetone, quite soluble in ethyl acetate, in chloroform and in warm water, from which it does not separate in good crystalline form. It is insoluble in ligroin, in benzene and in ether.

Anal. Subs., 0.1211: N, 30.4 cc. (32.5°, 757.3 mm.). 50% KOH used. Calcd.: N, 28. Found: 27.8.

IV. Rearrangement of the Azide of Isocrotonic Acid

Isocrotonic acid (Kahlbaum) purified according to the method suggested by Wislicenus⁹ was converted into isocrotonyl chloride by the action of a little less than the calculated amount of thionyl chloride upon an ether solution of the acid. Isocrotonyl chloride cannot be distilled at atmospheric pressure without isomerization to give the more stable crotonyl chloride. To avoid any change of this kind the ether was removed carefully and the acid chloride obtained from 10 g. of isocrotonic acid used directly.

Preparation of the Azide of Isocrotonic Acid.—An ether solution of this chloride treated with 14 g. of sodium azide was stirred for two days. During the first 12 hours the mixture was kept at a temperature between 15 and 20°. No nitrogen was formed so the temperature was increased to 25–28°. This caused a slow evolution of nitrogen.

Mono-*iso*-allyl Urea.—After two days the ether solution was filtered, cooled and treated with dry ammonia gas. This gave a small amount of colorless solid which was recrystallized from a mixture of ethyl acetate and chloroform by the addition of ligroin. It melted at 122° and was identical with the urea obtained from the azide of crotonic acid as described above.

V. Rearrangement of Cinnamhydroxamic Acid

Preparation of Cinnamhydroxamic Acid.—Although this compound has been prepared by several investigators,⁴ we found it more satisfactory to prepare it by the method used by Jones and Hurd in other preparations.¹⁰

The acid chloride of cinnamic acid was prepared by warming the acid with a 10% excess of thionyl chloride at 50°. When the reaction was complete, the liquid, still warm, was transferred to a distilling flask, the excess of thionyl chloride drawn off by means of a water pump, and the acid chloride distilled; b. p., 101° (2 mm.).

Free hydroxylamine was prepared by the method of Lecher and Hofmann¹¹ with the apparatus similar to that used by Hurd and Brownstein.¹²

A solution of 24 g. of cinnamic acid chloride in 60 cc. of dry benzene was added slowly to a suspension of 12 g. of free hydroxylamine in 100 cc. of dry benzene, while the flask was shaken and cooled in ice water. The reaction took place immediately; a white, viscous substance was formed. After all of the chloride was added the mixture was shaken for a few minutes and then filtered. The precipitate was washed twice by suspending it in water. It was collected and dried in a vacuum desiccator; wt., 24 g. The acid was recrystallized from hot ethyl acetate by the addition of ligroin. The first crystallization usually yielded an oil which solidified readily as it became cool. The melting point was finally raised to 119.5°. Thiele and Pickard gave 111° as the melting point.

Anal. Subs., 0.4749: N, 37.6 cc. (22.5°, 754 mm.). 50% KOH used. Calcd.: N, 8.95. Found: 9.03.

As a further check upon the constitution of the compound, a sample was hydrolyzed by heating it with 6 *M* hydrochloric acid. The ratio of cinnamic acid to hydroxylammonium chloride formed was found to be 1:1.

An attempt to prepare the hydroxamic acid by adding a few drops of water to an ether solution of the acid chloride in which equivalent quantities of sodium carbonate

⁹ Wislicenus, *Vierteljahrsschr. Naturforsch. Ges. Zürich*, **41**, 270–293 (1897).

¹¹ Lecher and Hofmann, *Ber.*, **55B**, 912 (1922).

¹² Hurd and Brownstein, *THIS JOURNAL*, **47**, 68 (1925).

and hydroxylammonium chloride were suspended resulted in the formation of a mixture of the mono- and dicinnamhydroxamic acids.

Preparation of the Benzoyl Ester of Cinnamhydroxamic Acid.—The best method for the benzoylation of the hydroxamic acid was found to be that of Heidelberger and Jacobs.

A solution of 6.55 g. of cinnamhydroxamic acid in a mixture of 30 cc. of glacial acetic acid and 30 cc. of a saturated solution of sodium acetate was shaken with 6 cc. of benzoyl chloride added in small portions, while the flask was immersed in ice water. After a short time the benzoyl ester separated as a white solid. One crystallization of it from hot ethyl acetate with addition of ligroin gave 8.5 g. of benzoyl ester, which melted at 150–152°. Further recrystallization from hot ethyl acetate and ligroin, or from hot dil. alcohol, yielded pure white crystals which melted sharply at 156.5°. Thiele and Pickard gave 144° as the melting point.

Preparation of the Potassium Salt of the Benzoyl Ester of Cinnamhydroxamic Acid.—The benzoyl ester was only slightly soluble in cold alcohol and less soluble in ether. On this account, the ordinary method of preparing a potassium salt of this class was not satisfactory. Acetone was found to be the most suitable solvent. In a typical experiment, 7.95 g. of benzoyl ester was dissolved in 130 cc. of warm, dry acetone, and a cold solution made by dissolving 1.02 g. of potassium in 30 cc. of absolute methanol was added. The potassium salt formed immediately as a white precipitate. The mixture was cooled rapidly by shaking the flask in ice water. Addition of about 100 cc. of dry ether increased the yield; weight of dry salt, 8.2 g. The sodium salt was prepared by the same method.

Anal. Subs., 0.0561: Na_2SO_4 , 0.0140. Calcd. for $\text{C}_{16}\text{H}_{13}\text{O}_3\text{NNa}$: Na, 7.96. Found: 8.08.

Rearrangement of the Potassium Salt in Water.—The potassium salt was only slightly soluble in water at room temperature, 2.5 g. dissolving in about 150 cc. of water. When this solution was heated, it became turbid at 40–45°. The precipitate could not be coagulated completely by any of the usual methods. By filtration, only a very small amount of a white precipitate was obtained. When it was crystallized from hot ethyl acetate or hot benzene, it melted at 152°. The same product was obtained when dicinnamhydroxamic acid was treated with an equivalent amount of sodium carbonate dissolved in water. During the rearrangement, a peculiar odor resembling that of benzaldehyde was noticed, but no aldehyde was ever detected when the solution was tested.

Anal. Subs., 0.0368: N, 2.7 cc. (21°, 760 mm.). 50% KOH used. Found: N, 8.5.

Summary

The azides of two pairs of *cis-trans* isomers, namely, cinnamic acid and allocinnamic acid, crotonic and isocrotonic acids have been prepared and caused to undergo rearrangement. The isocyanates formed by rearrangement were converted into monosubstituted ureas by addition of ammonia. Only one monostyryl urea and one *iso*-allyl urea could be obtained. This seems to indicate that during rearrangement the configurations of the styryl and *iso*-allyl radicals are changed and only the stable *trans* configuration appears in the ureas and undoubtedly, also, in the first product of rearrangement, the isocyanates.

The rearrangement of the potassium salt of the benzoyl ester of cinnamhydroxamic acid was studied. A definite product (m. p., 152°) was

obtained. It was not the *sym.*-disubstituted urea expected. It has not been identified.

THE USE OF NITROGEN TETROXIDE IN PLACE OF NITRIC ACID IN ORGANIC NITRATIONS¹

BY L. A. PINCK

RECEIVED MAY 5, 1927

PUBLISHED OCTOBER 5, 1927

It has been previously observed that when nitrogen tetroxide is allowed to react with organic substances, oxidation, nitration or diazotization may take place. In general, the experience of previous workers has been that both oxidation and nitration take place when a solution of nitrogen tetroxide in an organic substance is allowed to stand either in the dark or in sunlight for several weeks to several months. With nitro arylamines,² nitrogen tetroxide acts as a diazotizing reagent. It has also been found that solutions of nitrogen tetroxide in toluene and benzene form explosive mixtures.³

The reactions of oxides of nitrogen with organic substances described in the literature, as well as some preliminary experiments conducted in the course of this investigation, indicate that the direct nitration of organic substances with oxides of nitrogen is neither safe nor economically feasible, the chief objections being: (1) slowness of nitration at moderate temperature, (2) oxidation and (3) possible explosions at higher temperatures.

The present paper describes a study of the conditions governing the nitration of a number of aromatic compounds with nitrogen tetroxide in the presence of sulfuric acid.

Theoretical

The fact that nitric acid oxidizes and only partially nitrates an organic substance, whereas a mixture of nitric and sulfuric acids yields a complete nitration, led to the belief that oxidation and explosion hazard might be avoided by using sulfuric acid in conjunction with the oxides of nitrogen. Sulfuric acid mixed with nitrogen tetroxide serves a purpose quite distinct from its use in the mixed acid nitration, for not only does it function as a dehydrating reagent, but it has the additional function of forming nitric acid *in situ* as shown in the following equation

¹ Presented before the Division of Organic Chemistry at the 73rd Meeting of the American Chemical Society, Richmond, Virginia, April 11-16, 1927.

² Houston and Johnson, *THIS JOURNAL*, 47, 8011 (1925).

³ Raschig, *Z. angew. Chem.*, 35, 117 (1922).

This equilibrium can be shifted practically completely to the right, for, according to the law of mass action $\frac{(\text{N}_2\text{O}_4)(\text{H}_2\text{SO}_4)}{(\text{HSO}_3\text{N})(\text{HNO}_3)} = K$, there are two factors involved in reducing the concentration of nitrogen tetroxide to a minimum, namely, the use of an excess of sulfuric acid and the constant removal of the nitric acid owing to its interaction with the organic substance, yielding a nitro compound.

The nitrosylsulfuric acid formed in the reaction and any unreacted sulfuric acid present in the mixture act as dehydrating reagents, thus facilitating the nitration of the organic substance.

In such a system, about 50% of the oxide of nitrogen is utilized in the nitration of the organic substance, and approximately 50% is combined with the sulfuric acid in the form of nitrosylsulfuric acid. The complete reaction for a single-step nitration for benzene, for example, can be represented by the following equation

The subsequent reaction of nitrosylsulfuric acid and water which one would expect is negligible, owing to the formation of a very stable solution of nitrosylsulfuric acid in concentrated sulfuric acid which stands dilution with water to some extent with the establishment of corresponding equilibria.

Nitration of Benzene

Work, therefore, was undertaken to determine the practicability of this method as applied to the nitration of benzene. The apparatus used in these experiments consisted of a wide mouthed bottle with a ground-glass joint bearing a mercury seal for a stirrer. Just below the neck of the bottle were sealed to it a dropping funnel and a capillary tube with a stopcock. In general, the method of procedure was as follows. To a solution in the bottle consisting of 1.05 moles of nitrogen tetroxide in 1.25 to 1.75 moles of sulfuric acid, having a concentration ranging between 85 and 95%, a mole of benzene was slowly added from the dropping funnel. During the addition the temperature of the reaction mixture was maintained at 5 to 15°, and subsequent to the mixing of the reactants the temperature was raised to 40–60°, the working temperature range being essentially that recommended in the ordinary nitration of benzene. The reaction mixture was agitated during the addition and afterwards until the reaction was complete, the total time for each run being five hours. The stopcock on the capillary tube was turned whenever there was an appreciable difference between the internal and external levels of the mercury in the seal of the stirrer.

The yields found were somewhat lower than the true yields, owing to the small losses in the various steps in the process. The quantity of material used in each of these experiments was relatively small (25 cc. of benzene), hence the sum total of the various losses was a fair percentage of the total, and it was believed that a few of the actual yields were similar to those obtained in commercial practice.

The data of the more significant experiments are recorded in the following table.

TABLE I
NITRATION OF BENZENE
Molecular ratio of N_2O_4 to C_6H_6 = 1.05

Expt. No.	Moles H_2SO_4^a	Concn. of H_2SO_4	Temp., °C.	Yield of nitrobenzene (steam distilled), %
1	1.25	95	40-50	81.3
2	1.50	95	50-60	89.5
3	1.75	95	55-60	94.4
4	1.25	85	40	70.2
5	1.50	85	40-50	80.7
6	1.50	90	40-50	86.3

^a Per mole of benzene.

An examination of the table shows that there are the following possible variables, namely, (1) ratio of nitrogen tetroxide to benzene, (2) ratio of sulfuric acid to benzene, (3) concentration of the sulfuric acid and (4) temperature.

With regard to the ratio of nitrogen tetroxide to benzene, it has been previously stated that theoretically they should be molecular. However, in practice a slight excess of the oxide of nitrogen is preferable, for the purpose of hastening the final stage of the nitration as well as taking care of any volatilization of the nitrogen tetroxide. Hence, a molecular ratio of 1.05 nitrogen tetroxide was selected and was found to be very satisfactory.

As shown by the experimental data, it is more desirable to use a large excess of sulfuric acid. By using a higher molecular ratio of sulfuric acid, for example, 1.75, the nitration can be carried out at higher temperatures (55-60°) without any appreciable loss of the oxide of nitrogen, and consequently the reaction is completed in a shorter period of time.

The concentration of the sulfuric acid is a very important factor which is dependent upon the nature of the substance to be nitrated and upon the quantity of sulfuric acid used. It is well known that in the nitration of substances which are readily nitrated lower acid concentrations are more desirable than "concentrated" or fuming sulfuric acid. By maintaining the molecular ratio of sulfuric acid to benzene constant, a variation in the concentration of the sulfuric acid from 85 to 95% effects a 9-11% increase in yield of nitrobenzene. However, the higher yields can be obtained by using greater quantities of sulfuric acid of the lower concentration.

The temperature is determined by the quantity and concentration of the sulfuric acid.

Nitration of Mononitrobenzene

When 2 moles of nitrogen tetroxide and from 2.5 to 3 moles of concentrated and fuming sulfuric acid per mole of benzene were used, several unsuccessful attempts to effect a two-step nitration were made.

However, a 93.4% yield of dinitrobenzene was obtained by slowly adding a mole of nitrobenzene to a solution of 1.05 moles of nitrogen tetroxide in 2.8 moles of fuming sulfuric acid (containing 4.28 parts of free SO_3).

The effect owing to the variation of the molecular ratio and concentration of the sulfuric acid is shown in the following table.

TABLE II
NITRATION OF NITROBENZENE

Expt. No.	Moles of N_2O_4	Moles of H_2SO_4^*	Concn. of H_2SO_4	Time (hrs.)	Temp., °C.	Yield of di-nitrobenzene
1	1.1	2.8	104.3	1½	60-75	93.4%
2	1.05	2.0	104.3	1½	60-75	86.4
3	1.05	1.75	104.3	3	60-75	69.6

* Per mole of nitrobenzene.

Nitration of Toluene

Nitrotoluene was synthesized by adding a mole of toluene to a solution of 1.05 moles of nitrogen tetroxide in 1.6 moles of 95% sulfuric acid. The reaction mixture was agitated for three and one-half hours at a temperature of 50-55°, and at the end of the reaction the excess toluene was removed by vacuum distillation. The yield of nitrotoluene was 87.5% of the theoretical.

Nitration of Naphthalene

α -Nitronaphthalene was obtained by the reaction of 1.0 moles of naphthalene with a solution of 1.1 moles of nitrogen tetroxide and 1.5 moles of 95% sulfuric acid. The experimental procedure was similar to that used in the nitration of naphthalene with mixed acid. The yield of purified α -nitronaphthalene, recrystallized from alcohol, was 88.4% of the theoretical.

Summary

1. A method for the nitration of organic substances with nitrogen tetroxide in the presence of sulfuric acid is described, benzene, nitrobenzene, toluene and naphthalene being used as examples.

2. The method involves an intermediate reaction of the nitrogen tetroxide with the sulfuric acid whereby nitrating and dehydrating reagents are simultaneously formed.

3. The yields of the nitro compounds range from 87% to upwards of 90% of the theoretical.

DECOMPOSITION OF FREE AND COMBINED CYSTINE WITH SPECIAL REFERENCE TO CERTAIN EFFECTS PRODUCED BY HEATING FISH FLESH

By L. H. ALMY

RECEIVED JUNE 8, 1927

PUBLISHED OCTOBER 5, 1927

Other investigators have studied the effect of acid and alkali hydrolysis of proteins upon the combined cystine, as shown in a review of the subject by Hoffman and Gortner.¹ The experimental evidence on the extent of the breaking down of cystine during acid hydrolysis is somewhat divided, but the destructive effect of alkali hydrolysis is generally accepted. The variability of the results obtained by different investigators is due to the lack of uniformity in experimental conditions. The method employed in the study here reported differs decidedly from those generally used. The results, therefore, may not be compared strictly with those of others. Briefly, the procedure consists in heating flesh in a sealed tube with the addition of little or no water or aqueous solutions. This method of heating was decided upon since it was desired to use a procedure which would imitate to a degree the conditions existing in a can of food material during the sterilization process. The purpose of the study was to gain sufficient information on the changes which take place during the heating of proteinaceous food products to afford a basis for the interpretation of the hydrogen sulfide content of the canned product.

Experimental Procedure

The flesh from fresh marine fish of various species was ground thrice to make a homogeneous sample. Twenty grams of the flesh, with or without the addition of other substances, was placed compactly in a 20 × 150 mm. test-tube of soft glass. The tube was sealed in the blast lamp and heated in a constant-temperature bath for 45 minutes. It was then opened and the heated product examined. Because of the nature of the tests, but one determination could be made on the contents of each tube.

For the determination of hydrogen sulfide, the tube was inverted in a beaker containing about 25 cc. of 0.6% zinc acetate solution and the tip of the tube was broken off beneath the surface of the liquid. The beaker, with the tube, was placed in a vacuum desiccator, the evacuation of which drew the gas in the tube through the zinc acetate solution, thus trapping any hydrogen sulfide contained in the air space above the flesh and rendering possible the quantitative determination of the hydrogen sulfide remaining after the heating. The tube was then carefully broken in the center. The contents were ground thoroughly in a mortar and finally washed into a cylinder for the determination of hydrogen sulfide by the methylene blue method.² This method estimates both the gas which is combined as sulfide and that which exists free in the flesh. The term "hydrogen sulfide" as used throughout this paper includes both forms.

For the estimation of cystine, the tube was opened, the flesh ground in a mortar

with about 50 cc. of water, the protein precipitated by the tungstic acid method of Folin and Wu,³ and the mixture diluted to 100 cc. with distilled water. The protein-free filtrate therefrom was then analyzed for cystine by Sullivan's method.⁴

Hydrogen-ion determinations were made either electrometrically⁵ by means of the hydrogen electrode, or colorimetrically, and sometimes by both methods, on the filtrate from 25% aqueous suspensions of the finely divided material.

For certain of the tests cystine dissolved in *N* hydrochloric acid solution was added to the flesh before the heating. The cystine solution was varied in concentration, but was always used in the proportion of 2 cc. to 50 grams of flesh. Two cc. of *N* sodium hydroxide solution was then added to neutralize the hydrochloric acid. Cysteine was likewise added in *N* hydrochloric acid solution, the hydrochloric acid of the cysteine hydrochloride having first been neutralized with dilute sodium hydroxide solution. Control samples were similarly treated with equivalent quantities of *N* hydrochloric acid and *N* sodium hydroxide solution.

Experimental Results

Effect of Heating on the *P_H* of the Product.—As variations in the H-ion concentration may cause differences in the results, it was necessary to determine the extent of the change in reaction produced by the heating in soft glass. It was found that the *P_H* of the material before and after heating seldom differed by more than 0.2 of a Sørensen unit. This observation is in general harmony with that of Esty and Cathcart,⁶ who found that soft glass tubes affected the H-ion concentration of vegetable juices heated therein less than the hard glass tubes.

Effect of Heat on Fresh and Stale Flesh

The flesh of strictly fresh fish seldom contains hydrogen sulfide. Of twelve species examined by the methylene blue method, only one gave a measurable quantity of the gas. As the flesh becomes stale, it may or may not give a positive test. The amount of hydrogen sulfide obtained on heating the flesh in a sealed tube, however, increased with the length of time the product was held prior to the heating (Table I). Although the *P_H* shifts from the acid toward the alkaline side, it does not seem to be a requisite that the flesh be neutral or alkaline to yield a considerable quan-

tity of the gas. None of these samples of flesh before heating gave a test for hydrogen sulfide except the rockfish sample at the 72-hour period, the amount being only 13.4 mmg. (micromilligrams) per 100 g.

Effect of Added Cystine and Cysteine on Hydrogen Sulfide Produced by Heating Flesh

In an effort to determine what part cystine or cysteine plays in the production of hydrogen sulfide on heating the flesh, the following experiment was made.

Twelve 40 g. portions of rockfish flesh were thoroughly mixed with varying quantities of *N* hydrochloric acid and *N* sodium hydroxide solution to give samples having Sørensen values ranging from *P_H* 5.0 to *P_H* 8.4. There were thus obtained four groups of samples of three each, each group having a different Sørensen value. To one of the samples of each group was added 5 mg. of cystine and to another 5 mg. of cysteine, the remaining sample being used as a control. The dilution of each sample with liquid was made the same by appropriate additions of water. The total dilution amounted to but 3 cc. for each 20g. sample. The samples were heated in sealed tubes for 45 minutes at 120° and then analyzed for hydrogen sulfide. The test was made on fresh flesh and on flesh which had decomposed to some extent during 24 hours' standing at room temperature. The results are shown in Table II.

Flesh + 5 mg. cystine	7.8	0	8.4	2293
Flesh + 5 mg. cysteine	7.8	5	8.4	2137

Little, if any, hydrogen sulfide could be detected in the fresh samples after heating, regardless of the H-ion concentration. In the stale samples the amount of gas produced was greater the higher the *P_H* and also greater in the samples containing cystine or cysteine than in the flesh alone. In endeavoring to reach a satisfactory explanation of these results, the

author considered two possibilities. One is that neither cystine nor cysteine under these conditions decomposes to give hydrogen sulfide, the gas obtained having been derived from a thermolabile decomposition product of cystine and cysteine. The other is that these amino acids are decomposed by the heat with the direct production of hydrogen sulfide, the gas, however, being partially or wholly destroyed only in the case of the fresh flesh.

The following experiments were performed for the purpose of testing the validity of these explanations.

Decomposition of Cystine

If cystine, during its contact with the stale flesh, is changed to a thermolabile product, the longer the contact the greater the change. Accordingly, cystine was allowed to remain admixed with stale rockfish flesh for different periods before heating. The shortest period used was the minimum time required to insert the flesh in a tube, seal the tube, and place it in a hot calcium chloride brine bath. All samples were heated at 120° for 45 minutes. The results (Table III) show that the duration of contact of the cystine with the stale flesh had little influence, if any, on the amount of hydrogen sulfide produced. This tends to disprove the first hypothesis.

TABLE III

INFLUENCE OF DURATION OF CONTACT OF CYSTINE WITH SPOILED ROCKFISH FLESH (20 G.) ON THE AMOUNT OF HYDROGEN SULFIDE PRODUCED DURING HEATING OF THE MIXTURE FOR 45 MINUTES AT 120°

Material	Duration of contact, min.	Hydrogen sulfide, mmg.
Flesh alone	..	654
Flesh + 4.8 mg. cystine	3	825
Flesh + 4.8 mg. cystine	20	801
Flesh + 4.8 mg. cystine	40	836

Several experiments, the details of which it will not be necessary to describe, showed that when fresh flesh was heated, any hydrogen sulfide which may have been present was practically wholly destroyed, probably by oxidation. When stale flesh, which alone yielded large quantities of hydrogen sulfide when heated, was mixed with fresh flesh and then heated for 45 minutes at 120°, analysis revealed little or no hydrogen sulfide. Likewise, when hydrogen sulfide water was added to fresh flesh, none of the gas could be detected after heating the mixture. The gas was not lost in this way, however, when added to stale flesh.

Tillmans and Otto⁷ suggest three methods of detecting incipient decomposition of fish, all of which are based upon the reducing power of the flesh. The most delicate is an adaptation of Winkler's method⁸ for the

⁷ Tillmans and Otto, *Unters. Nahr. u. Genussm.*, 47, 25-37 (1924).

⁸ Winkler, *Ber.*, 21, 2843 (1888); 22, 1764 (1889); 24, 3602 (1891).

determination of dissolved oxygen in water. Five grams of ground flesh is placed in a Winkler bottle, distilled water is added to overflowing, the stopper is inserted, and the bottle is agitated to give a fine suspension. After incubation for one or two hours at 22°, the Winkler reagents are added and the determination of dissolved oxygen is completed. If no oxygen is present under these conditions, according to Tillmans and Otto, the product is unfit for human consumption.

That the reducing power of the flesh is quickly built up while the product is held at room temperature was shown in tests conducted by the author. The titration figures for fish flesh so held changed from about 1.0 cc. of 0.1 *N* sodium thiosulfate solution to practically nil in 18 hours. The possibility of the destruction of hydrogen sulfide by oxidation by the flesh before it has reached the reducing stage is thus explained.

The data presented thus far seem to point to the destruction of part at least of the cystine during the heating of either the fresh or the stale flesh. If heat will destroy the cystine, the destruction should be a function of the temperature. Using Sullivan's method,⁴ cystine was determined in flesh which had been heated at 100 and at 120° and to which cystine had been added prior to heating. The results showed an apparent destruction of the cystine, for the mixture (20 g. of flesh + 15 mg. of cystine) at 100° gave 18 mg. of cystine, whereas that at 120° gave only 5 mg. The flesh without cystine gave about 2 mg. of cystine after heating at 120°.

Such results, however, might be explained as being due to a combination of the cystine with other constituents of the flesh, the combining power of cystine being generally recognized. To settle this point, the cystine-flesh mixture, after heating, was hydrolyzed with 20% hydrochloric acid for six hours.⁹ Following the procedure recommended by Sullivan¹⁰ for the determination of cystine in casein, the hydrolysate was filtered, decolorized with Norit, neutralized and tested for cystine. The amount of cystine in 20 g. of the mixture before heating was 128 mg. After heating there were but 61 mg. Since only 15 mg. of cystine had been added, it is evident that some of the original combined cystine of the flesh was also destroyed by the heating. This was checked by heating flesh to which no cystine had been added. The cystine content of the hydrolysate decreased as a result of the heating from 107 mg. to 82 mg. There seems to be little doubt, therefore, that some of the cystine is destroyed during the heating of the flesh.

Summary and Conclusions

When fresh fish flesh was heated in a sealed tube at 120° for 45 minutes, either no hydrogen sulfide or only a comparatively small amount could

⁹ Sullivan, unpublished data.

¹⁰ The author acknowledges his indebtedness to Dr. M. X. Sullivan for his helpful suggestions in connection with this study.

be detected in the heated product. When the flesh had become somewhat stale, the same heat treatment yielded the gas in relatively large amounts. Added cystine increased the amount of residual hydrogen sulfide only in the case of the stale flesh. The cause of this difference in results with fresh and stale flesh was traced to the ability of the fresh flesh, and, conversely, the inability of the stale flesh, to destroy hydrogen sulfide formed by the heating. The gas is destroyed apparently by oxidation. Cystine added to fresh flesh, as well as that present in combined form in the flesh, is partially destroyed by this heating.

On the plausible assumption that the effect of processing a can of fish is the same as the effect of the above-mentioned heat treatment in a sealed tube, it may be concluded that the presence of considerable hydrogen sulfide in a canned product of this nature indicates that the raw material at the time of canning was in poor condition.

It is recognized that sulfur compounds other than cystine may exist in the protein or other constituents of the flesh examined, but the possibility of their existence therein need not be considered in connection with this study. While these results were obtained with fish flesh, which procedure had the advantage that the raw material could be obtained in fresh condition at any time desired with little inconvenience, it is probable that similar results would be obtained with other flesh products. Therefore, the conclusion seems justified that when flesh products in general are heated at temperatures above 100° some of the cystine is destroyed and hydrogen sulfide derived therefrom may be detected in the product, providing the gas is not oxidized by the material during the heating process.

**THE BECKMANN REARRANGEMENT OF SALICYLHYDROXAMIC
ACID DERIVATIVES¹**

BY ALFRED W. SCOTT AND J. H. MOTE

RECEIVED JUNE 20, 1927

PUBLISHED OCTOBER 5, 1927

Several benzene derivatives containing an hydroxyl group and a nitrogenous group in the ortho position to each other can be converted into oxycarbanil by suitable treatment.² Especially in the cases of urea and urethan derivatives is there the possibility of the intermediate formation

¹ This paper is based upon a thesis presented by Mr. J. H. Mote to the Graduate School of the University of Georgia, in partial fulfillment of the requirements for the degree of Master of Science.

of an isocyanate, for instance, in the pyrogenic treatment of *o*-oxyphenylurethan by Groenvik^{2a} or in the decomposition of *o*-oxydiphenylurea in

an alkaline aqueous solution by Leuckart.^{2c}

Marquis³ studied the rearrangement of salicylhydroxamic acid when it was treated with thionyl chloride. He assumed a true Beckmann rearrangement to take place and explained the formation of oxycarbanil without the intermediate formation of an isocyanate, as follows.

According to the theory advanced by Stieglitz⁴ the change of the radical from C to N would be caused by the loss of HCl from (A) and the formation of univalent nitrogen. After the interchange the compound would assume the structure of an isocyanate, as follows.

and consequently the formation of the oxycarbanil would take place from the isocyanate.

However Struve and Radenhausen⁵ in a study of the rearrangement of *o*-oxybenzazide in boiling water obtained *sym*.-di-*o*-oxyphenylurea, carbon dioxide and nitrogen. This is the Beckmann rearrangement of the Curtius type⁶ and according to the theory of the mechanism advanced by Stieglitz is assumed to proceed as follows.

² Marquis, *Compt. rend.*, **143**, 1164 (1907).

⁴ References given by Stieglitz and Leech, *THIS JOURNAL*, **36**, 272 (1914).

⁵ Struve and Radenhausen, *J. prakt. Chem.*, [2] **52**, 241 (1895).

⁶ Curtius and Leimbach, *ibid.*, [2] **65**, 20 (1902).

In the presence of water the isocyanate would hydrolyze to give an amine and carbonic acid. The amine would then react with some unchanged isocyanate to give a *sym.*-di-substituted urea.

In the reactions of both Marquis and of Struve and Radenhausen the same isocyanate would seem to be formed as an intermediate product in the rearrangement. However, in one instance a *sym.*-di-substituted urea resulted and in the other oxycarbanil was formed. Of course, since the experiments of Marquis were carried out in non-aqueous solution, this would account for the absence of the urea in their case and would indicate that the oxycarbanil was formed directly from the isocyanate in the absence of water. However, in the work of Leuckart^{2c} in an alkaline aqueous solution oxycarbanil was the product formed.

In view of these results, we decided to study another type of Beckmann rearrangement that should give us the same isocyanate, both in aqueous solution and in the dry state.

According to the theory of Stieglitz the alkali salts of the esters of hydroxamic acids undergo rearrangement as follows.

This isocyanate in aqueous solution would be expected to behave in accordance with Reactions III and IV given above. We studied a rearrangement of this type using the alkali salts of the acetyl and benzoyl esters of salicylhydroxamic acid. The isocyanate formed from these salts should be the same as that occurring in the cases previously discussed.

In aqueous solution oxycarbanil and an acetate or a benzoate were isolated from the mixture after rearrangement. We were unable to detect the presence of *o*-aminophenol, which would indicate the formation of *sym.*-dioxyphenylurea and its subsequent decomposition. Furthermore,

when the salts were exploded by heating, there was no trace of the characteristic odor of an isocyanate which is usually obtained when the salts of hydroxamic acid esters are decomposed by heat.

It would seem, therefore, that when the derivatives of salicylhydroxamic acid undergo the Beckmann rearrangement either in aqueous solution or in the dry state no isocyanate is formed or at least only momentarily. Oxycarbanil is formed, seemingly, either during the course of Reaction II or at least immediately upon its completion.

Experimental Part

Salicylhydroxamic Acid was prepared by the method of Jeanrenaud.⁷

The Acetyl Ester ($C_6H_4(OH)CONHOCOCH_3$) was prepared by mixing 1 g. of salicylhydroxamic acid with an excess of acetic anhydride and warming the mixture on a water-bath. The mixture became soft, then hardened. Acetic acid came off in the form of a vapor. The ester was recrystallized from alcohol and water and found to melt at 142° ; yield, 0.60 g.

Anal. Subs., 0.7200: 48.0 cc. of N (21° , 745.04 mm.). Calcd. for $C_9H_9O_4N$: N, 7.18. Found: 7.31.

The Potassium Salt of the Acetyl Ester was made by dissolving the ester in the least amount of absolute alcohol and treating the ester with alcoholic potash. The salt was precipitated on the addition of absolute ether. It was filtered off and washed with absolute alcohol and then with anhydrous ether. The salt was dried for one hour in a desiccator over concentrated sulfuric acid and was found to explode after fifteen seconds when immersed in a bath at 85° .

When the salt was exploded, we were unable to detect any odor of isocyanate, which might have been formed as an intermediate product and which is usually noticeable when hydroxamic acids are rearranged.

Rearrangement took place when the salt was dissolved in water and heated to boiling. On cooling down, oxycarbanil separated out as white needles which were recrystallized from hot water and found to melt at 139° . On acidifying the filtrate, acetic acid was set free. It was recognized by its odor. The aqueous solution from the rearrangement was diazotized and heated. We were unable to detect the presence of any pyrocatechol by the iron chloride reaction. This seems to show that there was no *o*-aminophenol present, which would indicate the formation of an urea which might subsequently change over into oxycarbanil.

The properties of the rearrangement product agreed in all respects with the oxycarbanil described in the literature.

Anal. Subs., 0.2063: 20.8 cc. of N (27° , 748.6 mm.). Calcd. for $C_6H_5O_2N$: N, 11.38. Found: 10.99.

The Benzoyl Ester ($C_6H_4(OH)CONHOCOC_6H_5$) was prepared by two methods.

(a) By the Schotten-Baumann reaction: To 1 g. of salicylhydroxamic acid was added an aqueous solution of sodium hydroxide containing 0.26 g. of sodium hydroxide (1 equiv.) and the mixture shaken until all dissolved. Then 0.92 g. of benzoyl chloride was added and the mixture thoroughly stirred to ensure thorough mixing. The flask was kept cool during the reaction.

The product was recrystallized from alcohol and water and found to melt at 153° ; yield, 0.80 g.

(b) By fusion with benzoic anhydride: Salicylhydroxamic acid (1 g.) was mixed

⁷ Jeanrenaud, *Ber.*, 22, 1270 (1889).

with an excess of benzoic anhydride and the whole warmed on a water-bath. The mixture became soft, then hardened again. Benzoic acid sublimed during the reaction. The mixture was repeatedly extracted with ligroin in order to remove all of the benzoic acid and unchanged benzoic anhydride. The ester was recrystallized from alcohol and water and found to melt at 153°; yield, 1.02 g.

Anal. Subs., 0.5639: 28.9 cc. of N (25°, 748.3 mm.). Calcd. for $C_{14}H_{11}O_4N$: N, 5.45. Found: 5.50.

The Potassium Salt of the Benzoyl Ester was prepared by the addition of the calculated quantity of alcoholic potash to the ester in absolute alcohol solution. The salt was precipitated by the addition of absolute ether.

The salt after drying for one hour over concentrated sulfuric acid was treated like the potassium salt of the acetyl ester and was found to explode after fifteen seconds when immersed in a bath at 81°. No odor of isocyanate was noticed when the substance exploded.

The salt on being dissolved in water and heated rearranged giving potassium benzoate and oxycarbanil. The potassium benzoate was recognized by causing benzoic acid to precipitate by the addition of acid to the solution. The benzoic acid after recrystallization melted at 121.5° and resembled in all respects the benzoic acid described in the literature.

Sodium Salt of Benzoyl Ester was prepared by treating the ester in absolute alcohol solution with the calculated quantity of sodium alcoholate. On the addition of absolute ether the sodium salt separated out. It decomposed on heating but gave no odor of isocyanate. In water solution it underwent rearrangement very much as the potassium salt.

Summary

The acetyl and benzoyl esters of salicylhydroxamic acid and their salts were made. Upon undergoing the Beckmann rearrangement these salts gave oxycarbanil instead of a *sym.*-di-substituted urea usually obtained under similar conditions from the alkali salts of the esters of other hydroxamic acids.

THE REACTION OF PARA-SUBSTITUTED BENZYL CHLORIDES WITH SODIUM HYDROGEN SULFIDE

BY CHARLES BARKENBUS, ELI B. FRIEDMAN AND RAYMOND K. FLEGE

RECEIVED JULY 14, 1927

PUBLISHED OCTOBER 5, 1927

Several years ago in connection with some work in progress at that time, there was needed some *p*-cyanobenzyl mercaptan. In attempting to prepare this compound by the action of sodium hydrogen sulfide on *p*-cyanobenzyl chloride a mixture of *p*-cyanobenzyl sulfide and *p*-cyanobenzyl disulfide was obtained instead of the mercaptan.¹ Shortly after our observation Horn² obtained the same results using *p*-nitrobenzyl chloride and found that the *p*-nitrobenzyl mercaptan was incorrectly described in the literature. Chloro-acetophenone also gives a mixture

¹ Friedman, *Thesis*, University of Kentucky, 1922.

² Horn, *THIS JOURNAL*, 43, 2610 (1921).

of the corresponding sulfide and disulfide when treated with sodium hydrogen sulfide.³

Since *p*-cyanobenzyl mercaptan and its derivatives are not described in the literature it was thought advisable to study the reaction of sodium hydrogen sulfide with *p*-cyanobenzyl chloride.

In order to study this reaction it was first necessary to prepare *p*-cyanobenzyl mercaptan and the corresponding sulfide and disulfide. The mercaptan was made by hydrolyzing 2-*p*-cyanobenzylmercapto-4-methyl-6-oxypyrimidine with dilute hydrochloric acid. The sulfide and disulfide were made by the usual methods.

The following reactions will account for the formation of *p*-cyanobenzyl sulfide and disulfide.

The formation of the disulfide is due to oxidation of the mercaptan and can be eliminated by carrying out the reaction in a non-oxidizing medium such as hydrogen or hydrogen sulfide. The formation of the sulfide first necessitates the formation of the sodium salt, which in turn reacts with *p*-cyanobenzyl chloride. With a slight excess of sodium hydrogen sulfide, as is generally used, the sulfide will be formed provided Reactions III and IV proceed as fast or faster than Reaction I. By adding sodium hydrogen sulfide to the reaction mixture as fast as it is used up, the mercaptan should be formed in greater amount provided the speed of Reaction I is the greatest. Only traces of the mercaptan could be obtained using this condition, which indicated that Reactions III and IV proceed as fast as Reaction I or faster. The only condition that gave enough mercaptan to isolate was when hydrogen sulfide was used as the non-oxidizing medium and sodium hydrogen sulfide was added as fast as it reacted. Other non-oxidizing media such as hydrogen gave only traces of the mercaptan. This can be explained by the retarding action of hydrogen sulfide on Reaction III. The best experimental conditions for the formation of the mercaptan are given in the experimental part, though many other runs were made using various solvents and temperatures.

In order to see what influence other groups might have, two small runs were made using *p*-carbethoxybenzyl chloride. In this case the resulting crude mercaptan and sulfide were obtained in about equal amounts. These results would indicate that the different groups in the para position affect the speeds of Reactions I, III and IV, but in varying amounts. The

³ (a) Tafel and Mauritz, *Ber.*, **23**, 3474 (1890). (b) Bertil Groth, *Arkiv. Kemi Mineral Geol.*, **9**, No. I, 63 (1924).

negative groups such as the nitro, cyano and carbethoxy seem to increase the speeds of Reactions III and IV, though not to the same extent. The positive chlorine in the para position, on the other hand, does not seem to increase the speeds of Reactions III and IV, since *p*-chlorobenzyl mercaptan has been made by treating *p*-chlorobenzyl chloride with potassium hydrogen sulfide and no mention was made of sulfide formation.⁴

During the course of these experiments the following compounds were made, as shown by the diagram.

p-Carboxybenzyl mercaptan could not be made from *p*-carboxybenzyl chloride by treating with sodium hydrogen sulfide since the sodium salt of this acid reacts with itself to give a complex ester.⁵ Attempts to prepare the sulfide or disulfide of *p*-carboxybenzyl mercaptan directly from it or by hydrolysis of the corresponding cyano or carbethoxy compounds always resulted in amorphous, white compounds having no definite melting point and insoluble in all solvents. The *p*-cyanobenzyl disulfide is light yellow, which may be due to partial dissociation into the free radicals.⁶

Experimental Part

2-*p*-Cyanobenzylmercapto-4-methyl-6-oxypyrimidine.—To 750 cc. of absolute alcohol were added 12.14 g. of sodium and 75 g. of 2-thio-4-methyl-6-oxypyrimidine. The mixture was stirred vigorously while being heated for two hours in a boiling water-bath. To the resulting sodium salt was added 80.4 g. of *p*-cyanobenzyl chloride and the heating and stirring were continued until the reaction mixture was neutral. On cooling, the white amorphous solid was filtered off, washed well with water and dried at 110° for 12 hours; weight, 133 g. The crude product was crystallized from glacial acetic acid in white, microscopic plates, m. p. 240–241°; yield 110 g. or 86.5%.

Anal. Calcd. for $\text{C}_{14}\text{H}_{11}\text{ON}_2\text{S}$: N, 16.34. Found: 16.27, 16.28.

***p*-Cyanobenzyl Mercaptan.**—One hundred and fifty g. of 2-*p*-cyanobenzylmercapto-4-methyl-6-oxypyrimidine and 1500 cc. of 6 *N* hydrochloric acid were heated to boiling with stirring for one hour. The solid pyrimidine gradually became oily and finally a thick oil remained. The mixture on cooling was extracted with ether, the ether layer washed with dilute sodium carbonate solution and water and then dried over anhydrous sodium sulfate. On distilling off the ether 82 g. of crude oil were obtained, which distilled at 135–138° at 7 mm. The oil solidified on cooling to a white crystalline mass having the characteristic garlic odor, m. p. 37°; yield 75 g. or 86.2%. It gave a white precipitate with alcoholic mercuric nitrate.

Anal. Calcd. for $\text{C}_7\text{H}_7\text{NS}$: S, 21.47. Found: 20.63, 20.79.

***p*-Cyanobenzyl Sulfide.**—The calculated amount of sodium was added to 100 cc.

⁴ Jackson and White, *Am. Chem. Jour.*, **2**, 167 (1880).

⁵ Barkenbus and Holtzclaw, *THIS JOURNAL*, **47**, 2189 (1925).

⁶ Lecher, *Ber.*, **48**, 524, 1425 (1915).

of absolute alcohol and to this solution were added 5 g. of *p*-cyanobenzyl mercaptan and 5 g. of *p*-cyanobenzyl chloride. The mixture was refluxed for four hours until neutral. The alcohol was evaporated off and the crude solid shaken up with water, filtered and crystallized from 95% alcohol, giving fine, white, odorless needles; m. p. 115°; yield 6 g. or 67.7%.

Anal. Calcd. for $C_{10}H_{12}N_2S$: N, 10.61. Found: 10.47, 10.48.

***p*-Cyanobenzyl Disulfide.**—Five g. of *p*-cyanobenzyl mercaptan was dissolved in 100 cc. of 95% alcohol and 25 cc. of concentrated ammonium hydroxide added. After standing exposed to the air for four days a light yellow, crystalline solid came out and was crystallized from 95% alcohol giving light yellow, odorless, flat needles; m. p. 148°; yield 3.5 g. or 70.4%.

Anal. Calcd. for $C_{10}H_{12}N_2S_2$: N, 9.46. Found: 9.32.

Reaction of Sodium Hydrogen Sulfide with *p*-Cyanobenzyl Chloride.—Fifty g of *p*-cyanobenzyl chloride was dissolved in 400 cc. of absolute alcohol and to this solution was added an absolute alcohol solution of sodium hydrogen sulfide made by saturating a sodium ethylate solution with hydrogen sulfide. A fast stream of hydrogen sulfide was passed into the boiling alcohol solution during the experiment. The sodium hydrogen sulfide solution was added very slowly while the mixture was stirred vigorously and the reaction mixture was tested every minute for alkalinity with methyl red. At no time was it alkaline until the calculated amount of sodium hydrogen sulfide had been added, indicating that the reaction took place as fast as it was added. As soon as the reaction mixture became alkaline, it was made slightly acid with hydrochloric acid and allowed to stand overnight in an atmosphere of hydrogen sulfide. A large amount of light yellow needles separated out. These were filtered off with suction, washed well with alcohol and then suspended in water to dissolve the sodium chloride. They were again filtered, washed well with water and dried at 100° for twelve hours. On crystallizing from 95% alcohol, long white needles were obtained, m. p. 115°, which indicated the sulfide.

The alcoholic filtrate was evaporated in a stream of hydrogen and a reddish oil mixed with some salt was left. The oil was taken up in ether, dried over anhydrous sodium sulfate and distilled. Eleven g. of crude oil was obtained, which on redistillation gave 5 g. of *p*-cyanobenzyl mercaptan; m. p. 32°; yield 10.2%; yield of *p*-cyanobenzyl sulfide, 34 g. or 78.2%. This was the best yield obtained of the mercaptan out of many different runs.

Reaction of Sodium Hydrogen Sulfide with *p*-Carbethoxybenzyl Chloride.—The calculated amount of alcoholic sodium hydrogen sulfide solution was added very slowly to a boiling solution of 35 g. of *p*-carbethoxybenzyl chloride in 175 cc of absolute alcohol. Sodium chloride precipitated out immediately, and the reaction mixture did not become alkaline until all of the sodium hydrogen sulfide solution had been added. It was then made slightly acid and poured into five volumes of water. An oil separated out which was taken up in ether and dried over anhydrous sodium sulfate. On evaporating the ether, 33 g. of crude oil remained, which on distilling yielded 19.7 g. of a clear oil with a garlic odor; b. p. 135–160° at 8 mm. The oil, even on redistilling, was impure, as shown by analysis, but it was identified as *p*-carbethoxybenzyl mercaptan by converting some of it into the sulfide. The residue from the original distillation was taken up in 95% alcohol, decolorized with carbon, and allowed to crystallize, giving long white asbestos-like needles; m. p. 78°; yield 9 g. Analysis showed this to be *p*-carbethoxybenzyl sulfide.

Anal. Calcd. for $C_{10}H_{12}O_4S$: S, 8.93. Found: 9.22, 9.16.

***p*-Carboxybenzyl Mercaptan.**—Five g. of *p*-cyanobenzyl mercaptan and 150 cc. of

concentrated hydrochloric acid were heated to boiling with vigorous stirring for three hours. A white solid separated out which was filtered off, dissolved in dilute sodium carbonate solution and then filtered from a small amount of insoluble material. On acidification a white, amorphous solid was obtained which was crystallized from 95% alcohol, giving white microscopic needles with only a faint odor; m. p. 176° ; yield 5 g. or 89.3%.

Anal. Calcd. for $C_8H_8O_2S$: S, 18.89. Found: 18.41, 18.50

***p*-Carbethoxybenzyl Mercaptan.**—Twenty-two g. of *p*-carboxybenzyl mercaptan was dissolved in 200 cc. of absolute alcohol which had been previously saturated with dry hydrogen chloride gas and the mixture heated under a reflux condenser for twelve hours. The resulting solution was filtered from a small amount of insoluble material, evaporated to 100 cc. and then poured into 500 cc. of water. The oil which separated was dissolved in ether, the ether solution washed free from acid and then dried over anhydrous sodium sulfate. After evaporating off the ether the remaining oil was distilled to a colorless and nearly odorless oil; b. p. $140-141^{\circ}$ at 6 mm.; yield 19.1 g. or 74.2%.

Anal. Calcd. for $C_{10}H_{12}O_2S$: S, 16.32. Found: 16.15, 16.29.

***p*-Carbethoxybenzyl Sulfide.**—The calculated amount of freshly prepared alcoholic sodium sulfide solution was slowly added with rapid stirring to a boiling solution of 5 g. of *p*-carbethoxybenzyl chloride in 100 cc. of alcohol. When all the sodium sulfide solution had been added, the mixture was cooled and diluted with water. The white precipitate was filtered off and crystallized from alcohol producing white, asbestos-like needles; m. p. 78° ; yield 3.5 g. or 77.7%. A mixture of this compound with the product obtained by the reaction of *p*-carbethoxybenzyl chloride with sodium hydrogen sulfide had the same melting point.

Summary

The reaction of *p*-cyanobenzyl chloride with sodium hydrogen sulfide has been studied, and a mixture of *p*-cyanobenzyl sulfide and disulfide was obtained instead of the mercaptan. If a non-oxidizing atmosphere is used, only a very small amount of *p*-cyanobenzyl mercaptan is formed, the main product being the sulfide. Negative groups such as the nitro, cyano and carbethoxy in the para position of substituted benzyl chlorides favor the formation of the sulfide, while the positive chlorine favors the formation of the mercaptan.

p-Cyanobenzyl mercaptan, *p*-carboxybenzyl mercaptan, *p*-carbethoxybenzyl mercaptan, *p*-cyanobenzyl sulfide, *p*-cyanobenzyl disulfide and *p*-carbethoxybenzyl sulfide have been prepared and described.

CONTRIBUTION TO THE THEORY OF ACID AND BASIC CATALYSIS. THE MUTAROTATION OF GLUCOSE

BY J. N. BRÖNSTED AND E. A. GUGGENHEIM

RECEIVED JULY 15, 1927

PUBLISHED OCTOBER 5, 1927

1. Introduction. The Conception of Acids and Bases

According to an extended conception of acids and bases,¹ a molecule, whether neutral or electrically charged, is defined as being an acid if it has a tendency to split off a hydrogen nucleus and as being a base if it has a tendency to unite with a hydrogen nucleus. If we compare the balanced reactions

the fact that some of the molecules are neutral and others electrically charged is trivial in comparison with the fundamental similarity of the three equilibria. In general we may write the acid-base equilibria as

where A is an acid and B the conjugate base; A and B may have any electrical charge, positive, zero or negative, but naturally that of the acid A is always one greater algebraically than that of the conjugate base B. It is of course possible for a molecule to be both an acid and a base; an obvious example is OH_2 which is an acid according to the scheme

the conjugate base being OH^- , whereas it is a base according to the scheme

the conjugate acid being OH_3^+ , the form in which the so-called hydrogen ion is present in aqueous solution; we shall always call OH_3^+ "oxonium" when we wish to distinguish it sharply from H^+ which we shall then call "proton."

We accordingly see that basic properties are common to all molecules tending to combine with a proton and hydroxyl is in no way unique except for the fact that in aqueous solution its conjugate acid is the solvent molecule. Similarly, since the proton does not exist in solution, the so-called "hydrogen ions" are different chemical molecules in different solvents and these various solvated hydrogen ions are in no way different from other acid molecules, except for the fact that the conjugate bases are the solvent molecules.

We shall not in the present paper enter into the important question of a general measure of the strength of acids and bases² and its dependence

¹ (a) Brönsted, *Rec. trav. chim.*, **42**, 718 (1923); (b) *J. Phys. Chem.*, **30**, 777 (1926).

on the solvent. In dilute aqueous solution, however, at a given temperature the strength of an acid A might be measured by the equilibrium constant K_A' of the process defining the acid; that is, K_A' is the limiting value at infinite dilution of the ratio $c_B \cdot c_{H^+} / c_A$ in which c_B , c_{H^+} and c_A are equilibrium values of the concentrations of B, H^+ and A, respectively. Owing to the fact that c_{H^+} is practically infinitesimal, K_A' is a purely formal quantity whose absolute value is too small to be measured. We can, however, also quite formally attribute an equilibrium constant K° to the process defining the acid property of oxonium ion; thus $K^\circ = c_{OH_2} \cdot c_{H^+} / c_{OH_3^+}$ where c_{OH_2} , c_{H^+} and $c_{OH_3^+}$ are equilibrium values of the concentrations of OH_2 , H^+ and OH_3^+ , respectively. Then the strength of the acid A relative to oxonium may be measured by the ratio K_A' / K° or $c_B \cdot c_{OH_2} / c_A \cdot c_{OH_3^+}$, which is the mass action constant of the actual double acid-base equilibrium in the solution. But as in dilute aqueous solution c_{OH_2} is constant we can equally well measure the relative strength of an acid A by the ratio $c_B \cdot c_{OH_3^+} / c_A$. This we shall call the acid constant and denote it by K_A . We shall find it convenient to measure the strength of the conjugate base B by the reciprocal of K_A ; this we shall call the basic constant of B and denote it by K_B .

For such an acid as acetic acid, K_A is identical with the ordinary electrical dissociation constant in water $c_{Ac^-} \cdot c_{OH_3^+} = c_{AcH}$. For such an acid as ammonium ion we have

$$K_A = \frac{c_{NH_3} \cdot c_{OH_3^+}}{c_{NH_4^+}} = c_{OH_2} \cdot c_{OH^-} \cdot \frac{c_{NH_3}}{c_{NH_4^+} \cdot c_{OH^-}}$$

which is usually called the hydrolysis constant of the ammonium ion. For water we have

$$K_A = \frac{c_{OH^-} \cdot c_{OH_3^+}}{c_{OH_2}} = \frac{K_W}{55.6}$$

where $K_W = c_{OH^-} \cdot c_{OH_3^+}$, the usual dissociation constant of water, and for oxonium ion

$$K_A = \frac{c_{OH_2} \cdot c_{OH_3^+}}{c_{OH_3^+}} = c_{OH_2} = 55.6$$

For a "strong" acid, such as hydrochloric acid, K_A is immeasurably great and for a hydrocarbon it is so small that one would generally say that a hydrocarbon is not an acid at all.

2. Catalysis by Acids and Bases

It is a well-known and striking fact that a considerable number of reactions in aqueous solution can be accelerated by increasing the concentration of hydrogen ion, that of hydroxyl ion or that of either. In most cases that have been carefully studied it is found that the increase in reaction rate is at least approximately proportional to the concentration of hydrogen ion or hydroxyl ion, as the case may be. That is to say, the velocity constant k of the reaction is given by

$$k = k_0 + k_{\text{OH}_3^+} \cdot c_{\text{OH}_3^+} + k_{\text{OH}^-} \cdot c_{\text{OH}^-}$$

where k_0 , $k_{\text{OH}_3^+}$ and k_{OH^-} are at each temperature constants for the reaction, while $c_{\text{OH}_3^+}$ and c_{OH^-} are the concentrations of hydrogen ion and hydroxyl ion, respectively; any of the constants k_0 , $k_{\text{OH}_3^+}$ or k_{OH^-} may be negligibly small or zero.

According to our present point of view the hydrogen and hydroxyl ions are not unique as the carriers of acid and basic properties; there is, however, no *a priori* reason to expect that the position they hold as catalysts is unique. On the contrary, one would expect that other acid and basic molecules should act as catalysts as well. The available experimental data do not disagree with this theory of more general acid and basic catalytic effects because in most actual cases the conditions of the experiments have been such that the effects of other catalysts would have been masked by those of OH_3^+ and OH^- . In the few cases where this is not so, "anomalies" in the catalytic actions are detectable³ for which our present suggestion seems to furnish a reasonable explanation.

This theory has already been verified in this Laboratory for the basic catalysis of the decomposition of nitramide.⁴ Dawson and Carter's more recent experiments⁵ on the reaction between acetone and iodine also show that this reaction is catalyzed not only by hydroxyl and oxonium ions but also by the anions and undissociated molecules of weak acids. In the solutions used by them, however, the effects of the various catalysts are difficult to separate and we cannot agree with their computations, which involve a confusion between concentration and activity.

The investigations on nitramide have shown that this substance decomposes slowly in aqueous solution at a rate unaffected by neutral salts at small concentration and by strong acids, provided the solution is at least slightly acid, but is decomposed very rapidly in alkaline solution; in other words, the reaction is not affected by oxonium, but is strongly catalyzed by hydroxyl ions. The decomposition has been studied in buffer solutions of the type acetic acid-sodium acetate and also in buffer solutions of the type aniline-anilinium chloride, the solutions being in all cases sufficiently dilute so that the salt effect could be neglected and sufficiently acid so that the effect of hydroxyl could be neglected. Any acceleration observed could thus only be due to the constituents of the buffer. The results obtained showed that there was a pronounced effect proportional to the concentration of the basic constituent of the buffer and independent of the acid constituent. This can be expressed by the formula

$$k = k_0 + k_B c_B$$

³ Kuhn and Jacob, *Z. physik. Chem.*, 113, 389 (1924).

⁴ (a) Brönsted and Pedersen, *ibid.*, 108, 185 (1924); (b) Brönsted and Duus, *ibid.*, 117, 299 (1925).

⁵ Dawson and Carter, *J. Chem. Soc.*, 1926, 2282.

where c_B is the concentration of the base and k_b a constant characteristic of the base.

Similarly, if a reaction is catalyzed by OH_3^+ we should expect it also to be accelerated by other acids such as the undissociated molecule of formic acid. It should be mentioned that this effect would be that postulated in the so-called "dual theory of catalysis."⁶ This theory was put forward owing to a misunderstanding of salt effect, now explained, on the basis of the theory of the complete dissociation of strong electrolytes,⁷ and has little in common with our present point of view.

3. The Salt Effect

So far in our discussion we have made no distinction between activity and concentration; in other words we have ignored salt effect, and we must now consider briefly what part it plays in catalysis.

According to the theory of reaction rate in dilute solution,⁸ which has now been confirmed experimentally in a number of cases,⁹ the velocity of a reaction between X and Y is given in dilute solution by the expression $k c_X c_Y f_X f_Y / f_{XY}$, where k is a constant for a given solvent and temperature, c_X and c_Y are the concentrations of the reactants, f_X , f_Y and f_{XY} are the activity coefficients of the molecular species X, Y and a complex XY, respectively. The addition of a neutral salt may affect the reaction rate in two ways. First, it may alter the factor $f_X f_Y / f_{XY}$; this is termed primary salt effect. Most catalytic reactions fall in the class where one of the reactants, say X, is uncharged, in which case the complex XY has the same charge as Y and so both f_X and f_Y / f_{XY} differ but little from unity; the factor $f_X f_Y / f_{XY}$ then varies but slightly and linearly with the concentration. Available data show that when only one of the reactants is charged, the primary salt effect is at the most 10% in decimolal solution and is usually much less. Secondly, addition of salt may affect the actual concentration c_X or c_Y of either reactant by causing a shift in an equilibrium involving X or Y; for example, if one of the reactants is hydroxyl ion in a buffer solution the addition of neutral salt may alter its concentration by shifting the buffer equilibrium. This is called secondary salt effect. It is often

possible, by choosing one's solutions judiciously, to avoid secondary salt effect in studying catalysis and this should for preference be done whenever it is desired to measure the effect of a definite catalyst.

4. The Mutarotation of Glucose

From the standpoint of the present theory the probability of an appreciable catalysis by ordinary acid and basic molecules in aqueous solution involves the presence of a marked effect by OH_3^+ and OH^- . In other words, the reaction to be investigated should be very sensitive to these two ions in order that the effect of weaker acids and bases may be detectable. The mutarotation of glucose fulfils these conditions of sensitivity.

The rather numerous researches on this reaction have been ably reviewed by Hudson¹⁰ and again by Kuhn and Jacob³ and therefore need not be considered in detail. It has been established that the process known as the mutarotation of glucose is a balanced one,¹¹

If k_α and k_β are the velocity constants of the two opposed processes, then equilibrium is approached according to the usual exponential law of a unimolecular process with the constant $k_\alpha + k_\beta$ the same from whichever direction the equilibrium state is approached. The constant whose value is always given in the literature is not $k_\alpha + k_\beta$ but $(k_\alpha + k_\beta) \log_{10} e$; to facilitate comparison we shall from now onward also use this constant and denote it by k .

In aqueous solutions k is given at least approximately by a formula of the type¹²

$$k = k_0 + k_{\text{OH}_3^+} c_{\text{OH}_3^+} + k_{\text{OH}^-} c_{\text{OH}^-}$$

where $c_{\text{OH}_3^+}$ and c_{OH^-} are the concentrations of hydrogen and hydroxyl ion, respectively, while k_0 , $k_{\text{OH}_3^+}$ and k_{OH^-} depend only on the temperature.

For the temperature 25° Hudson¹² gives the values $k_0 = 0.0096$, $k_{\text{OH}_3^+} = 0.258$ and $k_{\text{OH}^-} = 9750$, but we shall find that the value for k_{OH^-} is much more uncertain than the other two. Assuming, however, that these values are all of the correct order of magnitude, we see that there is quite a long range of P_H over which k does not differ appreciably from k_0 . The actual extent of this range of minimum velocity varies but slightly with the temperature, and between 15 and 30° it is from about $P_H = 4$ to $P_H = 6$.¹³ Provided then that apart from OH_2 , OH_3^+ and OH^- there are

¹⁰ Hudson, *THIS JOURNAL*, **32**, 889 (1910).

¹¹ That the mutarotation of sugars is a balanced reaction was first suggested by Lowry, *J. Chem. Soc.*, **75**, 212 (1899). It was verified experimentally for lactose by Hudson, *Z. physik. Chem.*, **44**, 487 (1903) and shortly after for glucose by Lowry, *J. Chem. Soc.*, **83**, 1314 (1903).

¹² Hudson, *THIS JOURNAL*, **29**, 1571 (1907).

¹³ Nelson and Beegle, *ibid.*, **41**, 559 (1919).

no catalysts present, k_0 is the minimum obtainable value of k . The reaction which is determined by k_0 , we shall call the "spontaneous reaction." It is easy to obtain reliable values for k_0 by using water containing a mere trace of acid; water saturated with the carbon dioxide from the air is probably sufficiently acid to give the minimum value of k . Hudson and Dale¹⁴ have collected and compared the values obtained by Hudson and others for k_0 at various temperatures; the agreement with the Arrhenius formula for temperature effect is excellent. The intrapolated value for 18° is 0.0052, while our own experiments give 0.00530.

$k_{\text{OH}_3^+}$ is determined most simply by measuring k in solutions of a strong monobasic acid of concentrations up to tenth or twentieth molal; assuming that the acid is completely dissociated, an assumption which for such dilute solutions gives an error certainly much less than the experimental one of 1 or 2%, the concentration of OH_3^+ is simply the stoichiometric concentration of the acid. If k is then plotted against this concentration, a straight line is obtained whose intercept on the k axis is k_0 and whose slope is $k_{\text{OH}_3^+}$. Hudson and Dale¹⁴ have in this way determined $k_{\text{OH}_3^+}$ at 25 and 30°. By extrapolation according to the Arrhenius formula the value for 18° is 0.13, while Meyer,¹⁵ on the basis of less accurate experiments, finds 0.124 and our own experiments give 0.145. Andrews and Worley¹⁶ in a recent paper state that they have confirmed Hudson's value for $k_{\text{OH}_3^+}$ at 25°. Their results are, however, given in terms of an unusual concentration scale and it seems probable that there has been some error in computing the concentrations, for their published data correspond to a value of 0.15 for $k_{\text{OH}_3^+}$ as compared with Hudson's value 0.26, while they find the same value, 0.0096, as Hudson for k_0 .

From the fact that good straight lines are obtained it follows that primary salt effect is undetectable in these dilute solutions. We have confirmed this in solutions containing, as well as the strong acid, various neutral salts up to an ionic strength of 0.1.

As far as hydrogen-ion catalysis is concerned, Hudson's experiments are still the clearest to interpret, the simplest to compute from and quite as accurate as any later ones. Most modern workers have, however, preferred to define their solutions by using the hydrogen electrode.^{3,17} This immediately introduces several unnecessary complications. First, there is the inevitable uncertainty of the liquid-junction e.m.f.; it is under the most favorable conditions doubtful to what extent this can be neglected; Scatchard¹⁸ has shown, moreover, that the presence of sucrose has a marked effect on its value and it is extremely probable that glu-

¹⁴ Hudson and Dale, *THIS JOURNAL*, **39**, 320 (1917).

¹⁵ Meyer, *Z. physik. Chem.*, **62**, 68 (1908).

¹⁶ Andrews and Worley, *J. Phys. Chem.*, **31**, 882 (1927).

¹⁷ Euler, Ölander and Rudberg, *Z. anorg. Chem.*, **146**, 45 (1925).

¹⁸ Scatchard, *THIS JOURNAL*, **48**, 2026 (1926).

cose, if present, will act similarly. Secondly, even if one succeeds in eliminating the liquid-junction e.m.f., the hydrogen electrode measures the activity of the hydrogen ion and not its concentration, which in dilute solutions determines the reaction rate. The situation becomes still more involved when the e.m.f. measurements are performed at a different temperature from that of the reaction velocity measurements, as has been done by Euler.¹⁷ A similar criticism applies to Nelson and Beegle's¹⁸ measurements of hydrogen-ion concentration by a combination of indicator and e.m.f. measurements, as the salt effect on the dissociation equilibrium of the indicator is a complicating factor which cannot be neglected. All these complications are, however, due to an injudicious use of the hydrogen electrode or an indicator in a case where it is much simpler and more accurate to use dilute solutions of a strong monobasic acid and equate the stoichiometric concentration of acid with the hydrogen-ion concentration, as done by Hudson.

As regards the effect of the hydroxyl ion, the situation is very different; the order of magnitude of k_{OH^-} is 10^4 and the reaction is immeasurably fast at a P_H greater than 9. It is therefore essential to work in buffer solutions, and we are at once disturbed by numerous difficulties when we try to determine the concentration of hydroxyl ion. Most modern workers have used the hydrogen electrode;^{3,17} one is thus faced with all the various complications mentioned before and in addition there is our ignorance of the value of the product $\epsilon_{OH_3^+} \cdot \epsilon_{OH^-}$ in more or less complicated salt solutions. In other words, one has to make assumptions about the activity coefficients of OH_3^+ and OH^- in the buffer solutions; this being so, one might as well assume reasonable values for activity coefficients from the beginning and calculate the hydroxyl-ion concentration directly from the composition of the buffer solution. By this method one introduces no new uncertainties and one does avoid that of the liquid-junction potential. Now most of the data are for buffer solutions containing carbonates, phosphates, citrates or other multivalent ions of which our knowledge of activity coefficients is rather meager. One exception is the experiments of Osaka¹⁹ performed at 25° in solutions containing mixtures of ammonia and ammonium chloride. Now the activity coefficients of HCl, KOH and the various alkaline chlorides, as given by Scatchard,²⁰ are probably accurate to 1% and at concentrations below 0.07 *M* they all agree to within 4%. We can, therefore, choose values for the activity coefficient of any univalent ion, in solutions containing no ions of higher charge, which are probably accurate to about 2%. The presence of glucose in the solution will presumably alter these values somewhat, but as we know nothing of the magnitude of this effect we must neglect

¹⁹ Osaka, *Z. physik. Chem.*, **35**, 661 (1900).

²⁰ Scatchard, *THIS JOURNAL*, **47**, 648 (1925).

it; this procedure would still be necessary in order to calculate hydrogen- or hydroxyl-ion concentration even if it were possible to measure hydrogen-ion activity accurately. The following table shows the results obtained from Osaka's experiments. The first two columns give the concentrations

of NH_4Cl and NH_3 , respectively; the third gives the value assumed for f_1 , the activity coefficient of a univalent ion at the corresponding concentration of NH_4Cl . Now from the equilibrium

we have

$$c_{\text{OH}^-} = \frac{c_{\text{NH}_3}}{c_{\text{NH}_4^+}} \frac{K_{\text{NH}_3}}{f_1^2}$$

where K_{NH_3} is the dissociation constant of NH_3 at zero salt concentration. The value assumed for K_{NH_3} at 25° is 1.81×10^{-5} .²¹ The fourth column gives values of K_{NH_3}/f_1^2 and the fifth those of c_{OH^-} calculated from this equation. The sixth column gives the values observed for k . If we assume that in these solutions the hydroxyl ion is the only cause of the variation in the velocity constant we should have an equation of the form

$$k = k_0 + k_{\text{OH}^-} c_{\text{OH}^-}$$

The value 0.0096 for k_0 at 25° found by Hudson¹² has been confirmed recently by the very careful experiments of Worley and Andrews.²² In the seventh column are given values of $(k - k_0)/c_{\text{OH}^-}$ or k_{OH^-} calculated from this value of k_0 . A glance at these values shows that there is an uncertainty of 50% in the value 9750 for k_{OH^-} computed by Hudson from the same data. It is noticeable that the two values of $(k - k_0)/c_{\text{OH}^-}$ that differ markedly from the remainder correspond to solutions of markedly higher salt concentration; it should, therefore, be emphasized that if we had not introduced the factor $1/f_1^2$ to account for secondary salt effect, the deviations in these cases would have been over 12% greater than they appear now. After discussing the results of our own experiments, we shall reconsider these deviations in the light of a possible catalytic effect of the NH_3 molecule.

²² Worley and Andrews, *J. Phys. Chem.*, **31**, 742 (1927).

It has been established that the same unimolecular constant is obtained for the mutarotation of glucose whether the progress of the reaction be measured by the optical rotation, the usual method, or by the refractive index or by the volume of the solution.²³ There is, moreover, little to choose between the three methods as far as accuracy is concerned.

5. Experimental Method and Method of Calculation

The method used by us was the dilatometric. The apparatus is shown in Figure 1. A is the mixing chamber fitted with a mechanical stirrer, a thermometer graduated in fiftieths of a degree centigrade and a quartz-platinum resistance thermometer used as

Fig. 1.

graph rose to H; the stopcock C was opened again so that mercury flowed up through C as far as I, when C was quickly closed. Finally, a slight suction was applied to K so as to bring the surface of the solution to a convenient level in the capillary F, and G was closed. The whole operation from the time the glucose was added took about seven minutes. The progress of the reaction was then followed by watching

a heating coil. At B was placed a plug of cotton wool. All three stopcocks being closed, the solution was placed in the mixing chamber and stirred; after it had attained the temperature of the thermostat, the thermometer reading was noted. The solution was then heated through rather more than 1° by means of the heating coil and the glucose (18 g. to 180 cc. of solution) was dropped in. It dissolved very rapidly and the temperature fell slightly below its original value. By carefully switching the current on and off it was possible to get the solution to its initial temperature correct to 0.01° within two minutes of dropping in the glucose. The stirrer, thermometer and heating coil were removed and A was closed with a rubber stopper through which passed a glass tube connected to a water pump. Suction was applied for about one minute to remove air bubbles. The stopcock C was then opened and by evacuating through D the solution was drawn up into the dilatometer E as far as the top of the capillary F when C was closed. The stopcock G was then opened so that the mercury filling that part of the apparatus shaded in the diagram

²³ (a) Pratolongo, *Rend. ist. lombardo Sci.*, (2), **45**, 961 (1912); (b) Riiber, *Ber.*, **55**, 3132 (1922); (c) **56**, 2185 (1923); (d) **57**, 1599 (1924).

the rise of the meniscus in the capillary; readings were taken with a magnifying glass viewed through a horizontal tube about 5 cm. in length so as to reduce the parallax. The capillary was graduated in millimeters and readings were recorded to 0.05 mm., the error probably being less than 0.1 mm. The graduation of the capillary was calibrated by noting the apparent length of a weighed thread of mercury at different places. It was found that the cross section of the capillary was about 0.60 mm. The scale graduations were uniform with an accuracy of $\pm 1\%$ throughout, but over a range of 70 mm. they were uniform with an accuracy of $\pm 0.25\%$ and only this part of the capillary was used.

Since the change in volume in this reaction is exceptionally small, it was of the greatest importance that there should be no leakage during a reaction. In a number of preliminary experiments in different apparatus, in which mercury was not used to confine the solution, it was found very difficult to keep the tap corresponding to C tight. Although this tap was freshly greased before each experiment, small leaks of the order of a cubic millimeter in several hours were apt to develop. When, however, the solution was confined in the dilatometer by the mercury column it was possible to make five to ten experiments before any leak was detectable and it became necessary to regrease C. The tightness of the stopcock C was easily tested before and after an experiment by applying strong suction to A and watching the meniscus of the liquid in F. An experiment was always rejected if a leak, however slight, was detected. In the reaction diacetone alcohol \rightarrow acetone, also studied in a dilatometer first by Koelichen²⁴ and recently by Åkerlöf²⁵ such small leaks as those described above would be of no significance. The apparatus was emptied by opening the stopcock M and sucking the solution through L. The capillary F of the dilatometer was cleaned with chromic acid after each experiment except the early ones. One cc. of chromic acid was allowed to trickle through F into E filled with distilled water and became so diluted that it did not attack the grease on the tap C.

The whole apparatus was in a thermostat at 18.0° , the regulation of which was similar to that previously used and described by Brönsted and La Mer.²⁶ The reading of the thermometer in the bath did not vary over several days more than 0.005° ; the temperature of the solution in the dilatometer would certainly fluctuate less than this owing to the insulating property of the glass wall of the dilatometer. The volume of the dilatometer was 165 cc. and the cross-sectional area of the capillary 0.60 sq. mm. The coefficient of expansion of water at 18° is 0.0002 cc. per $^\circ\text{C}$. The observed fluctuations of the height of the meniscus were generally less than 0.1 mm. This corresponds to a temperature fluctuation of $(0.1 \times 0.60)/(165 \times 1000 \times 0.0002) = 0.002^\circ$, that is, a little less than half the fluctuation of the bath itself. Åkerlöf²⁵ gives a similar calculation for his dilatometer, whose dimensions were not very different from those of ours, and finds that a fluctuation of 0.1 mm. corresponds to a temperature variation of only 0.00003° , but he takes the coefficient of expansion of his aqueous salt solutions to be 0.006 per $^\circ\text{C}$., which must be a mistake. If he observed fluctuations in height of the order of magnitude to be expected from his calculation of temperature effect, they must have been due to some other cause; they would not, however, affect the accuracy of his results, as the volume change of the reaction is so great. In our experiments the volume change calculated according to Riiber's²³ data was about 22 cc. mm., corresponding to a rise of 37 mm., of which about 4 mm. would correspond to the change already taken place in the seven minutes required to fill the dilatometer. The readings in the first ten minutes almost invariably seemed to be too low; this is believed to be due to a trace of water trickling down the wall of the capillary.

²⁵ Åkerlöf, *This Journal*, **48**, 3046 (1926).

²⁶ Brönsted and La Mer, *ibid.*, **46**, 555 (1924).

The method used for computing the velocity constant was that described by Guggenheim,²⁷ which avoids the unnecessarily large error of the usual formula owing to the great weight given to the end value, whose accuracy is often less than that of the other individual readings. A series of readings V is made at times t spread over an interval two or three times the length of the period of half-completion of the reaction. A second series of readings V' is then made, each at a time $t + \tau$ exactly a constant interval τ after the corresponding reading V , the interval τ being at least two to three times the period of half-completion. If $\log_{10} (V' - V)$ is then plotted against t , a straight line is obtained whose slope is $-k$. The half-time periods of our reactions were generally 30 to 50 minutes, and the period chosen for t was usually 120 minutes. This

method of computation was checked in a few experiments by using two different values for τ , and the results of the two computations always agreed to within 0.5% with each other and with that obtained by the usual formula, if one assumed a suitable value for the final reading agreeing within the experimental error of 0.1 mm. with both the observed end value and with the end-value obtained by extrapolation. An example of this test is given in the original paper describing the method.

We give in tabular form the complete data for two experiments. The first column gives the times *t* in minutes and seconds; the second column gives the readings *V* at the times *t*; the third gives the readings *V'* at times *t* + τ where τ is 120 minutes; the fourth gives the values of $\log_{10} (V' - V)$; when these are plotted against *t* the best straight line passes through points corresponding to the values of (*V'* - *V*) given in the sixth column. The last column gives the differences between the figures in the fourth and sixth columns; these differences measure the accuracy of the individual readings. In the first example the deviations were unusually great, whereas in the second experiment they were somewhat less than average.

The glucose used was Merck's best anhydrous α -glucose. Two different preparations were made, and a few experiments performed in duplicate

with the two samples gave identical results. Rough tests with indicators showed the distilled water used, which was presumably saturated with carbon dioxide from the air, to have a P_H between 5 and 6 and this was not appreciably altered by dissolving the glucose. Any trace of acid or alkali in the glucose would be negligible, as almost all the experiments, except those to determine the effect of hydrogen ion, were performed in buffer solutions with a P_H between 4 and 6, the range in which the effects of both hydrogen ion and hydroxyl ion are quite negligible; whenever the buffer solution contained a quantity of weak acid small compared with that of the corresponding salt, the amount of weak acid was checked by titration against very dilute sodium hydroxide, using phenolphthalein as indicator. For the same reason a trace of acid or alkali in the various preparations of weak acids and salts used would be negligible. Whenever there was any possible doubt about the P_H of the solution being within the range 4 to 6 it was tested colorimetrically.

It has been emphasized by Lowry²⁸ that one can never be certain that there is not present some minute trace of an unknown catalyst. But, whatever precautions one took to purify one's material, one could never be sure that this hypothetical catalyst was removed, as long as its nature or even existence was quite unknown. We were therefore satisfied with assuring ourselves that none of the materials used contained as impurity an appreciable quantity of any substance known to be a catalyst. As, however, the velocity constant for a given experiment appeared to be quite definite with an accuracy of 0.5%, as shown by the agreement between two independent computations using different values for the time interval τ , whereas the disagreement between individual experiments was occasionally over 2%, it is just possible that there was sometimes present a trace of such an obscure catalyst whose amount could not be controlled. It is also possible that there may have been some surface reaction at the glass wall varying with the state of the glass; but the regularity of our results indicate that any effects of this type must have been small, not greater than 2%. The only experiments, other than some of the earliest ones, that seem to show irregularities greater than 2% are those in solutions of a strong acid; this may conceivably have been due to some reaction of the acid with the glass. Partly through lack of time, but especially because our main object was to study the effect of catalysts other than hydrogen ion, we did not investigate the cause of the smaller accuracy of the experiments with a strong acid.

For each experiment 200 cc. of solution was made up to a definite concentration in gram molecules per liter. Of this, 180 cc. was used for the experiment, together with 18 g. of glucose; the remaining 20 cc. of solution was used for checking its P_H .

²⁸ Lowry, *J. Chem. Soc.*, 127, 1371 (1925).

6. The "Spontaneous" Reaction and the Hydrogen-Ion Catalysis

Table III gives the results of experiments to determine k_0 , in which experiments the solutions contained, apart from water, no acid or base. The table shows that the value $(5.30 \pm 0.10) \times 10^{-3} \text{ min.}^{-1}$ obtained for k was reproducible at various times over a period of one and a half years, was the same for both preparations of α -glucose and was unaffected by salts up to an ionic strength of 0.2, even with salts containing bivalent and trivalent ions. We therefore consider ourselves justified in refusing to admit the possibility of a neutral salt effect greater than 2% in the dilute solutions used in all our experiments.

TABLE III

EXPERIMENTS TO DETERMINE k_0 AND SHOW ABSENCE OF NEUTRAL SALT EFFECT ($t = 18^\circ$)

27-10-26	I	HClO_4 1.0×10^{-4}	$\text{Ba}(\text{NO}_3)_2$.025	5.30
6-4-27	II	HClO_4 1.0×10^{-4}	$[\text{Co}(\text{NH}_3)_6](\text{NO}_3)_3$.040	5.36
6-7-27	II	Distilled water ^a		5.42

^a If the water were saturated with carbon dioxide from the air the effect of hydroxyl ion would almost certainly be negligible. As, however, most of the carbon dioxide is probably sucked out before the solution is brought into the dilatometer, the P_{H} of the solution may have been just over 6; this would be sufficient to account for the slightly high value of the reaction rate constant in the experiment with distilled water as solvent.

Table IV gives the results of experiments with perchloric acid solutions to determine the effect of oxonium ion. The results are also shown plotted in Fig. 2, from which the value 0.145 was obtained for $k_{\text{OH}_3^+}$. The last column of the table gives values of $k \times 10^3$ calculated from the formula

$$k = 0.00530 + 0.145 c_{\text{OH}_3^+}$$

where $c_{\text{OH}_3^+}$ is the concentration of hydrogen ion reckoned as equal to the stoichiometric concentration of perchloric acid. As mentioned above this set of experiments is less concordant than any other set, the error of individual experiments being in some cases 3 or 4%. The results are,

however, sufficient to show that the effect of oxonium ion is proportional to its concentration and that primary salt effect is undetectable.

Fig. 2.—Catalysis by hydrogen ions.

Kuhn and Jacob³ claim to have shown that the effect of strong acid is proportional not to the hydrogen-ion concentration but to the hydrogen-

ion activity; but their experiments are not sufficiently accurate to distinguish between activity and concentration in the absence of neutral salt, while those in molar solutions of neutral salt are simply explained by a linear salt effect of the order 10% for a molar solution, which is no more than is to be expected.

* The experiments marked * were carried out at a considerably earlier period than the similar ones not so marked and in some cases are rather below average accuracy, especially when the reaction rate is high.

7. The Effect of Monobasic Acids and their Anions

In Table V the first three columns give the results of experiments performed to determine the catalytic effect of the anions of weak monobasic acids. All the solutions were made up in such a way that the *P_H* was between 4 and 6; there could therefore be no appreciable catalysis by

Fig. 3A.—Catalysis by anions.

either hydrogen or hydroxyl ion. As we have already shown that neutral salt effect is certainly not more than 2%, it follows that any considerable increase in the velocity constant can only be due either to the anions, acting as bases, or to the undissociated molecules of the acid. In Figs. 3A, 3B and 3C the values of *k* are plotted against the concentration of

the anion. They leave no doubt that the anions are catalytically active in proportion to their concentration. In the case of the strongest bases trimethylacetate, propionate and acetate ions the effect is over one-fifth

Fig. 3B.—Catalysis by anions.

that of oxonium ion; even cyanacetate ion, the weakest base of this type studied, has an effect about one-fortieth that of oxonium.

Fig. 3C.—Catalysis by anions.

In the first four columns of Table (VI) are given the results of experiments to determine the effect, if any, of the undissociated acid molecules. The method was to make a series of experiments with a constant concentration of the sodium salt, that is, of anion, and various concentrations of the acid, so far as possible keeping the *P_H* above 4; this was not always possible and in a number of cases the effect of oxonium is not quite negligible; the concentration of hydrogen ion can, however, be calculated approximately from the composition of the buffer solution, using rough values

for activity coefficients, and the values computed are given in the third column. As we have found k_{OH^+} to be 0.145, a hydrogen-ion concentration of 7×10^{-4} gives a catalytic effect of only $0.10 \times 10^{-3} \text{ min.}^{-1}$ so that the correction to be applied for the oxonium catalysis is never more than 2% except in the experiments with chloro-acetic acid.

Fig. 4.—Catalysis by anions and undissociated acids.

In Fig. 4 the values of k for each series of constant concentration of sodium salt are plotted against the concentration of acid. The slopes of the straight lines obtained give the values of k_A , the catalytic constants of the various acid molecules, except for the above-mentioned correction

for OH_3^+ catalysis. When two sets of experiments have been made with the same acid, the constant concentration of salt in each set being different in the two cases, two parallel straight lines are obtained; the different intercepts on the k axis correspond to the different concentrations of the catalytic anion. Each straight line as drawn has been made to pass through a point corresponding to a point on the lines in Figs. 3A, 3B, 3C; in other words, the computations of the acid and basic catalytic constants are not independent of each other. The catalytic effect of the undissociated acid molecule seems to be so small in the case of the weakest acids that the existence of any effect might be disputed, but the effect of the formic acid, glycolic acid and mandelic acid molecules is unquestionable. In the case of chloro-acetic acid the hydrogen-ion catalysis, though important, cannot account for more than one-third of the increase in the velocity constant with increasing concentration of acid. With a still stronger acid, such as cyanacetic acid, unless one used a high concentration of the salt, the hydrogen-ion catalysis would always be greater than that of the acid molecules. There is thus in this reaction a real difficulty in detecting this catalysis by undissociated acid molecules; if the acid is too weak the effect is too small to observe; if the acid is too strong the effect is masked by that of oxonium ion and most common acids of suitable strength are insufficiently soluble. The same difficulty may have obscured such an acid catalysis in other reactions where the whole effect has been ascribed to OH_3^+ . Our main evidence for catalysis by the "undissociated" acid molecules must rest on the experiments with formic acid, glycolic acid and mandelic acid; the results obtained with the weaker acids and with chloro-acetic acid, though not convincing by themselves, lend additional support.

The important question of how the acid and basic catalysis depends upon the strength of the acid or base is answered by the figures in Table VII. Here are given the catalytic constants k_A and k_B calculated from the data of Tables V and VI; the figures in the last column will be explained later. The acids are arranged in order of increasing acid (dissociation) constant K_A . The third column gives k_A the constant for acid catalysis by the "undissociated" molecules and the fourth gives k_B , the constant for the basic catalysis by the anions. The last columns of Tables V and VI give values for k calculated from the formula

$$k = 0.00530 + 0.145 c_{\text{OH}^+} + k_B c_B + k_A c_A$$

where k_B and k_A have the values given in Table VII, c_B and c_A are the concentration of anion (base) and undissociated molecule (acid), respectively.

T, trimethylacetate; Ph, phenylacetate; G, glycolate; S, salicylate; C, cyanacetate, P, propionate; B, benzoate; F, formate; o-C, o-chlorobenzoate; A, acetate; o-T, o-toluate; M, mandelate; Ca, chloro-acetate

Fig. 5.—Dependence of basic catalysis on the strength of the basic anion.

In the experiments of Table V the second term is always quite negligible and the last either negligible or small so that the formula becomes approximately

$$k = 0.00530 + k_B c_B$$

In the data of Table VI the second term is never greater than 0.00010 except in the experiments with chloro-acetic acid and the third term is constant for each series.

Brönsted and Pedersen⁴⁸ found a very simple relation between k_B , the catalytic constant of an anion in the decomposition of nitramide, and K_B , the basic constant of the anion, which by definition is the reciprocal of K_A , the dissociation constant of the conjugate acid. The relation was

$$k_B = 6.2 \times 10^{-5} K_B^{0.88}$$

so that plotting $\log k_B$ against $\log K_B$ they obtained a straight line of slope 0.83. In Fig. 5 we have plotted the results for the anion basic catalysis of the mutarotation of glucose in a similar way. In this case we also obtain an approximate straight line, but the slope is 0.34 and the relation between k_B and K_B is less exact than for the nitramide catalysis. The last column of Table VII gives values of k_B corresponding to the straight line in Fig. 5. These values agree with the observed values in most cases within $2 \times 10^{-3} \text{ min.}^{-1}$, but formate ion is a noticeable exception.

The figures in Table VII show that the acid catalytic constant k_A increases with K_A , as is to be expected, but the range of the accurate values for k_A is so small that it is not worth while attempting to find an empirical relation.

8. The Effect of Other Types of Basic Catalysts

All the basic catalysts so far mentioned have been molecules with one negative charge like hydroxyl ion. Further experiments were performed to show that basic molecules with other electric charges were also effective catalysts. The first uncharged basic molecule tried was aniline, but in this case there was some other reaction as well as the mutarotation; this showed itself by an initial contraction of the solution, the volume reaching a minimum value after about 35 minutes; it was nearly 80 minutes before the volume increase followed the unimolecular law. The disturbing process slowed down more rapidly than a unimolecular process and it therefore seemed probable that there was some combination between the aniline and the glucose, such a reaction being known to take place at high temperatures. Consequently one does not know the concentration of free aniline remaining and so no quantitative conclusions could be drawn from these experiments.

It was thought that with a tertiary base this disturbing reaction should be absent, experiments with pyridine pyridinium perchlorate buffer solutions gave quite normal results showing the pyridine molecule to have a catalytic constant $k_B = 82.2 \times 10^{-3}$ and the pyridinium ion to have no measurable effect. The results are given in Table VIII.

Ammonia being a much stronger base than pyridine, it would be expected to be a more powerful catalyst; it is in fact too strong a base for

its effect to be accurately measured, because in ammonia-ammonium buffer solutions the hydroxyl effect will always be great unless the concentration of ammonium salt is great; the difficulty is analogous to that of measuring the effect of the undissociated cyanacetic acid molecules. It will be remembered that when we computed Osaka's data¹⁹ for ammonia-ammonium chloride buffers (see Table I) and assumed hydroxyl ion to be the only catalyst other than water, we found that the solutions with high concentrations of NH_4^+ and NH_3 gave high results for the velocity constants. Now Osaka also performed three experiments in solutions containing ammonium chloride but no ammonia and these show that any possible effect of NH_4^+ up to a concentration of $6-7 \times 10^{-2}$ is undetectable. There remains the possibility of the NH_3 molecules being catalytically active and our experiments with pyridine make this probable. If we assume, as Hudson did in computing Osaka's results, that k_{NH_3} is zero, then the best value for k_{OH^-} is 9120, but if we do not make this unwarranted assumption we find that the data are best fitted by the formula

$$k = 0.0096 + 6200 c_{\text{OH}^-} + 3.2 c_{\text{NH}_3}$$

This is shown in Table IX where k_1 is the value of k obtained from this formula and k_2 from the formula

$$k = 0.0096 + 9120 c_{\text{OH}^-}$$

We do not in any way claim that the values we have assumed for k_{OH^-} and k_{NH_3} are accurate, but only that the k_1 values agree with the data

appreciably better than the k_2 values. We shall later give independent evidence that the value chosen for k_{NH_3} is of the order of magnitude to be expected. The ammonia molecule is thus a catalyst about ten times as powerful as hydrogen ion.

While only little is known about the strength of simple basic molecules with unit positive charge, there are a number of acid molecules with three positive charges whose dissociation constants have been determined quite accurately and their conjugate bases with two positive charges are very suitable for our purpose. The catalytic effect of two such ions was measured. The first was $[\text{Co}(\text{NH}_3)_6\text{OH}]^{++}$ of which the conjugate

acid is the well-known roseo ion $[\text{Co}(\text{NH}_3)_5\text{OH}_2]^{+++}$. The second was the green ion $[\text{Cr}(\text{OH}_2)\text{OH}]^{++}$ conjugate to the blue acid $[\text{Cr}(\text{OH}_2)_6]^{+++}$. The results of these experiments are given in Table X. The last column

gives values calculated for k assuming that the acid ions are catalytically inactive while the basic ion $[\text{Co}(\text{NH}_3)_5\text{OH}]^{++}$ has a catalytic constant $k_B = 0.78$ (five times that of oxonium) and the basic ion $[\text{Cr}(\text{OH}_2)_5\text{OH}]^{++}$ has a catalytic constant²⁹ $k_B = 0.41$.

The last experiment in the table shows that the luteo ion $[\text{Co}(\text{NH}_3)_6]^{+++}$, whose structure is extremely similar to that of the roseo ion $[\text{Co}(\text{NH}_3)_5\text{OH}_2]^{+++}$ but which unlike the roseo ion is neutral, has no detectable effect. It appears that primary salt effect is negligible even with trivalent ions at the concentrations of these experiments.

The catalytic effect of bases with two positive charges is considerably greater than that of a base of the same strength with a negative charge. This agrees with the results obtained in the nitramide reaction, which is extremely sensitive to the influence of such ions.

Finally, as an example of a base with two negative charges, the sulfate ion was chosen. Whereas the acid constant of sulfuric acid is immeasurably great, that of the bisulfate ion³⁰ is 1.15×10^{-2} . Hence the sulfate ion SO_4^{--} is a somewhat weaker base than cyanacetate and would thus be expected to have only a small effect. Provided, however, this effect is not too small to be detected at all, it will be simpler to measure than that of, say, oxalate ion; for in order to suppress the hydroxyl-ion concentration in oxalate solutions one would have to have present, as well as $\text{C}_2\text{O}_4^{--}$, a quite considerable amount of HCO_4^- ; but HCO_4^- is both an acid and a base and so its catalytic properties might not be simple. With sulfate solutions, however, the merest trace of excess acid is sufficient to keep the P_H well below 6. The solutions used were made up as follows. To a volume of standard sulfuric acid enough standard sodium hydroxide

²⁹ A possible effect of the $[\text{Cr}(\text{OH}_2)_4(\text{OH})_2]^+$ -ion has been disregarded in this calculation.

³⁰ Sherrill and Noyes, *THIS JOURNAL*, **48**, 1861 (1926).

was added to make the solution just alkaline to methyl red; two or three drops of normal acetic acid were then added to bring the solution to the acid side of the methyl red end-point; the solution was then diluted to the required extent. The value found for $k_{\text{SO}_4^{--}}$ was 4.0×10^{-3} . The results are given in Table XI

9. Interpretation of the Spontaneous Reaction and the Mechanism of Mutarotation

We have now obtained evidence that in dilute aqueous solution any molecule, charged or neutral, if a sufficiently strong base or acid, will increase the velocity of mutarotation in proportion to the concentration at which it is present. There remains the question of interpreting k_0 the minimum value of k , or constant of the "spontaneous" reaction in aqueous solution. It was suggested in the work of Brönsted and Pedersen^{4a} that the "spontaneous" nitramide decomposition is actually a basic catalysis by the solvent molecules, and a similar interpretation in the case of the mutarotation seems very plausible. Much light is thrown on this question by the work of Lowry and others³¹ on tetramethylglucose. This sugar has approximately the same rate of mutarotation in water as glucose and has the advantage of greater solubility in anhydrous solvents and can be obtained in a much purer state. Lowry and Richards have succeeded in showing that in dry ethyl acetate the mutarotation of tetramethylglucose could be arrested over a period of about 24 hours; in chloroform containing a trace of phosgene, which removes organic bases, an arrest was obtained over a period of 10 days. We do not wish to enter into a discussion of whether mutarotation takes place not at all or only extremely slowly in a pure inert solvent, but it is at any rate established that the actually observed minimum rate in water is due practically entirely to the water itself. In other words, the OH_2 molecule is a catalyst to which we can assign a catalytic constant $k_3/55.6 = 9.5 \times 10^{-5}$. (As in assigning values to the acid and basic constants of OH_2 we had to ignore the association of the water, we have to do the same in assigning a value to its catalytic constant; as our purpose is eventually to discuss the interdependence of these constants these errors will to some extent balance each other.) The next question that suggests itself is whether the OH_2 molecule acts

³¹ (a) Lowry and Richards, *J. Chem. Soc.*, 127, 1385 (1925). (b) Lowry and Faulkner, *ibid.*, 127, 2883 (1925); (c) 128, 1938 (1926).

as an acid or as a basic catalyst. This question has also been answered by Lowry^{31b} who showed that the rate of mutarotation of tetramethyl-glucose in dry pyridine, a base, and in dry cresol, an acid, was less than 3% of its rate in water, but that by using as solvent mixtures of pyridine and cresol high rates could be obtained up to twenty times that in water. Lowry²⁸ interprets this to mean that both an acid molecule and a basic molecule take part in the reaction. It is generally agreed among organic chemists that in the change from α -glucose to β -glucose the aldehyde form of glucose is an intermediate product.

There is a considerable difference of opinion as to which of these three forms may be hydrated, but this question need not concern us. The fact that mutarotation follows the unimolecular law can be simply interpreted only by assuming that the change from the α - or β -form to the aldehyde form is slow compared with the change from the aldehyde form to either of the others. Thus the observable rate of the mutarotation is determined by the velocities of the change from α - or β -form to aldehyde form, processes involving only a change of position of one proton. Lowry's²⁸ interpretation of the mechanism of the catalysis is that the basic catalyst removes a proton from one part of the glucose molecule and the acid catalyst supplies a proton to another part of the molecule. If we write symbolically HG for α -glucose and GH for the aldehyde form, then the mechanism of the primary process in water is, in the absence of other catalysts

where one OH_2 molecule acts as an acid and one as a base. In catalysis by oxonium ion OH_3^+ , or by an undissociated molecule of mandelic acid MH , an OH_2 molecule acts as a base.

In catalysis by hydroxyl ion OH^- , or by acetate ion Ac^- or by the pyridine molecule Py , one molecule of OH_2 acts as an acid.

We have given these processes in some detail because, while entirely agreeing with Lowry as to the reasonableness of this mechanism, we consider that in his own description of it there is some confusion between the catalytic effect of the hydroxyl ion in an aqueous solution of pyridine

and the effect of the pyridine molecule itself; except in solutions containing very little water the former effect will be the greater of the two. We also wish to emphasize the similar catalytic action of the various bases, regardless of their electric charge, and likewise the similar catalytic action of the several types of acids.

10. The Interrelation between Strength and Catalytic Effect of Acids and Bases

The question of an interrelation between the strength and the catalytic activity of acids and bases has already been considered in Section 7 for the case of univalent basic anions. Evidence from the later sections permits of a more general discussion of this problem and also a very considerable extension of the region of acidity and basicity considered.

The data for typical acid and basic catalysts of various types are given in Table XII. The first two columns give a number of conjugate acid-base pairs of various types; the third column gives values of K_A for the

TABLE XII
CATALYTIC CONSTANTS ($t = 18^\circ$)

Acid	Base	K_A	k_A	k_B
OH_3^+	OH_2	5.6×10	1.4×10^{-1}	9.5×10^{-5}
OH_2	OH^-	1.0×10^{-16}	9.5×10^{-5}	$^a 6 \times 10^3$
Mandelic acid	Mandelate ion	4.3×10^{-4}	6×10^{-3}	1.1×10^{-2}
Acetic acid	Acetate ion	1.8×10^{-5}	2×10^{-3}	2.7×10^{-2}
Pyridinium ion	Pyridine	3.5×10^{-6}		8.3×10^{-2}
$[\text{Co}(\text{NH}_3)_6\text{OH}_2]^{+++}$	$[\text{Co}(\text{NH}_3)_6\text{OH}]^{++}$	1.6×10^{-6}		7.8×10^{-1}

HSO_4^-	SO_4^{--}	1.2×10^{-3}		4×10^{-3}

^a At 25° .

acid; the fourth gives the catalytic constant k_A for the acid and the fifth the catalytic constant k_B for the base. In Fig. 6, $\log k_A$ and $\log k_B$ are plotted against $\log K_A$. Included in the table are the values of k_B for hydroxyl ion and the ammonia molecule computed from Osaka's data; these values are halved in the plot because Osaka's experiments were at 25° whereas our own were at 18° , a correction which is not of great importance.

The plot shows the points corresponding to basic catalysis to lie approximately on a straight line except for the bases having a double positive charge. The slope of this line is 0.42, while for univalent anions, as mentioned, the slope 0.34 was found. The values for OH^- and OH_2 , however, are uncertain for several reasons. For instance, in basic solution, in addition to the OH^- ion, there will exist strongly basic glucose anions which may have a considerable catalytic effect and so make the OH^- ion appear more effective than it actually is. It should be noted also that no attention has been paid here to the influence of statistical factors,^{2,4a} such as would

be necessary for the establishment of an exact relation between the strength and the catalytic effect of an acid or base.

The position of the point for the NH_3 molecule justifies our belief that the value computed from Osaka's data is at least of the right order of magnitude.

The basic molecules with two positive charges seem to possess a particularly strong basic effect. This agrees with the results found in the nitramide catalysis and also with theoretical considerations.²

Fig. 6.—Dependence of acid and basic catalysis on the strength of acid and base.

The curve for acid catalysis is not so well established as the one for basic catalysis, but the increasing catalytic effect with increasing acid strength is obvious. When one considers that the plot covers a range of 10^{18} in K_A and of 10^8 in k_B , the connection between the catalytic effect of an acid or base and its strength is striking. It indeed appears that one could predict the catalytic effect, at least correct to one power of 10, of any acid or basic molecule or ion merely from the knowledge of its strength.

Summary

1. In correspondence with an extended conception of acids and bases a new theory of acid and basic catalysis has been presented, in which the catalytic effect is ascribed, not particularly to the hydrogen and hydroxyl ion, but to the action of acid and basic molecules in general. Previous work in the field has been discussed and criticized.

2. The mutarotation reaction of glucose has been studied by a dilato-

metric method under the influence of a number of acids and bases of various electric charge types. The results of the experiments have given strong support to the theory presented.

3. The catalytic effect of acid and basic molecules on the mutarotation of glucose increases with their strength as acids and bases. There seems to be a simple relationship between catalytic efficiency and strength, shown by the fact that a logarithmic plot of the basic catalytic constant against the basic strength constant, covering the range of 10^{18} in the latter, comes out approximately as a straight line with slope about 0.4.

4. The laws of mutarotation are in marked conformity with the laws previously found for the decomposition of nitramide.

THE REDUCTION OF BENZIL BY THE BINARY SYSTEM, MAGNESIUM + MAGNESIUM IODIDE (OR BROMIDE)

BY M. GOMBERG AND W. E. BACHMANN

RECEIVED JULY 18, 1927

PUBLISHED OCTOBER 5, 1927

Recently we described the reducing action of a mixture of magnesium iodide (or bromide) and magnesium on aromatic ketones.¹ This class of ketones was found to give pinacolates through the intermediate formation of free radicals, ketyls

According to our hypothesis, the active reducing agent was magnesium subiodide, generated by the interaction of the metal and halide

and present as such only in minute quantities at any one moment. The reaction has now been extended to the diketone, benzil.

Benzil with its two carbonyl groups reacts with the binary system fundamentally in much the same fashion as do the aromatic ketones, except that here the newly created carbon-carbon bond remains within the original molecule, giving rise, therefore, to an unsaturated glycolate.

The reaction proceeds *quantitatively* according to the above equation. In the process of reduction the solution displays a series of deep colors, green, brown, red and finally yellow. The halomagnesium glycolate

¹ (a) Gomberg and Bachmann, *THIS JOURNAL*, **49**, 236 (1927); (b) Gomberg, *Chem. Reviews*, **2**, 309 (1925).

(I) was isolated in solid, crystalline state; it was found to be colorless and to have the composition indicated by the formula.

On hydrolysis this glycolate gives the unsaturated glycol, stilbene-diol, $C_6H_5C(OH)=(HO)CC_6H_5$ (II), which tautomerizes rapidly to the stable form, benzoin (III). Titration of the magnesium hydroxide and estimation of the benzoin produced showed that the hydrolysis proceeds quantitatively according to the equation:

Like the benzil dipotassium compound, $(C_6H_5COK=)_2$, of Staudinger and Binkert,² and the benzil disodium derivative of Nef,³ the unsaturated halomagnesium glycolate reacts with benzoyl chloride and gives α,β -dihydroxystilbene dibenzoate (IV); with acetyl chloride the corresponding diacetate is formed.

Benzyl chloride and methyl iodide were used in the attempt to make ethers, but not much reaction took place with these reagents. With triphenylchloromethane, however, a decided reaction occurred with the formation of benzil and triphenylmethyl.

Iodine and bromine are absorbed mole for mole by the halomagnesium glycolate, the resulting mixtures on hydrolysis giving practically quantitative yields of benzil. The reaction is best formulated as giving the hypothetical compound (V), although it is equally probable that the halogen may detach the MgI without previously adding itself to the glycolate. The reaction with bromine requires but a few minutes; that with iodine is slower.

Considerable heat is generated on exposing the solid glycolate to the air. A solution of the compound, which is transparent and light yellow in

² Staudinger and Binkert, *Helv. Chim. Acta*, 5, 703 (1922).

³ Nef, *Ann.*, 308, 287 (1899).

color, instantly becomes opaque, dark brown in color through the action of even a minute amount of oxygen. The total amount of oxygen that can be taken up corresponds to one atom of oxygen for one mole of glycolate. The primary products of oxidation are probably in the form of an oxide (VI). Addition of water yields benzil and a compound that gives benzoic acid on hydrolysis and may be considered as a polymer of the anhydride of this acid (VII); frequently some benzoic acid is also produced. Because of the extreme sensitivity of the glycolates to oxygen, great care had to be exercised throughout this work to prevent undue exposure to air.

Not only the binary system magnesium-magnesium halide can accomplish the reduction of benzil, but other systems as well can bring about the same reaction with varying degrees of rapidity, even when the metal element is not the same as the metal in the halide.

In view of the remarkable reactivity of the glycolate, is it not possible that we have here a partial opening of the double bond to a single bond, giving rise to two reactive trivalent carbon atoms in the same molecule? Similar explanations have been advanced in order to account for the unusual reactivity of certain compounds.⁴

Experimental

Reduction of Benzil.—(a) By $\text{MgI}_2 + \text{Mg}$. A solution of magnesium iodide was prepared from 5.2 g. (0.04 atom) of iodine and excess of powdered magnesium in a mixture of 20 cc. of anhydrous ether and 40 cc. of dry benzene. The colorless solution was filtered into a 70cc. test-tube and 4.20 g. (0.02 mole) of benzil was added; a reddish colored solution resulted at this point, due in part to liberation of iodine (see discussion, p. 2591). A weighed rod of magnesium (8.9900 g.) was inserted and the tube carefully stoppered with a cork. Almost immediately red streamers began to flow from the rod and the solution soon possessed a deep reddish-brown color. After a time the color changed to an opaque greenish-black. In the course of 18 hours the solution became lighter in appearance, shifting to a reddish-brown, then to red and finally to a light yellow color. At the end of the reaction a perfectly clear, transparent solution remained. The rod was removed, and it now weighed 8.5020 g., which represents a loss of 0.4880 g. The theoretical value (Equation 3) is 0.4864 g. (0.02 atom). Dozens of such estimations gave values differing by only a few milligrams from the theoretical.

By using an excess of magnesium turnings complete reduction was effected in one hour; when magnesium powder was employed 10–20 minutes were sufficient to carry 4.20 g. of benzil through the color changes just described. When exactly 0.4864 g. of magnesium turnings was added to 4.20 g. of benzil, the latter was completely reduced and no trace of metal remained at the end of the reaction. The advantage of using a rod is obvious; it can be readily withdrawn from the solution at any time and weighed, thus allowing the reaction to be studied on a strictly quantitative basis.

(b) By $\text{MgBr}_2 + \text{Mg}$. The procedure here was identical with that above except for the preparation of the halide. The synthesis of magnesium bromide from the elements is not feasible; accordingly it was prepared⁵ from mercuric bromide and mag-

⁵ Ref. 1 a, p. 245.

nesium. Five g. of dry mercuric bromide is placed in a flask with 25 cc. of ether and 10 cc. of benzene, a reflux condenser being provided. One and one-half g. of magnesium powder is now added, followed by 30 cc. of benzene and then the mixture is boiled until reaction is complete. After the mixture has stood for a time the supernatant liquid is decanted through a hardened filter paper; there is thus obtained a pure, colorless solution of anhydrous magnesium bromide. As a rule the mixture was filtered into a narrow graduated cylinder, 1 cc. of the solution removed, decomposed with water, and the concentration of $MgBr_2$ determined by titration with silver nitrate solution. The exact volume of the salt solution requisite for the experiment could now be calculated. The above ether-benzene mixture is capable of dissolving magnesium bromide to the extent of 0.75–0.80 *N*.

For most experiments we used solutions of the glycolate, prepared as above, since the isolation of the solid glycolate itself is accompanied by loss of material. Usually the iodide was used because of the ease of its preparation. For some purposes, as in the study of the color phenomena, the bromide proved more suitable; this was also the case when it was desired to isolate the reaction products in the solid state, the bromide being less soluble than the iodide.

Isolation and Analysis of the Bromomagnesium Glycolate.—This compound is quite soluble when the proportion of benzene to ether is large. In ether alone it is not very soluble, but the reduction of benzil in this solvent is ever so much slower, due to the formation of some magnesium etherate compound in the form of an insoluble oil. Excellent reduction and precipitation occurs in a mixture of solvents consisting of 1 part of benzene to 3 parts of ether. Furthermore, this mixture dissolves magnesium bromide more readily than one richer in benzene.

A solution of magnesium bromide was prepared from 20 g. of mercuric bromide and magnesium in 54 cc. of ether and 18 cc. of benzene. Eight and four-tenths g. of benzil was added and a rod of magnesium inserted. In ten minutes the solution became green, and this color persisted for two days, when the solution became brown. Several days later the reduction was complete; however, shaking was continued for several weeks. During this time a large amount of white, granular glycolate precipitated out. The crystals were filtered from the solution and washed several times with ether-benzene mixture (3:1) and finally with ether alone. After the free solvent had been removed, the crystals weighed 9.82 g. All operations were carried out in an atmosphere of dry nitrogen, for the glycolate is extremely sensitive to oxygen and moisture.

Weighed samples of the solid were decomposed with water; the magnesium hydroxide thus produced was determined by titration with acid; the bromine by titration with silver nitrate; and the benzoin, containing a small amount of oxidation products, was isolated, dried and weighed. On a separate sample the total magnesium was determined as MgO by ignition with nitric acid. The solvent of crystallization was obtained by difference, and it was found that the glycolate crystallized with two molecules of ether. From the results of analysis, the percentages of the constituents were calculated on a solvent-free basis. The results given below were obtained on samples each of which came from a different reduction experiment.

Anal. Subs., 4.982, 1.197, 3.750. Calcd. for $(C_8H_6COMgBr)_2$: benzoin, 50.3; Mg, 11.6; Br, 38.3. Found: benzoin, 49.9, 50.6, 49.1; Mg, 12.6, 11.6, 11.7; Br, 38.3, 37.8, 39.2.

Reduction of Benzil to Glycolate is Quantitative.—Since the glycolate is somewhat soluble it cannot be isolated in quantitative yields from the reduction mixture. We

have proved, however, that the reduction of benzil to the glycolate is, nevertheless, quantitative, by hydrolyzing the reduction mixture itself without previous isolation of the solid glycolate. Repeated runs on 4.20g. samples of benzil gave with water yields of benzoin corresponding to 92–95%. Finally, an experiment was carried out, with rigorous exclusion of air throughout, in which one-tenth of a mole of benzil was reduced, the solution hydrolyzed and the amounts of the components carefully determined.

The colorless solution of magnesium iodide from 28 g. of iodine and 5 g. of magnesium in 50 cc. of ether and 200 cc. of benzene was filtered into a 300cc. Drechsel bottle filled with nitrogen and containing 21.00 g. of benzil. A dark red solution resulted. A weighed rod of magnesium was inserted and the bottle was tightly stoppered by means of a cork. Reaction began immediately with the characteristic production of successive color effects. At the end of 45 hours the solution was light yellow; no precipitate of any kind was present. The magnesium rod was withdrawn, washed, dried and weighed. Loss in weight, 2.435 g.; calculated, 2.431 g.

The clear ether-benzene solution was poured into water which had been freed from air by boiling. Dilute sulfuric acid was used to dissolve the copious precipitate of magnesium hydroxide that had been produced. One and one-half liters of benzene was required to dissolve the benzoin that had crystallized out. The solution was filtered from the small amount of insoluble white substance, which consisted of oxidized glycolate with some magnesium hydroxide adsorbed or occluded. This product weighed 0.25 g., and gave on hydrolysis with sodium hydroxide 0.17 g. of benzilic acid. The main solution was extracted with dilute sodium carbonate and this alkaline solution gave an additional 0.08 g. of benzilic acid.

After the treatment with sodium carbonate, the ether-benzene solution was dried over calcium chloride and the solvent removed by distillation. The white, solid residue, consisting of benzoin and a small amount of benzil, was digested with 70 cc. of cold anhydrous ether in order to remove the benzil, the mixture was filtered, and the undissolved benzoin was washed with ether, in which it is only slightly soluble. The ethereal extract was evaporated to dryness and the light yellow solid was extracted in a Soxhlet extractor with 30–40° petroleum ether. The benzoin is almost completely insoluble in this solvent while the benzil is readily soluble. The separation is as nearly quantitative as can be desired. In the extraction thimble was left 0.32 g. of benzoin; from the petroleum ether extract was obtained 0.42 g. of benzil. In spite of all precautions taken, there still resulted some oxidation of the glycolate to benzil and polymerized benzilic acid. The results may be summarized as follows: benzoin, 20.48 g. (96.6%); benzil, 0.42 g. (2.0%); polymer + benzilic acid, 0.25 g. (1.2%).

We feel justified, therefore, in stating that the reduction of benzil to glycolate is quantitative. In using for our many experiments the reduction solution of benzil without previous isolation of the glycolate, we have thus taken for granted that the amount of glycolate in the solution corresponds exactly to the amount of benzil taken.

The reaction of benzil with magnesium may proceed to completion, although more slowly, in the presence of even small amounts of magnesium halide. For example, yields of benzoin amounting to 78–94% were obtained, though the amount of magnesium halide was only 1–25% of a mole. In all cases the theoretical amount of magnesium was dissolved. As happens with the pinacolates,⁶ the metal halide is continuously split off from the halomagnesium glycolate and is thus made available for

⁶ Ref. 1, p. 243.

further reaction. The magnesium glycolate, $\text{C}_6\text{H}_5\text{C}=\text{CC}_6\text{H}_5$, is less

$$\begin{array}{c} \text{OMgO} \end{array}$$

soluble than its precursor and so precipitates out as a colorless solid during the reduction.

Reaction with Oxygen.—The amount of oxygen that can be taken up by the glycolate was measured by means of the absorption apparatus usually employed for similar purposes in the study of free radicals. In the gas buret was placed the same mixture of solvents as was used for the solution of the glycolate, and the bottle was shaken by mechanical means. A solution of the glycolate from 2.10 g. of benzil was connected to the absorption apparatus. Soon the solution became dark brown as the oxygen was taken up. The total volume absorbed was 97 cc. (corr.); calculated for one atom of oxygen to one mole of glycolate, 112 cc. Absorption was rapid at the beginning, gradually becoming slower. Hydrolysis showed the presence of 5% of unoxidized glycolate, 40% of benzil, 40% of benzilic acid polymer and 13% of benzoic acid.

A number of experiments were performed in which the amount of oxygen was not measured, dry air or oxygen being passed through the solution of the glycolate until oxidation was complete. Both the bromomagnesium and the iodomagnesium salts of the stilbene-diol yield the same products on oxidation, benzil (43–73%), benzilic acid, free and as polymer, (17–32%) and benzoic acid (5–16%). The bromomagnesium glycolate becomes colorless on oxidation while the iodomagnesium compound liberates a large amount of iodine. Staudinger and Binkert² obtained only benzilic and benzoic acids and no benzil on oxidation of the potassium salt of the stilbenediol.

Although oxidation of the glycolate and subsequent hydrolysis of the product results in the production of benzil and polymerized benzilic acid, yet very little, if any, of these are present as such in the solution before water is added. Repeated experiments have shown that colorless solutions of completely oxidized bromomagnesium glycolate, when subjected anew to re-reduction with magnesium, display no characteristic color phenomena and no loss of metal occurs. The benzil and the polymer prior to hydrolysis must, therefore, exist in the form of some non-reducible magnesium compound such as the oxide (VI). Whether on oxidation only a single compound (VI) is formed, which on hydrolysis gives rise to the two substances, benzil and polymer, or whether these two substances come from two distinct oxidation products cannot be decided at this time. It is not unlikely that two stereo-isomeric oxides are produced, *cis* and *trans*,

on hydrolysis gives benzil; the other, either before or after hydrolysis, under-

goes rearrangement to the benzoic acid derivative. Other derivatives of the glycol are known to exist in two forms.²

Color Effects during Reduction.—Although the halomagnesium glycolates are colorless in the solid state and are only light yellow in solution, yet when mixed with benzil, especially in equivalent amounts, deep brown solutions are produced. The same colors persist in the solution during reduction of benzil to the glycolate as long as any unreduced benzil is present. They are also formed when the colorless glycolate becomes partially oxidized by air. Under certain conditions the initial color produced on reduction of benzil is brilliant emerald-green. The bromide forms this most readily, solvent and concentration being important factors upon which the formation of the green color depends. Ether was found to favor the formation of green, benzene that of red. With magnesium bromide the initial color is green even with benzene-ether in the ratio 1:1; with magnesium iodide the red color usually appeared, but by using almost entirely ether, green also could be obtained. Moreover, dilution of a green mixture gave a reddish-brown color.

Characteristic color effects have been obtained also in the case of the sodium and potassium derivatives of benzil. Schlenk and Thal⁷ consider the blue compound which they obtained to be a substance containing

a trivalent carbon atom, $C_6H_5\overset{\diagup}{C}(OK)-COC_6H_5$; Nef and Staudinger and Binkert are of the opinion that this compound is the quinhydrone, $[C_6H_5\overset{\diagup}{C}(OK)=(KO)CC_6H_5][C_6H_5\overset{\diagdown}{C}O-COC_6H_5]$. Whether in our case

the green color represents a free radical, $RC(OMgX)-COR$, or whether both the green and the brown are two distinct quinhydrone compounds, each requiring certain specific conditions for existence, is left undecided.

Reaction with Benzoyl Chloride and with Acetyl Chloride.—The clear yellow solution of the glycolate prepared from 4.20 g. of benzil was treated with a solution of 6 g. of benzoyl chloride in 15 cc. of ether and 30 cc. of benzene. In three minutes a white precipitate of magnesium salt began to settle out. After the mixture had stood for 15 hours water was added. The crude product obtained from the organic solvents was recrystallized by dissolving it in a small amount of hot benzene and adding petroleum ether. The dibenzoate of the stilbene-diol was obtained in the form of large, glistening crystals, m. p. 157–158°; reported in the literature, 159°; yield, over 75% of that possible. In like manner the corresponding diacetate was prepared; m. p. 116–117°. Nef and Staudinger and Binkert give 118–119°.

Reaction with Alkyl Halides.—A warm solution of triphenylchloromethane in 20 cc. of benzene was added to a solution of iodomagnesium glycolate from 3.00 g. of benzil, care being taken to prevent access of air. As the two solutions were mixed a deep green color was produced and a white precipitate of magnesium salt appeared. On shaking the mixture, the green color gave way to a bright orange and the mixture became very thick with the solid. After being warmed for one hour and standing at room temperature for several hours, the product was decomposed with water; there was no precipitation

⁷ Schlenk and Thal, *Ber.*, **46**, 2850 (1913).

of magnesium hydroxide, showing that reaction was complete. The benzene-ether solution was filtered from a few large, brilliant yellow crystals (triphenylmethyl ether of the unsaturated glycol ?); m. p. 180–190°. From the solution was isolated 2 g. of benzil and the following oxidation and reduction products of triphenylmethyl: 1.5 g. of triphenylcarbinol, 1 g. of triphenylmethane, 0.25 g. of triphenylmethylperoxide. With benzyl chloride and with methyl iodide the glycolate showed no reaction.

Reaction with Bromine and with Iodine.—A solution of 3.43 g. of bromine in 50 cc. of carbon tetrachloride was used for titration of the glycolate from 4.20 g. of benzil and all operations were carried out in an atmosphere of nitrogen. The bromine was absorbed as fast as it was added. A few drops were sufficient to change the yellow color of the bromomagnesium glycolate solution to a dark brown color; further addition produced an opaque brownish-black mixture, and as more bromine was dropped in the solution became lighter in color, going to a transparent red, then to orange and finally to the yellow of benzil solution, which was taken as the end-point. Calcd. for 1 mole of bromine to 1 mole of glycolate: 3.15 g. Found: 3.15 g. Decomposition with water gave 4.00 g. of benzil (95%).

With iodine, instead of titration, the calculated amount of solid iodine was introduced at one time. A considerable amount of heat was generated in the reaction that followed and the solution became opaque brownish-red in color. After half an hour the mixture was translucent, but even after ten days some iodine was still present. Addition of water, followed by the usual separations, gave 94% of the calculated amount of benzil, the other products being benzilic acid, 3%, and benzoin, 1%.

Reaction of Benzil with Magnesium Bromide and with Magnesium Iodide.—Magnesium bromide and benzil form a complex without perceptible change in the yellow color of the solution. By keeping a mixture of 5.25 g. of benzil and 4.5 g. of magnesium bromide in 25 cc. of ether and 35 cc. of benzene in a cool place for two weeks, a large amount of nearly colorless crystals was obtained. The complex was found to have the composition $(C_6H_5CO-COC_6H_5).MgBr_2.(C_2H_5)_2O$. It is readily decomposed by water into its constituents.

The addition of benzil to a solution of magnesium iodide gives rise to a deep red color, occasioned in part by liberation of iodine. A mixture of 4.20 g. of benzil and 5.5 g. of magnesium iodide in 60 cc. of benzene-ether was kept in a dark place for 12 hours. The solution was then poured into water containing a small amount of acid. By titration with sodium thiosulfate 0.32 g. of free iodine was found to be present and there was formed a corresponding amount of magnesium hydroxide. Although the most careful search failed to reveal the least amount of benzoin, we have none the less tentatively assumed the existence of an equilibrium reaction

If oxygen be passed through such a mixture, the glycolate, if actually present, would be fixed as the oxide (VI), thus driving the reaction to the right. Accordingly, dry air was passed through a warm solution of 2.0 g. of benzil and 7.5 g. of magnesium iodide in ether-benzene for two hours. The solution was then hydrolyzed; there were obtained benzil and benzilic acid polymer, 50% of each, and 3.17 g. of iodine was found to be present.

Yet another method suggested itself whereby the assumed reaction could be driven to the right, namely, by removing the iodine by means of some metal other than magnesium. We have found that the addition of molecular silver, of mercury or of zinc actually accomplishes this result and that halomagnesium glycolate is formed in con-

siderable amounts. On hydrolysis yields of benzoin were obtained that corresponded to 55–79% of that possible.

Magnesium bromide, unlike the iodide, gives with benzil no detectable amount of free halogen. Nevertheless, when silver, mercury or zinc is added reaction sets in, in some cases very slowly, and there is produced bromomagnesium glycolate. Hydrolysis resulted in benzoin being formed to the extent of 50–60%.

Benzil with Other Binary Systems.—The binary system Be–BeI₂ with benzil after five days of shaking gave a 95% yield of benzoin on addition of water; the system, Zn–ZnI₂, gave a 71% yield after 22 days. The amount of benzoin indicates the extent of reduction.

Reduction of Benzil by Magnesium Amalgam.—Magnesium alone has no effect on benzil, but in the presence of mercury, which soon coats the magnesium with amalgam, reaction takes place with the production of the usual dark, reddish-brown color. On hydrolysis a 72% yield of benzoin was obtained. Likewise, amalgam prepared by heating together magnesium and mercury was able to reduce benzil.

Mechanism of the Reaction.—The reaction between magnesium, magnesium halide and ketone has been interpreted by us not as a tri-molecular reaction but as one consisting of two bimolecular reactions: (a) a subhalide of magnesium, MgX, is formed; (b) the subhalide adds itself to the oxygen of the carbonyl group. This interpretation we now find fully applicable to the diketone, benzil.

Since benzil, when acted upon by MgX₂ in the presence of silver or mercury, gives the unsaturated halomagnesium glycolate, other interpretations are possible. An unstable addition product may be formed from which the halogen, linked to the carbon atom, is then taken up by the metal directly or through its previous rejection as free halogen (Equation 5).

Considerably more experimental evidence is essential before a final explanation, or explanations, can be advanced as to the mechanism of the reduction accomplished by the various binary systems.

Summary

Benzil in ether-benzene is reduced by the binary systems, Mg–MgI₂ and Mg–MgBr₂, quantitatively to the halomagnesium salt of stilbene-diol, $C_6H_5C(OMgX)=X(MgO)CC_6H_5$.

These unsaturated glycolates were found to be extremely reactive with various reagents; with water benzoin is produced; with acid chlorides esters result; bromine and iodine yield benzil; with oxygen two products are formed, benzil and a polymer of the anhydride of benzilic acid.

Other binary systems were found to reduce benzil in a similar manner. The possible mechanism of the reduction has been discussed.

It may be added that considerable data have been accumulated on the behavior of aliphatic-aromatic ketones, aromatic aldehydes and esters toward the binary systems. The reactions seem to be more complex, though in general of the same nature as described for the ketones.

NITROGEN TRICHLORIDE AND UNSATURATED KETONES

BY G. H. COLEMAN AND DAVID CRAIG

RECEIVED JULY 18, 1927

PUBLISHED OCTOBER 5, 1927

Unsaturated aliphatic hydrocarbons react with nitrogen trichloride to form N-dichloro-C-chloro amines. Thus with 2-butene, 2-chloro-3-dichloro-aminobutane is obtained.¹ Reaction will also take place with benzene and toluene but mixtures are obtained which are difficult to separate.²

The present work was carried out in order to study the effect of the presence of the carbonyl group on the addition reactions of nitrogen trichloride and to compare the reaction of nitrogen trichloride on benzalacetophenone with the reaction of phosphorus trichloride on this compound as studied by Conant.³

The reaction of this unsaturated ketone with nitrogen trichloride takes place in carbon tetrachloride solution with the evolution of a large amount of nitrogen, the formation of ammonium chloride, the dichloride of benzalacetophenone and an N-dichloro-C-chloro-amino ketone (I). This compound was first converted into a C-chloro-amino ketone (II) by treatment with concentrated hydrochloric acid. The reducing action of hydrochloric acid on the chloro-amino group was first reported by Berg.⁴

The C-chloro-amino ketone formed by this reaction was isolated as the hydrochloride and on further reduction with sodium amalgam yielded the corresponding amino alcohol (III). The molecular weight of this amino alcohol and that of the corresponding amino ketone, which would have been formed had the ketone group not been reduced, are so nearly the same that a nitrogen analysis does not suitably differentiate between them. Since several acyl derivatives of this compound were found to be oils, the acetylation value was determined with acetic anhydride.⁵

This showed the presence of an hydroxyl group. Since there was the possibility of the formation of a pinacol in the reduction of the ketone,⁶ a molecular-weight determination was made. This indicated that the product was not a pinacol. In order to prove the position of the amino group this amino alcohol was also prepared from the monoxime of dibenzoylmethane by the action of sodium amalgam. This shows Compound III to be a β -amino alcohol, indicating that the chloro-amino

group, in the primary addition, added to the carbon atom farthest from the ketone group. The reactions for the addition and for the proof of the structure of the product are as follows:

No attempt was made to separate racemic mixtures. The preparation of derivatives and the determination of physical properties did not indicate the presence of more than one racemic mixture.

In other addition reactions of benzalacetophenone, where the ketone group is not involved, the negative part of the adding molecule attaches itself to the carbon atom farthest from the carbonyl group. Thus with hydrogen chloride⁷ the chlorine atom goes to the β -position, as does also the cyanide group when hydrogen cyanide⁸ is used. With ammonia and amines⁹ the part containing the nitrogen atom goes to the β -position. This is true of other unsaturated ketones, having been investigated with ammonia and mesityl oxide¹⁰ and particularly well investigated with amines¹¹ and various unsaturated ketones.

While it might be possible to explain the formation of product (I) by a series of reactions following a 1,4 addition to the conjugated system, similar to that which occurs with phosphorous trichloride, it seems more probable that the addition involves only the $-\text{C}::\text{C}-$ linkage, as in the typical addition to unsaturated hydrocarbons.

Experimental Part

The Preparation of the Hydrochloride of 1-Amino-2-chloro-1,3-diphenylpropanone-3.—One hundred and twenty g. of benzalacetophenone was dissolved in 800 cc. of dry carbon tetrachloride in a flask fitted with a mercury-sealed stirrer and connected to a gasometer. The solution was cooled to 0° and 350 cc. of a carbon tetrachloride solution containing 220 mg. moles of nitrogen trichloride was added slowly through a separatory funnel. The nitrogen trichloride was prepared and analyzed by the method described by Coleman and Noyes¹ with the modifications as described by Coleman and Howells.¹

The time required for the addition was about three hours. The evolution of nitrogen began in a few minutes and continued for some time after all of the solution had been run in. The reaction mixture was allowed to stand overnight, during which time it came to room temperature. A small amount of ammonium chloride was filtered off and analyzed. The filtrate contained the dichloride of benzalacetophenone and an N-dichloro-C-chloro-amino ketone and was shaken with 50 cc. of concentrated hydrochloric acid. After 30 minutes, 50 cc. of water was added and the hydrochloride of 1-amino-2-chloro-1,3-diphenylpropanone-3 filtered off. The average yield of the crude

hydrochloride from a large number of runs was about 10%, calculated from the nitrogen trichloride used. This was dissolved in the least possible amount of hot methyl alcohol and precipitated by the addition of a large amount of dry ether. The compound melted with decomposition at 206–208° (uncorr.).

Anal. Subs., 0.1009, 0.1016: 19.96, 19.67 cc. of 0.01634 *N* HCl. Calcd. for $C_{18}H_{14}ClON.HCl$: N, 4.73. Found: 4.53, 4.43.

Subs., 0.1096, 0.1048: 7.45, 7.02 cc. of 0.1 *N* $AgNO_3$. Calcd. for $C_{18}H_{14}ClON.HCl$: Cl, 23.96. Found: 24.10, 23.76.

Benzoyl-1-amino-2-chloro-1,3-diphenylpropanone-3.—This compound was obtained from the amine hydrochloride by acylation with benzoyl chloride according to the usual Schotten-Baumann procedure. The product after recrystallizing several times from benzene melted at 186–187° (uncorr.).

Anal. Subs., 0.2605: 7.14 cc. of 0.1 *N* $AgNO_3$. Calcd. for $C_{22}H_{18}ClO_2N$: Cl, 9.76. Found: 9.72.

1-Amino-1,3-diphenylpropanol-3.—Five g. of the hydrochloride was dissolved in 80 cc. of methyl alcohol and 20 cc. of water; 290 g. of 2.5% sodium amalgam was added slowly, with stirring, and with the addition of 6 *N* hydrochloric acid rapidly enough to keep the solution just acid to litmus. The alcohol was boiled off and the free amine extracted from an alkaline solution with ether. The amine was extracted from the ether by 6 *N* hydrochloric acid, the layers were separated and the ether was boiled out of the aqueous layer. The free amine was obtained as a flocculent precipitate by making the solution alkaline. On recrystallizing the product seven times from benzene, the melting point was 122–124° (uncorr.). The product did not contain chlorine, as was shown by the Beilstein test.

Anal. Subs., 0.1254: 5.30 cc. of 0.1038 *N* HCl. Calcd. for $C_{18}H_{17}NO$: N, 6.17. Found: 6.14.

Acetylation Value.—Subs., 0.2422: 2.26 mg. equiv. of acetic anhydride. Calcd. for one OH and one NH_2 , 2.00. Found: 2.12.

Since this value and others similarly obtained were slightly higher than the theoretical, a similar test was made with benzylamine. This gave an acetylation value of 1.10 instead of 1.00. Possibly in both cases a small amount of the diacetylamine compound is formed.

Molecular Weight Determination.—The boiling-point method was used. Subs., 0.3973: 94.0 g. of benzene: boiling-point elevation, 0.053°. Calcd. for $C_{18}H_{17}NO$: 227. Found: 214.

Preparation of the Amino Alcohol from the Monoxime of Dibenzoylmethane.—The monoxime of dibenzoylmethane was prepared according to the method of Wislicenus.¹² It was reduced with sodium amalgam by the same method used in the reduction of the hydrochloride of the aminochloro ketone and yielded the same product; m. p. 122–124° (uncorr.). Mixed melting points showed no depression. Compound (III) is therefore a β -amino alcohol.

Anal. Subs., 0.1229: 5.18 cc. of 0.1038 *N* HCl. Calcd. for $C_{18}H_{17}NO$: 6.17. Found: 6.10.

Summary

1. The reaction of nitrogen trichloride with benzalacetophenone in carbon tetrachloride solution has been shown to form among other products 1-dichloro-amino-2-chloro-1,3-diphenylpropanone-3. The addi-

¹² Wislicenus, *Ann.*, **308**, 250 (1899).

tion is probably a simple addition to the —C=C— bond and does not involve the ketone group.

2. This compound was reduced to 1-amino-2-chloro-1,3-diphenylpropanone-3 by concentrated hydrochloric acid and on further reduction with sodium amalgam 1-amino-1,3-diphenylpropanol-3 was obtained.

A QUANTITATIVE STUDY OF THE INFLUENCE OF SODIUM ACETATE, SODIUM BORATE, SODIUM CITRATE AND SODIUM PHOSPHATE UPON THE ACTIVITY OF PANCREATIC AMYLASE

BY H. C. SHERMAN, M. L. CALDWELL AND JANE E. DALE

RECEIVED JULY 18, 1927

PUBLISHED OCTOBER 5, 1927

In continuation of our study of the nature and properties of pancreatic amylase it became important to obtain further quantitative information on the influence of electrolytes upon its action. The first series of experiments described briefly here deal with the sodium salts of acetic, boric, citric and phosphoric acids.

Data dealing with the influence of these salts upon enzymic activity have been reported from time to time by various investigators but unfortunately they are conflicting and hard to interpret because of failure to recognize the simultaneous importance of other factors such as the hydrogen-ion activities of the solutions, the concentrations of substrates and electrolytes and the value of strictly comparable data obtained under parallel conditions.

Experiments were, therefore, planned in which each of these factors was carefully considered.

Experimental

The general plan was to study the influence upon the amylase activity, of each salt alone in solutions in which the hydrogen-ion activities differed at close intervals (by about 0.1 Ph) and then to make a quantitative parallel comparison of the influence of the different salts, the solutions being adjusted in each case to the hydrogen-ion activity which had been found to favor the optimal activity of the enzyme in the presence of that salt.

The same preparation of pancreatin was used throughout and its activity measured under constant conditions, half-hour hydrolyses of 2% starch at 40°. The hydrogen-ion activity of each starch solution used was measured electrometrically at room temperature.

As has been shown in earlier papers from this Laboratory,¹ amylase

¹ Sherman and co-workers, *THIS JOURNAL*, 32, 1073, 1087 (1910); 33, 1195 (1911); 34, 1104 (1912); 35, 1617, 1784 (1913); 37, 623 (1915); 41, 231 (1919); 43, 2461 (1921).

activity may be measured quantitatively by determining, under carefully controlled conditions, the increase in the reducing action of the hydrolysis mixture caused by the formation of reducing sugar from the starch by the enzyme. The details of the method will not be repeated here.

All salts were recrystallized and air-dried. Sodium acetate, tertiary sodium citrate and mono- and disodium phosphates were used as such. Sodium borate was obtained in the starch solutions by adding recrystallized boric acid and adjusting the hydrogen-ion activities with 0.01 *M* sodium hydroxide. The influence of the salts was measured in the presence of 0.05 *M* sodium chloride.

Discussion of Results

Experiments with Sodium Phosphate.—The total concentration of sodium phosphate in the solutions was varied from 0.0005 to 0.05 *M* and the hydrogen-ion activities were adjusted by the use of suitable proportions of equimolar solutions of mono- and disodium phosphate. The activity of pancreatic amylase was found to be independent of these concentrations of phosphate provided the hydrogen-ion activities of the solutions were suitably adjusted to *P_H* 7.0 to 7.2 for the lower concentrations and to *P_H* 7.0 for solutions containing 0.05 *M* sodium phosphate. A concentration of 0.004 *M* was chosen as suitable for the comparison of sodium phosphate with the other salts studied.

Experiments with Sodium Citrate.—In the presence of 0.004 *M* sodium citrate the enzyme was found to exert its optimal activity in solutions of *P_H* 7.0 to 7.2. Direct comparisons showed that the amylase was practically as active in the presence of citrate as in the presence of phosphate

Experiments with Sodium Acetate.—As this salt is not effective as a buffer in solutions of about *P_H* 7.0 it was difficult to control the hydrogen-ion activities of the solutions as accurately as is desirable for work with enzymes. The data obtained, however, indicate no marked difference in the influence of acetate and phosphate upon pancreatic amylase. In comparable experiments, the activity of the enzyme although more irregular was nearly if not quite as high in the presence of acetate as in the presence of phosphate and the differences and irregularities in the results with the acetate solutions can readily be explained by slight departures from the optimum conditions in the less adequately buffered solutions.

Experiments with Sodium Borate.—Experimental difficulties in controlling the hydrogen-ion activities of the solutions containing sodium borate were also encountered, and probably here too because the solutions were inadequately buffered. It was found, however, that when the solutions were adjusted to about *P_H* 7.0, ten-fold variations in the borate concentration from 0.001 *M* to 0.01 *M* did not influence the activity

of the enzyme and that the activity of the enzyme, in the presence of borate, while less regular and slightly lower, was within the experimental limits of its activity in the presence of phosphate.

Experiments in the Absence of any "Buffer" Salt.—A further comparison of the activity of pancreatic amylase in solutions with and without phosphate was made. The hydrogen-ion activities were adjusted in one series of solutions with phosphate and in the other with sodium hydroxide, no phosphate being added. Sodium chloride, 0.05 *M*, was present in both series. The results in the unbuffered solutions were more irregular and the activity of the enzyme was often, but not always, slightly lower than in the presence of phosphate. The results as a whole indicate that the addition of phosphate to the substrate aids the enzymic activity by its favorable influence in helping to control the hydrogen-ion activities of the solutions rather than because of any "specific" influence of the phosphate itself.

Conclusions

The activity of pancreatic amylase in the presence of 0.05 *M* sodium chloride and under optimal conditions of hydrogen-ion activity is practically the same in the presence of equimolar concentrations of citrate and phosphate. It is slightly lower in the presence of borate and acetate but this decrease in activity seems to be more probably due to less adequate control of hydrogen-ion activity in the less adequately buffered solutions rather than to any specific effect of the acetate or borate ions.

When acting in the presence of 0.05 *M* sodium chloride and 0.004 *M* concentrations of the sodium salts of boric, citric and phosphoric acids for half-hour periods at 40°, pancreatic amylase exerts its optimum activity in solutions of *PH* 7.0 to 7.2.

In the presence of 0.05 *M* sodium chloride the activity of the enzyme appears to be independent of the concentrations of phosphate from 0.0005 to 0.05 *M* and of borate from 0.001 to 0.01 *M* provided the optimal conditions of hydrogen-ion activity are maintained.

Given optimal hydrogen-ion activity, the activity of the enzyme appears to be practically the same in starch solutions containing 0.05 *M* sodium chloride and no phosphate, as it is in solutions containing phosphate as well.

In view of the fact that the activity of the enzyme in the absence of any salt except sodium chloride may be as great as in the presence of phosphate and that the activity is practically the same in the presence of acetate, borate, citrate or phosphate, it seems improbable that these salts have any marked specific effect upon the enzyme.

THE DIFFERENTIAL CLEAVAGE OF THE CARBON TO CARBON LINKAGE BY ALKALI METALS

BY J. B. CONANT AND B. S. GARVEY, JR.

RECEIVED JULY 20, 1927

PUBLISHED OCTOBER 5, 1927

Schlenk¹ has shown that dissociable ethanes such as hexaphenylethane react with one per cent. sodium amalgam, forming such colored sodium compounds as triphenylmethyl sodium. Later Ziegler² found that the action of the liquid sodium-potassium alloy was so vigorous that even tetraphenylethane was cleaved with the formation of potassium diphenylmethyl. Like the other metallic derivatives this reacted with water, yielding the methane, and with carbon dioxide, forming the salt of diphenylacetic acid.

In a previous paper³ we have reported the use of Ziegler's reagent in preparing xanthanoic acid from dixanthyl. As would be expected, a similar reaction takes place between the substituted dixanthyls and the alloy.⁴ The acids prepared from metallic derivatives from four substituted dixanthyls are reported in the experimental portion of this paper.

Although dibenzyl dixanthyl at 25° absorbs oxygen as rapidly as a dissociated ethane, it does not react with one per cent. amalgam in dry ether or benzene even on 24 hours' shaking at room temperature. Under the same conditions in either solvent hexaphenylethane gives a bright red color in five minutes, due to the formation of the metallic derivative. At 80° a solution of dibenzyl dixanthyl begins to show a color which fades on cooling. This fact together with its extreme reactivity toward oxygen makes it evident that at room temperature it is either somewhat dissociated in solution or a number of the molecules are in a reactive state closely akin to "real" dissociation. Yet one per cent. sodium amalgam serves to differentiate this compound from hexaphenylethane, which is about 20% dissociated in a dilute solution at 80° and only slightly dissociated at room temperature.⁵

In the hope of finding other reagents that would differentiate between carbon linkages of varying reactivity, we studied 40% sodium amalgam, which is also a liquid at 25°. This reagent reacts with hexaphenylethane and the substituted dixanthyls listed in Table I at room temperature in both ether and benzene. It reacts with dixanthyl at an appreciable rate only in ether and does not react at all with tetraphenylethane.

⁵ Gomberg, *Chem. Reviews*, **1**, 107 (1924).

Table I summarizes a series of experiments carried out for the purpose of comparing the reactivity of certain ethanes and dixanthyls. The conditions were as nearly the same as possible in all the experiments and the results are therefore strictly comparable. It is evident that by the use of sodium-potassium alloy and the two liquid sodium amalgams in either benzene or ether it is possible to differentiate between hexaphenylethane, the substituted dixanthyls (with primary groups), dixanthyl, tetraphenylethane and dibenzyl. The differentiation is sharp although it is undoubtedly a question of relative rates of reaction. Thus, although the substituted dixanthyls showed no color with one per cent. amalgam in five minutes or in 24 hours, after many days of continuous shaking a reddish color developed.

TABLE I
THE CLEAVAGE OF CERTAIN COMPOUNDS BY ALKALI METAL

Substance	Na-K ether	Na-K C ₆ H ₆	40% Na-Hg ether	40% Na-Hg C ₆ H ₆	1% Na-Hg ether	1% Na-Hg C ₆ H ₆
Hexaphenylethane	+	+	+	+	+	+
Dibenzyl	+	+	+	+	—	—
Di- <i>n</i> -butyldixanthyl	+	+	+	+	—	—
Diethyldixanthyl	+	+	+	+	—	—
Dimethyldixanthyl	+	+	+	+	—	—
Dixanthyl	+	+	+	—	—	—
Tetraphenylethane	+	+	—	—	—	—
Dibenzyl	—	—	—	—	—	—

A + sign indicates appreciable cleavage in five minutes as judged by appearance of red color.

A — sign indicates no cleavage in five minutes.

In each case 0.00025 mole of the ethane in 5 cc. of the solvent was shaken with 1 cc. of the liquid metal. The tubes were all shaken violently by hand for five minutes.

The Rate of the Cleavage Reaction Using Sodium-Potassium Alloy

The rate of the cleavage reaction may be followed by either of two methods which give only approximate results. The potassium derivative may be decomposed with carbon dioxide and the resulting acid isolated and weighed. A more rapid method is to titrate the mixture with moist benzene until the color of the metallic derivative disappears. In both methods separate tubes must be used for each time interval. A comparison of the amount of cleavage determined by the two methods with dixanthyl and with tetraphenylethane gave results as follows: (a) dixanthyl fast shaking five min., by carbon dioxide 23%, by titration, 13%; (b) dixanthyl 50 minutes' slow shaking (on a machine), by carbon dioxide 14%, by titration 4.4%; (c) tetraphenylethane 250 minutes' shaking, by carbon dioxide 55%, by titration 45%. The rate of shaking is very important as the results with dixanthyl show and as others with diethyldixanthyl demonstrated; rapid shaking by hand is more effective than the slow

shaking of the shaking machine. The amount of alloy and the concentration of the solution are also important. Thus a solution of 0.09 g. of dixanthyl in 5 cc. of ether with 0.25 cc. of alloy required four minutes' shaking for the development of color, with 0.5 cc. of alloy twenty seconds' and with 1 cc. of alloy five seconds'. Because of these variable factors which can be only partially controlled, exact data on the rates of this heterogeneous reaction could not be obtained. In all the comparative experiments we took pains to use the same size and shape of tubes, the same concentration of materials, the same amount of liquid alloy (or amalgam) and to shake in the same manner.

The rates of cleavage of dixanthyl, dimethyldixanthyl, diethyldixanthyl and dibutyldixanthyl were compared using sodium-potassium alloy (1 cc.) and 10 cc. of a 0.025 molar solution. The rate was followed by the titration method and while duplicate determinations in many cases showed considerable divergence the general course of the reaction was evident. (The numerical results are given in the experimental portion of the paper.) Interesting enough, these substances (except dimethyldixanthyl) reacted with sodium-potassium alloy in ether at approximately the same rate. The dimethyldixanthyl reacted at about the same rate as the others during the first five minutes but then the rate fell off rapidly and after 250 minutes only 25% had reacted. It seems probable that with this substance some irreversible rearrangement or decomposition may have been catalyzed by the alloy, and that three-quarters of the material may have been transformed before it had an opportunity of reacting. The reaction of these same compounds with 40% sodium amalgam was so slow that no reliable figures could be obtained; the indications were that the dialkyl dixanthyls reacted about ten times as rapidly as the parent substance.

There might seem to be an inconsistency between the results given in Table I and those mentioned in the preceding paragraph. Forty per cent. sodium amalgam acting on a benzene solution differentiates clearly between dixanthyl and the primary alkyl derivatives. Yet the rates of cleavage by the alloy in ether are not appreciably different. We interpret these results as showing that in the reaction with the alloy the rate-determining process is physical and not chemical, and that only with the 40% amalgam does the difference in reactivity of the compounds manifest itself. It is evident that no heterogeneous reaction involving the mixing of two liquid phases will be likely to proceed instantaneously. The rate will depend on the diffusion of material at the boundary where the reaction proceeds. This rate will be affected by relative volumes, method of mixing and concentrations, as has been noted in our experiments.

The rate of the reaction may also be determined by the solubility of the product and its tendency to cling to the metallic globules. Therefore,

the results obtained by using a graded series of reagents (Table I) would be expected to yield more information regarding the rate of the *chemical* reaction than the experiments with sodium-potassium alloy alone.

Experimental

The Formation of Substituted Xanthanoic Acids by Cleavage of Substituted Dixanthyls

One gram of the substituted dixanthyl in 100 cc. of absolute ether was shaken with 10 cc. of sodium-potassium alloy in an atmosphere of nitrogen for 16 hours. The red solution containing a red precipitate was treated with dry carbon dioxide, the alloy removed and the ether layer extracted with water. The aqueous layer was acidified and the precipitated acid purified by recrystallization, usually from a mixture of methyl alcohol and water. The physical properties and analysis of the acids obtained in this way are given in Table II. The methyl esters (also given in Table II) were prepared by the action of dimethyl sulfate on the alkaline solution.

TABLE II

Compound	Prepared from	M p °C.	Found % C		Found % H		Equivalent weight by titration, NaOH		Molecular weight in freezing benzene

Determination of the Rate of Cleavage

The solution of the material under investigation and the alloy were placed in glass tubes of 15-20 cc. capacity. These were sealed off after filling with dry, oxygen-free nitrogen. (The final purification of the nitrogen consisted in passing it through a solution of sodium triphenylmethyl in ether at 0°.) After shaking (at $23 \pm 3^\circ$) the tube was placed in a larger cylindrical container of stout glass. This was filled either with dry carbon dioxide or the purified nitrogen, depending on whether the acid was to be isolated or the metallic derivative was to be titrated. By a sharp shake the tube containing the reaction mixture could be broken (a file scratch at the shoulder near the constriction facilitated this operation).

In the titration experiments moist benzene was run in from a buret, the end-point being the disappearance of color. The moisture reacts so much more rapidly with the metallic derivatives than with the alloy that the presence of the latter did not seriously interfere. The benzene was saturated with water at a definite temperature and the solubility of water in benzene as given in Seidell's⁶ tables was used in the calculation.

⁶ Seidell, "Solubilities of Organic and Inorganic Compounds," D. Van Nostrand Company, New York, 1919.

In the experiments reported below, 1 cc. of the liquid metal and 10 cc. of the solvent containing 0.00025 mole of the substance were used. All of the tubes were of the same size. They were shaken violently for 30 seconds to disperse the metal and then on the shaking machine for the time indicated. The calculation of the per cent cleavage from the data is illustrated by the following typical run: 0.09 g. of dixanthyl, 10 cc. of ether, 1 cc. of sodium-potassium alloy, shaken 50 minutes, 6.5 cc. of benzene saturated with H_2O at 23° required; theoretical cc. for complete cleavage 16.7 (at 23° 100 cc. of benzene holds 53.7 mg. of water); per cent. cleaved, 39.0.

Rate of cleavage of **dixanthyl**. With sodium-potassium alloy in ether (the numbers are the per cent. cleavage): 5 min., 39.0, 42.0; 125 min., 71.8, 77.8. With 40% sodium amalgam: 125 min., 1.2; 250 min., 1.4, 1.4. With sodium-potassium alloy in benzene: 250 min., 6.0, 6.8. With 1% amalgam in ether or 40% amalgam in benzene, no perceptible cleavage in 250 min.

Rate of cleavage of **dimethyldixanthyl**. With sodium-potassium alloy in ether: 5 min., 6.2, 6.2; 50 min., 8.6, 12.3; 125 min., 14.2, 16.6; 250 min., 23.3, 24.6. With sodium-potassium alloy in benzene, 250 min., 5.2, 5.2. With 40% amalgam in ether, 250 min., 1.2, 2.0. With 1% amalgam, none in 250 min.

Rate of cleavage of **diethyldixanthyl**. With sodium-potassium alloy in ether: 5 min., 9.9, 15.7; 50 min., 51.1, 47.1; 125 min., 59.9, 69.7. With sodium-potassium alloy in benzene: 125 min., 4.8; 250 min., 5.5, 7.2. With 40% amalgam in ether: 125 min., 3.1; 250 min., 4.9, 10.5. With 40% amalgam in benzene: 250 min., 1.4, 4.8. With 1% amalgam, none in 350 min.

Rate of cleavage of **di-n-butyldixanthyl**. With sodium-potassium alloy in ether: 5 min., 1.7, 4.1; 50 min., 42.0, 47.5; 125 min., 63.6, 73.3. With sodium-potassium alloy in benzene: 125 min., 4.2; 250 min., 6.0, 7.5. With 40% amalgam in ether: 125 min., 3.1; 250 min., 2.7, 7.4. With 40% amalgam in benzene: 250 min., 5.5, 6.0. With 1% amalgam in ether, none in 330 min.

Summary

1. The action of sodium-potassium alloy, 40% sodium amalgam and 1% sodium amalgam on a number of substituted dixanthyls and certain ethanes has been studied. By using these reagents in benzene or ether one can differentiate between certain compounds which contain a reactive carbon to carbon linkage.

2. The rate of cleavage by sodium-potassium alloy is essentially the same for a number of substituted dixanthyls and dixanthyl itself. This is probably due to the fact that with this powerful reagent a physical process controls the rate of the heterogeneous reaction.

A COMPARISON OF HETEROCYCLIC SYSTEMS WITH BENZENE

II. REDUCTION POTENTIALS OF QUINONES CONTAINING THE PYRIDINE, IMIDAZOLE, TRIAZOLE AND THIOPHENE RINGS

BY LOUIS F. FIESER AND MARION A. AMES

RECEIVED JULY 27, 1927

PUBLISHED OCTOBER 5, 1927

In the first paper of this series¹ a description was given of an experimental method of studying various unsaturated ring systems which consists in comparing, by means of oxidation-reduction potential measurements, the oxidizing power of a compound such as α -naphthoquinone, in which a benzene ring is fused to a quinone grouping, with the oxidizing power of a quinone formed by replacing the benzene ring of α -naphthoquinone by a heterocyclic nucleus. The relative extent to which the reduction potential of benzoquinone is decreased by the attachment of the benzene ring and of the heterocycle furnishes a means of characterizing quantitatively the relationship between the two cyclic systems.

The interpretation of the results of such a study would be greatly simplified if it were possible to obtain and perform measurements with simple heterocyclic analogs of the naphthoquinones; but it appears that, in the case of certain heterocycles, this is very difficult if not impossible. Both 4,5-indazolequinone¹ and, as we have now found, 1-phenylbenzotriazole-4,5-quinone(I)² undergo decomposition too rapidly to permit of satisfactory e.m.f. measurements in alcoholic solution. The destruction of these quinones is undoubtedly due to the 1,4 addition of solvent, acid or a second quinone molecule to the conjugated system, and it can often be prevented by the introduction of a sulfonic acid group in the reactive 4 position. Thus 2-phenylbenzotriazole-4,5-quinone-7-sulfonic acid (II)

which was synthesized from 2-phenyl-5-hydroxybenzotriazole was, like indazolequinone sulfonic acid, well suited to the purpose at hand. We were unable, however, to obtain the corresponding 1-phenyltriazole derivative. Unlike many similar *o*-quinones, 1-phenylbenzotriazole-4,5-quinone (I) does not react with sodium bisulfite, so that the direct

¹ Fieser, *THIS JOURNAL*, **48**, 1097 (1926).

² Fries and Empson, *Ann.*, **389**, 345 (1912).

preparation of the sulfonated hydroquinone could not be accomplished. It was found, moreover, that although 1-phenyl-5-hydroxybenzotriazole readily couples with diazonium salts, it fails to yield a nitroso derivative with nitrous acid, so that the convenient reaction of *o*-nitrosophenols could not be utilized. Further obstacles encountered in the 1-phenyl-triazole series are recorded in the Experimental Part.

In view of this experience and because difficulties in the synthesis of other heterocycles were anticipated, it seemed advisable at this time to determine to what extent some of the more readily available heterocyclic quinones would serve to furnish the desired comparison with benzene. To this end a given compound must be at least slightly soluble in alcohol or water, it must be stable in solution and undergo strictly reversible reduction. It is essential, moreover, that sufficient data for related compounds are available in order to interpret the results adequately. In the present study we have examined several known quinones and two new ones from the experimental standpoint and we expect to supply in the future such additional data as now appear necessary for a proper evaluation of some of the results.

Samples of 2-phenyl- α,β -naphthotriazole-4,5-quinone (VI, below)³ and the isomeric 3-phenyltriazole derivative⁴ were kindly furnished for this investigation by Professor Charrier, to whom we wish to express our sincere thanks. Since these compounds, as well as the 1-phenyltriazole isomer,⁵ were obtained by the oxidation of the tricyclic analogs of phenanthrene, and since α -naphthoquinolinequinone (III) has been prepared by the oxidation of α -naphthoquinoline,⁶ it might be expected that a number of other quinones could be obtained in a similar manner. It appears, however, that the method is not one of very general application.

While α,β -naphthotriazole-4,5-quinone (VIII, below)⁷ was readily prepared by the oxidation of α,β -naphthotriazole, no products possessing the properties of a quinone were obtained by the oxidation of 2-methyl- α,β -naphthimidazole⁸ or 2-phenylnaphthimidazole (IV).⁸ Skraup and

Cobenzl⁶ attempted to convert β -naphthoquinoline into the corresponding quinone but found that oxidation always involved cleavage of the central ring; the experience of Beretta⁹ with 2-phenyl-5,6-quinolinetriazole was entirely similar. Although few of the corresponding linear tricyclic compounds appear to have been studied, Fries and Empson report a similar failure to convert N-diphenyl-diethenyl-1,2,4,5-tetra-aminobenzene into a quinone by direct oxidation.²

Another method of synthesizing analogs of phenanthrenequinone utilizes 1,2-dihydroxy-3,4-diaminonaphthalene as the starting material.⁷

By condensing this substance with formic acid and oxidizing the product, α,β -naphthimidazole-4,5-quinone (V) was readily obtained.

Determinations of the reduction potentials of the quinones which have been mentioned, and of certain others which are described in the literature, were carried out by electrometric titration with titanous chloride. A hydrogen electrode containing some of the solvent which was used to dissolve the quinone formed the reference half-cell. Measurements were made when possible in aqueous solution, but in most cases the solvent employed was 50% alcohol containing 0.1 mole of hydrogen chloride and 0.2 mole of lithium chloride per liter, the latter electrolyte being added to increase the conductivity of the solution. Though most of the compounds studied dissolve only to a very slight extent in this solvent, no difficulty was experienced in working with the dilute solutions. The results are summarized in Table I. The term "50% alcohol" is used to signify the solution described above. Values found for the normal reduction potentials by interpolation of the titration curves at the point corresponding to half-reduction are given under the heading E_0 , while under ΔE_1 and ΔE_2 are given the average differences between E_0 and the potentials at 20% and 80% reduction, respectively. The theoretical value is 17.8 millivolts.

In considering the results, attention may first be called to the fact that the potentials of some of the quinones containing nitrogen increase with increasing acidity of the solution. The variation is probably due to changes in the extent of the basic dissociation of the organic substances.¹⁷ The normal reduction potentials referred to the undissociated oxidant and reductant, which we regard as the most significant for the purpose of correlating reduction potentials and structure, are probably somewhat lower than the values obtained for 0.1 *N* hydrochloric acid and cannot now be accurately evaluated. In view of this uncertainty, too great significance should not be attached to the exact values of the "normal potentials" of those compounds whose potentials change with acidity. Thus the potential of α -naphthoquinolinequinone in 0.1 *N* hydrochloric acid is 0.112 v. higher than that of phenanthrenequinone, but the variation with acidity indicates that the difference between the potentials would be less in a solution of such acidity that no dissociation could occur. While it seems unlikely that such a large difference can be due entirely to the effect of ionization, and while the present results thus point to a surprising difference between the pyridine and the benzene nucleus, it is best to reserve judgment on this point until further data are available.

In the case of the phenyltriazole derivatives there is evidence that the results are not influenced by ionization, for the potential of the sulfonated quinone, II, is independent of the acidity of the solution. More

¹⁷ Clark and Cohen, *Pub. Health Repts.*, **38**, 666 (1923).

confidence can thus be placed in the values for this compound and for those similarly constituted.

It will be observed that the values for the normal reduction in 50% alcoholic solution of 2-phenyl- α,β -naphthotriazole-4,5-quinone (VI) and for phenanthrenequinone are very nearly the same. The substitution of the 2-phenyltriazole nucleus for one of the benzene rings in phenanthrenequinone thus produces an alteration in the reduction potential that is scarcely perceptible, which indicates a close relationship between

the two cyclic systems. It is important that the same conclusion may be inferred from entirely independent data; the reduction potential of 2-phenylbenzotriazole-4,5-quinone-7-sulfonic acid (II) in aqueous solution is 0.643 v.; that of 1,2-naphthoquinone-4-sulfonic acid (IX) is 0.630 v.

That the potentials of the benzenoid quinone and the heterocyclic quinone differ by almost exactly the same amount here as in the tricyclic series is excellent evidence of the general validity of the method and indicates that phenanthrenequinone may be taken as a standard for comparison even though the relationship of the potential to that of β -naphthoquinone is not yet understood.¹⁸

While 2-phenyl- α,β -naphthotriazole-4,5-quinone (VI) is very similar in potential to phenanthrenequinone, the value for the 3-phenyl isomer (VII) differs by the considerable quantity of 0.047 v. The results for the three

compounds indicate that the 2-phenyltriazole system, $\begin{array}{c} \text{---C---N---} \\ || \quad | \\ \text{---C---N---} \end{array} \text{N---R,}$ like the benzene ring, represents a condition of greater stability, or of less reactivity and unsaturation, than the isomeric grouping, $\begin{array}{c} \text{---C---N---R} \\ || \quad \diagup \\ \text{---C---} \end{array}$.

¹⁸ Conant and Fieser, *THIS JOURNAL*, **46**, 1858 (1924).

On the basis of this evidence, it seems likely that the unsubstituted triazoles, which can conceivably correspond in structure to either of the phenyl derivatives, have the structure of the more stable isomer, namely,

some support to this conclusion, for it approaches more closely that of the 2-phenyl derivative than that of the isomer. Moreover, since a phenyl group lowers somewhat the potential of benzoquinone,¹⁹ it would be expected that the potential of the true phenyl derivative of naphthotriazolequinone would be perhaps lower, but surely not higher, than that of the parent compound. This relationship is maintained only if the above structure for the triazole ring is adopted.

This structure for the 1,2,3-triazoles was first advanced by Griess,²⁰ though Zincke²¹ showed that the evidence was unsatisfactory. On the other hand, the evidence which led Zincke to favor the double-bond structure does not now appear to exclude definitely the Griess formula.²² The present results indicate that a reexamination of this problem is desirable.

Though it is too early to consider the matter in detail, it is of interest to compare briefly our results in the triazole series with those of other investigators. Zincke²³ found that many benzotriazole derivatives were hardly distinguishable from the corresponding naphthalene compounds; Fries,²⁴ by the extensive application of more definite comparative methods, concluded that the two isomeric phenyl derivatives are exactly similar to each other and to naphthalene. The present work supports these conclusions in a general way, though it points to a difference between the phenyltriazoles. It is of course possible that the electrochemical method reveals differences which are too slight to be detected by a study of the course of substitution reactions; but in view of our results for the pyrazole nucleus¹ and the tentative results for pyridine, it seems more probable that the two methods do not furnish precisely the same information concerning the character of the ring systems in question. For one thing, our method is concerned solely with equilibria, while most of

²⁰ Griess, *Ber.*, **15**, 1878 (1882).

²¹ Zincke, *J. prakt. Chem.*, [2] **53**, 97 (1896).

²² A third possible structure for benzotriazole, as well as for its 2-N substitution products, involves the "oso-triazole," or quinone-di-imine grouping. Fries, however, has recently shown (*Ann.*, **454**, 137 (1927)) that this structure is inconsistent with the properties of these substances.

²³ Zincke, *Ann.*, **311**, 277 (1900).

²⁴ (a) Fries, *Ann.*, **389**, 305 (1912). (b) Fries and Roth, *ibid.*, **389**, 318 (1912). (c) Fries and Empson, *Ref. 2*. (d) Fries, Sudhoff and Brettschneider, *ibid.*, **454**, 131 (1927).

the methods employed by Fries depend largely upon the relative rates of competing reactions.

It is of interest that Charrier's statement⁴ that 2-phenyl- α,β -naphthotriazole-4,5-quinone is more closely related to phenanthrenequinone in physical properties than the 3-phenyl isomer corresponds with the electrochemical results.

Our results have some bearing on the anomalous relationship between the potentials of some of the benzenoid quinones.¹⁸ Since the attachment of a phenylene group to *o*-benzoquinone lowers its potential by 0.222 v., two such groups would be expected to lower the potential by 0.444 v.; the actual value is considerably less, namely, 0.335 v. In the same way it may be calculated that the attachment of a phenylene group and a 2-phenyltriazole group to *o*-benzoquinone should lower its potential by 0.431 v., if the effects are additive; but the actual value is 0.313 v. The relationship between the compounds of the bi- and tricyclic series is thus the same whether or not one ring is heterocyclic, and it seems probable at the present time that the position of phenanthrenequinone on the potential scale is due to the angular structure of the compound rather than to some peculiar property or structure of the benzene rings of the quinone or its reduction product.

It is important to determine if a similar situation obtains in the series of the linear tricyclic substances such as anthraquinone and its heterocyclic analogs. Unfortunately, the results with the triazole derivatives, X and XI, are not altogether satisfactory; the value for X

X(R = $-\text{C}_6\text{H}_5$)

XI(R = $-\text{C}_6\text{H}_4\text{CH}_3$)

XII

may be as much as 10 mv. too high; that for XI is probably accurate to within 5 mv. However, there can be little doubt as to the general position of the potentials of these compounds, and they may be compared with that of anthraquinone, which is 0.155 v. If compound X were related to anthraquinone in the same way that the angular isomer VII, which also contains the 3(1)-phenyltriazole ring, is related to phenanthrenequinone, the reduction potential of X would be 0.055 v. higher than that of anthraquinone, or 0.210 v.; but the actual value, 0.256 v., is appreciably higher than this. The two imidazole derivatives, V and XII, may be compared in the same way, though they are not isomeric. Since the potential of the angular substance, V, is 0.070 v. above that of phenanthrenequinone, it would be expected that the value for the linear

isomer, β,β -naphthimidazolequinone, would be in the neighborhood of 0.225 v. The potential of the N-methyl-N-phenyl derivative (XII) of this compound should be even lower than this value and, since the actual value is 0.320 v., it seems clear that the assumption that the heterocyclic ring bears the same relationship to the benzene ring in the linear tricyclic compounds as in the angular series does not hold. There seems to be some specific property of the benzenoid and of the heterocyclic rings which only becomes manifest in the linear tricyclic series.

Now the potential of anthraquinone itself is much lower than can be accounted for by supposing that the effect of two phenylene groups attached to *p*-benzoquinone is just twice the effect of one. It is difficult to account for this fact on the basis of the structure of anthraquinone, but it must be remembered that the reduction potential of a quinone is a measure of the free energy of the conversion of the quinone into its hydroquinone and that the structure of the reduction product must also be taken into consideration. The abnormally low potential of anthraquinone may not be due to any peculiarity of the quinone but to some specific property of anthrahydroquinone which renders it particularly reactive and prone to pass over into its oxidation product. It does not appear unwarrantable to consider that this property is due to an ortho-quinonoid structure of the hydroquinone, according to Formula XIII,

in which Ring a, like the corresponding ring of *o*-benzoquinone, has a tendency to pass into the truly benzenoid condition and so contributes to the reactivity of the molecule as a whole.

If the Armstrong formulation of anthracene is adopted for heterocyclic analogs of this hydrocarbon, the question arises as to whether Ring a or Ring a' of XIII has been replaced by the heterocycle, that is, whether it is the benzene ring or the heterocycle which has the quinonoid structure. The problem is similar to the question of the structure of unsymmetrical azines which was explored by Kehrman²⁰ and may, in theory, be treated in the same way. If, for example, the ring XIV-a is more reactive than XV-b, the compound will exist chiefly in the form of XV; this form would predominate in the equilibrium mixture. Any nucleus which has the *o*-quinonoid grouping of linkages possesses a certain tendency to rearrange into a more stable structure, but the rearrangement

²⁰ Kehrman, *Ber*, 31, 977 (1898)

of XIV into XV, which would result if the strained *o*-quinonoid condition of XIV-a is to be relieved, is opposed by the reverse rearrangement due to the tendency of XV-b to pass into a condition of greater stability. Thus an equilibrium between the two forms would result and the point of this equilibrium would depend upon the relative reactivities, in the sense indicated, of the quinonoid rings XIV-a and XV-b. Various methods of estimating these reactivities are conceivable, and one of them is being investigated by Fries.²⁶ He states that dihydro-imidazole (XVII) is a

stable substance which is devoid of the tendency to pass into dehydrogenated derivatives which characterizes dihydrobenzene (XVI). Since these two compounds have structures similar to XIV-a and XV-b, it is reasonable to suppose that XV-b is the least reactive of the two and, therefore, that the substance in question corresponds to XV. The substance thus differs from anthrahydroquinone or any other heterocyclic analog in a very essential respect and a simple relationship between these various compounds is not to be expected. From the foregoing analysis we can only say that the linear arrangement of the three nuclei should not result in such a pronounced tendency to undergo oxidation in the case of the heterocyclic substance, XV, as in the case of anthrahydroquinone, in other words, the reduction potential of the quinone corresponding to XV should be higher than that of anthraquinone and higher by an amount not accounted for by the relationship between corresponding angular tricyclic compounds. It is clear that this interpretation agrees with the experimental results.

In the case of the triazole derivative, X, the results indicate that the triazole nucleus approximates much more closely the character of the benzene nucleus. The few pertinent chemical facts which are known²⁶ concerning the triazoles support this conception.

It thus appears highly probable that the specific factor which is operative only in the linear tricyclic series is concerned with the *o*-quinonoid structure of anthracene and its analogs. In order to test this hypothesis further, it is necessary to have some general method of determining the relative tendency of the various cyclic systems to rearrange from the quinonoid into the benzenoid condition. It occurred to us that very precise information on the point in question would be furnished by the determination of the reduction potentials of heterocyclic analogs of *o*-benzoquinone or its derivatives in the event that such determinations

²⁶ Fries, *Ann.*, 454, 127 (1927).

are possible. At present, however, very few quinones of the type indicated are known. We have studied one such compound, thionaphthenequinone (XVIII), and have found that it can be brought within the scope of the

electrochemical method of treatment. Its reduction potential ($E_0 = 0.264$ v.) is very low in comparison to that of β -naphthoquinone, XIX ($E_0 = 0.597$ v.). This means that the thiophene ring, present in the reduction product of XVIII, is much more prone to pass into the quinonoid or dihydride condition than is benzene. It is a less stable system.

The relatively high potential of thiophanthrenequinone XX (E_0 , 0.250 v., as compared with 0.155 v. for anthraquinone) may well be related to this fact, though data on other thiophene derivatives are required before the question can be properly analyzed.

Experimental Part

1. **Synthesis of 2-Phenylbenzotriazole-4,5-quinone-7-sulfonic Acid (II).**—2-Phenyl-4-nitroso-5-hydroxybenzotriazole, a compound which has been described by Fries and Roth,^{24b} formed the starting point for this synthesis. In preparing this substance, 2-phenyl-5-aminobenzotriazole was obtained in 76% yield by reduction of the corresponding nitro compound with stannous chloride,²⁷ and converted into the hydroxy derivative in the manner described by Fries and Roth, though it was found that the use of boric acid¹ improved the latter process considerably. By the addition of 1.5 molecular equivalents of boric acid to the solution of the diazotized amine before boiling the mixture, the yield was increased from 60% to 85–90% and the time required for the complete evolution of nitrogen was greatly shortened.

2-Phenyl-4-amino-5-hydroxybenzotriazole-7-sulfonic Acid (XXI).—The 4-nitroso derivative prepared from 2.1 g. of 2-phenyl-5-hydroxybenzotriazole was suspended, while still moist, in a solution of 3.1 g. of sodium bisulfite in 150 cc. of water and the

mixture was stirred for several hours until no more material appeared to go into solution. The solution was then filtered, concd. hydrochloric acid was added in excess, and the solution was allowed to stand at 35° for one day, when the separation of almost colorless crystals of the reaction product had ceased. The substance is very sparingly soluble in

²⁷ Kehrman and Messinger, *Ber.*, **25**, 898 (1892). Willgeroth, *J. prakt. Chem.*, [2] **46**, 131 (1892).

water. It dissolves readily in hot sodium bisulfite solution, and on cooling the solution deposits yellow needles of the sodium salt. The free acid was obtained in pure condition, in the form of colorless micro-crystals, from the crystallized sodium salt. It retains combined water even on drying in a vacuum at 100°.¹⁸

Anal. Calcd. for $C_{12}H_{10}O_4N_4S \cdot 1\frac{1}{2}H_2O$: C, 43.23; H, 3.93. Found: C, 43.13; H, 3.88.

Potassium 2-Phenylbenzotriazole-4,5-quinone-7-sulfonate (II).—Oxidation of the above compound was accomplished by stirring 1 g. of the material into 2 cc. of 25% nitric acid. On warming slightly all of the material dissolved and orange needles of the ammonium salt of the quinone soon began to separate. After adding saturated ammonium chloride solution and cooling, the precipitate was collected and well washed with ammonium chloride solution. The salt dissolves readily in water and is moderately soluble in alcohol. The potassium salt, which is less soluble, crystallized from water in the form of small, orange-yellow needles.

Anal. Calcd. for $C_{12}H_8O_4N_4SK$: K, 11.39. Found: K, 11.35.

This quinone is very similar in properties to 1,2-naphthoquinone-4-sulfonic acid. It is decomposed by alkalis, giving a green solution from which a red substance precipitates on acidification, while on treatment with concd. sulfuric acid, sulfur dioxide is rapidly evolved and a yellow substance is precipitated on diluting the red, acid solution. The compound is readily reduced by sulfur dioxide and can be condensed with amines. For the purpose of characterization, the *p*-toluidino compound was prepared.

2-Phenyl-7-(*p*-toluidino)-benzotriazole-4,5-quinone (XXII).—A mixture of aqueous solutions of equivalent weights of ammonium 2-phenylbenzotriazole-4,5-quinone-7-sulfonate and *p*-toluidine was heated at the boiling point for ten minutes. The toluidino compound, which was deposited in the form of small, dark red needles, was crystallized from methyl alcohol, in which it is moderately soluble; m. p., 215°.

Anal. Calcd. for $C_{19}H_{14}O_4N_4$: C, 69.07; H, 4.27. Found: C, 69.02; H, 4.42.

2. Experiments in the 1-Phenylbenzotriazole Series.—1-Phenylbenzotriazole-4,5-quinone (I) was prepared by the method of Fries and Empson² and crystallized from glacial acetic acid. In addition to the properties reported by these authors, it was noted that, although the quinone is readily reduced by sodium hyposulfite, it is completely insoluble in bisulfite solution. It was also found that nitrous acid is without action on 1-phenyl-5-hydroxybenzotriazole, though this compound couples with diazotized amines.

1-Phenyl-4-benzene-azo-5-hydroxybenzotriazole (XXIII).—To a solution of 2.1 g. of 1-phenyl-5-hydroxybenzotriazole² in 25 cc. of water containing 2 g. of sodium hydroxide was added a benzene diazonium chloride solution prepared from 0.93 g. of aniline. After warming for a time and neutralizing the solution, the product was collected and crystallized from alcohol; yield, 2.7 g. (85%). It forms bright red crystals which are sparingly soluble in organic solvents and soluble in alkalis.

Anal. Calcd. for $C_{18}H_{13}ON_4$: C, 68.66; H, 4.16. Found: C, 68.49; H, 4.29.

Attempts to reduce the azo compound to an amine with sodium hyposulfite in alkaline solution were unsuccessful; reduction took place but no product was obtained corresponding in properties to the substance desired.

3. α,β -Naphthotriazole-4,5-quinone.—In preparing this compound according to the directions of Zincke and Noack⁷ it was found that β -naphthoquinone, which forms the starting-point of the synthesis, could be most satisfactorily nitrated in the following

¹⁸ Compare the behavior of 1-amino-2-naphthol-4-sulfonic acid, Schmidt, *J. prakt. Chem.*, [2] 44, 523 (1891).

ether and the ether evaporated. A brown oil remained. When this was dissolved in alcohol and poured into water, an emulsion was formed and crystallization finally took place. These crystals were purified from dilute alcohol.

The diacyls were saponified by dissolving in 10% potassium hydroxide and then acidifying with hydrochloric acid. The precipitate was purified by recrystallization from dilute alcohol. All analyses were made by the Kjeldahl method.

Summary

1. The heavier *iso*-carbopentoxy group replaces both the *n*- and the *isocarbobutoxy* from the nitrogen in diacyl derivatives of *o*-aminophenol.

2. The benzoyl group does not behave the same with the *n*-carbopropoxy and the *iso*-carbopropoxy groups in diacyl derivatives of *o*-aminophenol. In the case of the *n*-carbopropoxy derivative the benzoyl group goes to the nitrogen, but in the case of the *isocarbopropoxy* group the benzoyl group goes to oxygen.

3. New diacyl derivatives of *o*-aminophenol have been prepared and studied.

THE HYDROGEN-ETHYLENE REACTION IN THE PRESENCE OF EXCITED MERCURY ATOMS

BY A. R. OLSON AND CHARLES H. MEYERS

RECEIVED AUGUST 1, 1927

PUBLISHED DECEMBER 10, 1927

In a former paper the authors¹ concluded from semi-quantitative evidence that ethane was formed from hydrogen and ethylene when a mixture of the latter is illuminated with ultraviolet light in the presence of mercury vapor. However, it was also known at this time that in addition to ethane other substances must be formed. The experiments about to be described were undertaken to determine the products of the reaction more definitely.

The experimental arrangement used to expose the gas to the light was the same as that described in our former paper except that the gases were kept in constant circulation.

The ethylene and hydrogen were prepared as described in our former paper. Ethane was prepared by treating an ether solution of C_2H_5MgI with dilute sulfuric acid. The ethane was dried and purified by bubbling through concentrated sulfuric acid and by means of liquid air fractionally distilled three times, the middle portion only being saved for each subsequent distillation.

In Experiment I a mixture of hydrogen at a pressure of 39 cm. and ethyl-

¹ Olson and Meyers, *THIS JOURNAL*, **48**, 389 (1926).

manner, the success of the process depending largely on having the proper acid concentration. Twenty g. of β -naphthoquinone was stirred into 40 cc. of nitric acid (sp. gr. 1.40) and the mixture was warmed on the water-bath until nitric oxide became apparent and the quinone went into solution (about one minute). The flask was at once transferred to an ice-bath and several small pieces of ice were added. On stirring, crystallization took place almost immediately and after 15 minutes the product was collected and washed successively with concd. nitric acid, glacial acetic acid and ether; yield, 20.6 g. (80%); m. p., 156° . Conversion of this compound, through its hydroquinone, into 3-amino-1,2-naphthohydroquinone was accomplished in 85% yield. We have nothing to add to Zincke and Noack's description of the remaining steps or of the triazole quinone except that this substance, like most *o*-quinones, dissolves readily in sodium bisulfite solution. On adding acid to such a solution, the quinone is apparently reduced by sulfur dioxide, for a salt of the hydroquinone is slowly precipitated.

α,β -Naphthotriazolequinone was also obtained by the oxidation of α,β -naphthotriazole²⁸ with chromic anhydride in glacial acetic acid solution. Samples prepared in these two ways were purified by crystallization from glacial acetic acid solution and compared by determination of the reduction potential, since the substance has no melting point. The two samples were identical.

4. α,β -Naphthimidazole-4,5-quinone (V).—A mixture of 1 g. of 1,2-diamino-3,4-dihydroxynaphthalene dihydrochloride⁷ and 1.1 g. of fused sodium acetate was covered with 85% formic acid and heated under the reflux for one hour. The excess acid was then removed by distillation and the residue dissolved in water. After filtering, the solution was neutralized with ammonia and allowed to stand until separation of the naphthimidazolehydroquinone was complete. The substance was colored bluish-gray due to oxidation; it was not isolated but was at once converted into the quinone by adding it to sufficient nitric acid (sp. gr. 1.4) to bring the material into solution. The orange quinone precipitated on the addition of a small amount of water. When crystallized from alcohol, it formed clusters of orange needles which darken at 210° but remain unmelted at 250° . It is insoluble in benzene or toluene and moderately soluble in alcohol or glacial acetic acid. The solution in concd. sulfuric acid is a deep orange-red; the alkaline solution is rose color. The quinone is readily reduced by sodium hyposulfite and, when the solution in sodium bisulfite is acidified, a salt of the hydroquinone separates.

Anal. Calcd. for $C_{11}H_6N_2O_2$: C, 66.66; H, 3.05. Found: C, 66.50, H, 3.17.

5. *E.m.f. Measurements.*—The results given in Table I were obtained by measuring the potential difference between a half-cell containing the quinone-hydroquinone solution and a hydrogen electrode half-cell containing the same solvent. The potentiometer was accurate to 0.5 mv. Titanous chloride solutions, containing approximately from 0.03 to 0.4% of this reagent, were prepared from the 20% standardized solution immediately before each determination. In those cases in which the solubility of the quinone is very slight, the solution was prepared by digesting an excess of the quinone with 300 cc. of the solvent at 60° , cooling to 20° and filtering. Judging from the solubility of phenanthrenequinone in water, which is 3.6×10^{-3} at 25° ,³⁰ the solutions of the quinones ranged in molar concentration from about this value to about 1×10^{-3} . The concentration of titanous chloride required to furnish a titration curve of suitable dimensions was determined in a preliminary experiment.

Most of the measurements require little comment, though it may be noted that with all of the compounds, with the exception of the first one listed in Table I, constant

ene at a pressure of 25 cm. in the presence of mercury vapor was illuminated by ultraviolet light for thirty-nine hours, at which time the pressure drop was 24 cm. At the end of this time further illumination did not cause a further pressure decrease.

In Experiment II a mixture of hydrogen at a pressure of 40 cm. and ethylene at 2 cm. in the presence of mercury vapor was illuminated until the pressure became constant at 40 cm.

In Experiment III ethane at a pressure of 66 cm. and mercury vapor were exposed to ultraviolet light for fifty hours, at the end of which time the pressure drop was less than 2%.

In a fourth experiment pure unilluminated ethane was used.

The mixtures in these four experiments were then analyzed in the positive-ray apparatus described by Hogness and Lunn.² By this method the gases are ionized by electronic impact and the ions are then sent through electric and magnetic fields. It is possible to plot the number of ions of a given mass against the mass. Due to the characteristics of the apparatus, ions of a definite mass are distributed about the point corresponding to the mass of the ion, so that it is necessary to use the area under the curve as a measure of the number of ions rather than the height of the peak. This measure of the number of ions assumes that the efficiency of ionization by electronic impact of the various molecular species is the same. In the case which we are about to consider this condition is probably closely obeyed. The results of these positive-ray analyses are summarized in Table I, where the amount of ethane, for convenience, is taken as unity.

potentials were reached only after considerable periods of time, and a complete titration often required three or four hours. In the case of the 2-phenylbenzotriazole-4,5-quinone-7-sulfonic acid, electrode equilibrium was established with great rapidity in aqueous solution, but the measurements in alcoholic solution were unsatisfactory because of the decomposition of the quinone. The first few points of the titration curve, instead of forming the usual inflection, fell on a straight line which included the point corresponding to the potential of the solution before any reducing agent had been added. This is clear evidence of the reaction of the quinone and the solvent with the production of reduction products and this conclusion is supported by the fact that the potential at half-reduction was not reproducible and was much lower than the value which might reasonably be predicted for the normal potential. Titration curves of exactly similar characteristics were obtained with 1-phenylbenzotriazole-4,5-quinone (I) and the results were consequently rejected.

A curious behavior was observed in carrying out measurements with 1-phenyl- β,β -naphthotriazole-4,9-quinone (X). On adding an increment of titanous chloride solution, the e.m.f. of the cell very slowly changed to a less positive value and finally became constant. When the quinone had been about half reduced, equilibrium was established much more rapidly, but somewhat beyond this point the cell potential fell in the normal manner after the addition of the reducing agent, remained poised at a constant value for a few minutes, and then began to rise. The effect was particularly evident toward the final stages of reduction. This behavior may be due to the action of the reducing agent on parts of the molecule other than the quinone grouping. By carrying out rapid titration in which the "poised potentials" were recorded, values for the normal potential were obtained which are probably not greatly in error, though the slopes of the titration curves, indicated by ΔE , deviated widely from the theoretical. In the case of the *p*-tolyltriazole derivative XI the situation was similar, though the potentials did not rise as rapidly as before and the results are somewhat more accurate.

Since thionaphthenequinone is the first substance of its type which has been found to give, in mixtures containing its reduction product, definite electrode potentials which conform to the usual electrochemical equation, it seems advisable to include further details concerning our experiments with this compound than are given in Table I. The results of a typical titration, together with the values for the normal potential which have been calculated from the equation $E_0 = E_{\text{cell}} - 0.0296 \log [\text{Oxid.}]/[\text{Red.}]$, are given in Table II. The oxidation-reduction half-cell

substances formed, we can calculate the final pressures in cm. of mercury of all the gases. The results of these calculations are collected in Table II.

From the experiments already reported in our former paper, as well as from the results of other investigators, it is shown that at least two primary processes occur

where Hg^* stands for the excited state, and

In the present set of experiments the formation of methane and propane demonstrate that a third primary process occurs by the breaking of the ethylene bond

It seems reasonable to assume that the amount of CH_2 formed is proportional to the amount of ethylene present.

We must now consider the reactions between the products of these primary reactions and the original substances to form the final products. It is clear at the outset that the chance of CH_2 adding molecular hydrogen must be very low, for otherwise the concentration of methane would be much higher or the concentration of propane much lower than was found. There remain, then, the following reactions to be considered

where C_2H_2^* is a molecule of ethylene which has been activated probably by loss of hydrogen.

From the postulated reactions and the final pressures of the products, we can calculate the amount of ethylene (measured in cm. of mercury) of the reaction

which is required to produce the calculated amounts of the above products. The results of these calculations are collected in Table III.

TABLE III
CALCULATED AMOUNTS OF ETHYLENE (CM. OF MERCURY)

Expt. no.	By reactions (5), (6) and (7)	By reactions (5), (6) and (8)
I	6.74	2.99
II	0.222	0.222
Ratio I/II	30.4	13.5

We have already assumed the amount of CH_2 formed to be proportional to the ethylene pressure, or 12.5 times as much in Experiment I as in

contained a gold-plated and a platinized platinum electrode, both of which were always used in making the readings. While with most compounds the two readings usually agree well, it was found that with thionaphthenequinone the gold-plated electrode easily became polarized and that the potentials recorded were inconstant, irreproducible and differed from those recorded on the platinized electrode, which behaved in normal fashion, by 2-10 mv. These readings were disregarded. No consistent results were obtained with either type of electrode in alcoholic solution.

We wish to acknowledge our indebtedness to the Cyrus M. Warren Fund of the American Academy of Arts and Sciences for a grant used to purchase the electrical instruments employed in this work.

Summary

1. On comparing the reduction potentials of the quinones of the naphthalene and phenanthrene series with quinones containing the 2-phenyltriazole nucleus in place of one of the benzene rings, it has been found that a striking similarity exists between this heterocyclic nucleus and benzene. The 1,2,3-triazole ring is similar to these other two and probably has the structure of the 2-phenyl derivative, for a quinone containing the 3-phenyltriazole grouping is much higher in potential than the corresponding triazolequinone or its 2-phenyl derivative.

2. Preliminary results indicate that the pyridine and the imidazole nuclei do not produce a lowering in the potential of quinones to which they are attached which is at all comparable with the effect of a phenylene group.

3. Heterocyclic analogs of anthraquinone do not bear the same relation to this substance which the angular isomers bear to phenanthrenequinone. A tentative explanation of these facts, based upon the *o*-quinonoid theory of the structure of anthracene, has been suggested.

4. The reduction potential of thionaphthenequinone, the first substance of its type to which the electrochemical method has been successfully applied, has been determined in aqueous solution.

BRYN MAWR, PENNSYLVANIA

Experiment II. If we compare this ratio with the required amount of CH_2 in Table III, we see that it agrees very closely if we assume mechanisms (5), (6) and (8), but it is less than half of that required for mechanisms (5), (6) and (7). We conclude, therefore, that Reaction (7) does not take place to an appreciable extent under these conditions. The tremendous decrease of butane with decrease of ethylene must be accounted for by an increased rate of hydrogenation of the activated ethylene molecules.

The fact that Reaction (7) does not take place is in agreement with the fact that the higher hydrocarbons are absent, for these would all involve reactions between three or more ethylene molecules or radicals formed from ethylene before complete hydrogenation took place.

At high pressures of ethylene, the chance of reaction between CH_2 and ethylene is large compared with the chance of CH_2 being completely hydrogenated, whereas at low pressures of ethylene almost all of the CH_2 is removed as methane. This is clearly shown by reference to Table I. The average pressure of ethylene in Experiment I is 12.5 times as high as in Experiment II. The amount of methane formed in Experiment II per unit amount of ethane is 12.2 times as high as that found in Experiment I, while the amount of propane decreases at the same time 16-fold.

We take pleasure in acknowledging our indebtedness to Mr. Hamline M. Kvalnes of this Laboratory for making the positive-ray analyses.

Summary

Mixtures of hydrogen and ethylene react when subjected to the action of excited mercury atoms. By positive-ray analysis it is shown that the products of reaction are methane, ethane, propane and butane. Mechanisms for the formation of these substances are proposed. It is demonstrated that the carbon-hydrogen bond in ethylene and the ethylene bond itself require less than 4.9 volts of energy for rupture.

UNSYMMETRICAL PHENANTHRIDONES. II. A NEW PREPARATIVE METHOD: 7-NITROPHENANTHRIDONE BY BECKMANN REARRANGEMENT OF 2-NITROFLUORENONE OXIME

BY F. J. MOORE AND E. H. HUNTRESS¹

RECEIVED AUGUST 1, 1927

PUBLISHED OCTOBER 5, 1927

Shortly after the discovery of the Beckmann rearrangement of oximes in 1884, Beckmann and Wegerhoff² attempted to expand the scope of the new reaction to the oximes of cyclic ketones. Studying fluorenone oxime as a typical example, they reported that heating with a mixture of acetic anhydride and hydrogen chloride in a closed tube effected only acetylation, and that the use of concentrated sulfuric acid as a rearranging agent yielded a mixture of sulfonic acids. After boiling the oxime with a solution of phosphorus pentachloride in phosphorus oxychloride, however, removal of the solvent left a viscous oil from which they were unable to isolate a chloride. Nevertheless, after treatment with water, the oil yielded a yellow powder from which a nearly colorless, chlorine-free compound melting at 287° was obtained. This material was formed in such small amount and proved so difficult to purify that after an analysis its definite characterization was abandoned.

Application of the usual principles of Beckmann rearrangement to the case of fluorenone oxime (I) indicates that the rearrangement product should have been phenanthridone (II).

At the time of Beckmann and Wegerhoff's work this substance was unknown, and although only four years later Graebe and Wander³ prepared the material by a method which demonstrated its structure, and their melting point of 293° was very close to that of Beckmann's product, no attempt to establish the identity of the two substances has ever been reported.

¹ This paper is constructed from a second portion of the thesis submitted by E. H. Huntress to the Faculty of the Massachusetts Institute of Technology, in January, 1927, in partial fulfilment of the requirements for the degree of Doctor of Philosophy. Owing to the death of Professor Moore, the junior author assumes responsibility for the statements in this article.

RESEARCHES ON THIAZOLES. XIV. THE SYNTHESIS OF 2-ORTHO- AND META-AMINOPHENYL-6-METHYLBENZOTHAZOLES; NEW ISOMERS OF DEHYDROTHIO-PARATOLUIDINE, AND OF INCIDENTAL COMPOUNDS¹

BY MARSTON TAYLOR BOGERT AND LEONARD SMIDTH²

RECEIVED AUGUST 2, 1927

PUBLISHED DECEMBER 10, 1927

In recent papers by Bogert and Allen,^{3,4} there have been described isomers of the well-known dye intermediate dehydrothio-*p*-toluidine carrying the methyl group in Positions 5 or 7, and the amino groups in various positions on the 2-phenyl nucleus. The present contribution supplements this by reporting additional isomers in which the methyl, but not the amino, group is located as in dehydrothio-*p*-toluidine itself.

These new isomers were synthesized in the same way as outlined in previous papers from these Laboratories dealing with other isomers, namely, by condensing the zinc salt of the appropriate aminothiocresol with *o*- or *m*-nitrobenzoyl chloride to the 2-nitrophenyl-6-methylbenzothiazole and then reducing the latter to the amine.

These amines should yield dyes corresponding to Chloramine Yellow (Colour Index No. 814), when their sodium sulfonates are oxidized by alkaline hypochlorite solution. This reaction followed a normal course with the *m*-aminophenyl derivative, giving a product of similar properties to Chloramine Yellow, which dyed cotton a much paler shade and was manifestly inferior to it. In the case of the *o*-aminophenyl derivative on the other hand, the reaction pursued an abnormal course and no Chloramine Yellow dye was obtained.

Experimental Part

2-(*m*-Nitrophenyl)-6-methylbenzothiazole.—An intimate mixture of 3 g. of zinc 2-amino-5-methylphenyl mercaptide with 3.7 g. of *m*-nitrobenzoyl chloride was heated at 100° for an hour while the viscous melt was well stirred. The pulverized cold fusion cake was warmed for an hour with *N* sodium hydroxide solution and the undissolved material then removed, washed, dried and crystallized from glacial acetic acid. Small yellow needles were obtained, m. p. 166° (corr.), readily soluble in chloroform, moderately soluble in boiling alcohol and practically insoluble in ether, acetone or benzene; yield, 1.4 g. or 58%.

⁴ Bogert and Allen, *This Journal*, **49**, 1315 (1927).

That it is not unreasonable to expect Beckmann rearrangement of fluorenone oxime is indicated by the studies of Wallach⁴ who showed that cyclomethylene ketoximes were quite generally rearranged by concentrated sulfuric acid to isoximes or lactams of amino acids, into which they could readily be converted by hydrolysis. Thus, cyclopentanone oxime yielded the six-membered piperidone, otherwise known as the lactam of δ -aminovaleric acid. Again, Beckmann and Liesche,⁵ in an article which appeared during the progress of this research, have effected a normal rearrangement both of quinone monoxime and of anthraquinone monoxime. Except for Beckmann's early work, however, the only reference to the possible rearrangement of fluorenone oxime itself is the report of Pictet and Gonset⁶ who found that when heated with zinc chloride at 260–280°, a 30% yield of phenanthridone identical with Graebe and Wander's product could be isolated. Although the conditions used by Pictet and Gonset were far more vigorous than those of an ordinary Beckmann transformation, their results strengthened our belief that Beckmann and Wegerhoff's reaction product was really phenanthridone.

Our interest in this reaction was based upon the hope of using the Beckmann rearrangement of substituted fluorenone oximes as a method for the preparation of substituted phenanthridones. Not only is the literature of these substances very fragmentary but the synthesis of certain monosubstitution products from the corresponding diphenic acid derivatives is a process of considerable length and difficulty.⁷

We have repeated Beckmann and Wegerhoff's experiments on the rearrangement of fluorenone oxime by phosphorus pentachloride and by the method of mixed melting points established the identity of the product with phenanthridone synthesized according to Graebe and Wander.³ The change apparently involves nearly quantitative conversion of the oxime to a chloride which hydrolyzes slowly or rapidly, according to conditions, to give excellent yields of phenanthridone. Since our purpose was merely to establish the validity of the rearrangement, we have not attempted to study its mechanism in detail.

Although fluorenone oxime itself can exist in but one form, theory predicts for each of the unsymmetrical monosubstitution products the possible existence of two stereo-isomers, according to whether the substituted nucleus is on the same or opposite side of the carbon-nitrogen double bond as the oxime hydroxyl group. Beckmann rearrangement of these isomers would be expected to yield two different but isomeric

tin was boiled for two hours, although a clear solution resulted after one hour's boiling. The acid solution was made strongly alkaline with 4 *N* sodium hydroxide solution and kept warm for an hour. The insoluble material, when removed and crystallized from alcohol, formed colorless needles, m. p. 181° (corr.), easily soluble, without appreciable fluorescence, in alcohol, acetone, ether, chloroform or benzene; yield, 0.85 g. or 64%.

Anal. Calcd. for $C_{14}H_{12}N_2S$: C, 70.00; H, 5.00. Found: C, 70.29; H, 5.14.

Sulfonation of 2-(*m*-Aminophenyl)-6-methylbenzothiazole.—A solution of 0.75 g. of the thiazole in 5 cc. of concd. sulfuric acid was cooled to 25° and 5 cc. of fuming (50% free SO_3) sulfuric acid added gradually while the temperature of the solution was maintained below 50°. After the solution had been kept at 40–50° for eight hours, it was entirely soluble in dilute ammonium hydroxide solution and the sulfonation was adjudged complete. It was poured upon cracked ice, the yellow flocculent precipitate collected, dissolved in warm dil. caustic alkali, the alkaline solution reprecipitated with sulfuric acid and the precipitate dried in the oven. The product was a dark brown solid; yield, 0.7 g.

A Yellow Dye Analogous to Chloramine Yellow.—A solution of 0.5 g. of the above sulfo acid in 100 cc. of water and 0.1 g. of sodium hydroxide, when oxidized at 10–15° by an aqueous solution of sodium hypochlorite, turned violet at first, then wine-red and cloudy. After it had stood for twenty-four hours, dil. sulfuric acid was added and the precipitate removed and dried. It formed a brown powder which gave a deep carmine-red color with concd. sulfuric acid, similar to that produced from Chloramine Yellow itself.

Comparative dyeing tests (2%) on cotton showed that the shades obtained were paler than those yielded by Chloramine Yellow, but that in other respects it resembled the latter closely.

2-(*o*-Nitrophenyl)-6-methylbenzothiazole.—When a mixture of dry *o*-nitrobenzoyl chloride and the zinc mercaptide was warmed, a reaction ensued with explosive violence and carbonization. When the chloride (2 cc.) and mercaptide (2 g.) were dissolved in glacial acetic acid (5 cc.), no reaction was perceived in the cold, so the solution was heated at 100° for thirty minutes, then poured into water and the precipitate collected and warmed for an hour with *N* sodium hydroxide solution, which changed it to a viscous tar from which no crystalline product could be obtained. It was therefore distilled under diminished pressure and a product secured which congealed to a yellow gum; yield, 0.9 g. or 57%. As this product looked like unpromising material for analysis, it was reduced (1 g.) directly to:

2-(*o*-Aminophenyl)-6-methyl-benzothiazole, by boiling it for three hours with concd. hydrochloric acid (10 cc.), water (90 cc.) and granulated tin (10 g.). The double salt formed remained insoluble in the acid solution and was removed and digested with warm caustic soda. The crude, insoluble amine was crystallized from alcohol and then appeared in rosetts of colorless needles, m. p. 137° (corr.); yield, 0.7 g. or 62%. The compound dissolved freely in alcohol, acetone, chloroform, carbon tetrachloride, ether, carbon disulfide or benzene. The solution in alcohol or acetone exhibited a fine blue fluorescence.

Anal. Calcd. for $C_{14}H_{12}N_2S$: C, 70.00; H, 5.00. Found: C, 69.90; H, 5.12.

The Acetyl Derivative, from the amine and acetic anhydride, crystallized from alcohol in colorless needles, m. p. 150° (corr.), easily soluble in alcohol, ether or benzene; yield, 77%.

Anal. Calcd. for $C_{16}H_{14}ON_2S$: C, 68.08; H, 4.96. Found: C, 67.64; H, 4.87.

The sulfonation of the *o*-aminophenyltoluthiazole (1 g.) was attempted with fuming sulfuric acid, by the process outlined for the *m*-isomer. The sulfonation solution when

substituted phenanthridones. Thus, assuming with Meisenheimer^{8,9,10} that *trans* interchange of radicals occurs, the expected products from the two forms of 2-nitrofluorenone oxime would be as follows

We have found, however, that treatment of 2-nitrofluorenone with hydroxylamine hydrochloride gives 75–85% yields of one of the two possible stereo-isomers, and that this product is rearranged by phosphorus pentachloride and oxychloride to give almost quantitative yields of 7-nitrophenanthridone. We have shown that the direct effect of the phosphorus halides is to replace chlorine for hydroxyl but that a mixture of two compounds is obtained which analyzes correctly for chlorine content yet is not readily separable by crystallization. Since reaction of this mixture with water yields 87% of 7-nitrophenanthridone with no indication of any of the 2-nitro isomer, we suspect that the mixture of chlorides represents an equilibrium between the oxime chloride and its rearrangement product, and that hydrolysis of the latter causes progressive conversion to the single 7-nitrophenanthridone as follows.

Whether this suspicion be confirmed or not, it is certain that oximation of 2-nitrofluorenone gives excellent yields of one stereo-isomer which undergoes smooth Beckmann transformation to give 7-nitrophenanthridone in yield of 90%. The process is therefore admirably suited to

poured upon ice gave a dark green, gelatinous precipitate which dried out in the oven to a hard, black solid; yield, 0.8 g. The color of an aqueous solution of the sodium salt was deep blue, which changed to dark green when acidified. Hypochlorite oxidation of this supposititious sodium sulfonate failed to yield any dye.

Summary

1. By the action of *o*- and *m*-nitrobenzoyl chlorides upon the zinc salt of 2-amino-5-methylphenyl mercaptan, the corresponding 2-nitrophenyl-benzothiazoles have been prepared.

2. Reduction of these nitro derivatives gave amines isomeric with dehydrothio-*p*-toluidine.

3. From the *m*-aminophenyl derivative, by hypochlorite oxidation of its sodium sulfonate, a direct cotton dye was prepared, presumably isomeric with Chloramine Yellow (Colour Index No. 814), but giving paler yellow shades. From the isomeric *o*-aminophenyl derivative, no similar dye could be obtained.

ULTRAVIOLET ABSORPTION SPECTRA OF CYCLOHEXENE, ETHYL ETHER, METHYL-NORMAL-AMYL ETHER AND ETHYLENE CHLOROHYDRIN. A CORRECTION TO OUR PREVIOUS ARTICLE¹ UNDER THIS TITLE AND REPLY TO DR. DE LASZLO²

By ALPHEUS W. SMITH, CECIL E. BOORD, CLYDE S. ADAMS AND CHARLES S. PEASE

RECEIVED AUGUST 4, 1927

PUBLISHED DECEMBER 10, 1927

The results contained in our previous paper have been challenged by Dr. de Laszlo with the contention that the absorption was in every case due to benzene. It is concluded "that benzene may have been present as an impurity either in the material or apparatus in amounts sufficient to explain the results as reported by these authors."

After a careful re-examination of ethylene chlorohydrin, methyl-*n*-amyl ether and ethyl ether in the light of these contentions we are compelled to admit that the results shown in our paper are due to benzene. It will be of general interest to know wherein this error arose.

As to cleanliness let it be said that it has been our unvarying practice to wash the absorption cells with chromic acid mixture after each run and that blank exposures through these same cells showed no absorption.

One comes then to the second alternative, namely, that the compounds examined contained benzene as a common impurity. A careful re-exami-

serve as a method of preparation for this latter substance, which, it should be noted, is that isomer most difficult to obtain by the synthetic series involving the isomeric 4-nitrodiphenamic acids and recently reported by us.⁷ The new method possesses the very real advantage of starting from the easily obtainable fluorene¹¹ instead of from phenanthrene, and of requiring only a few stages as compared with the diphenic acid procedure. Should the studies now in progress in this Laboratory show that other position isomers and substituents likewise yield only one of two possible fluorenone oximes, the utility of this method as a synthetic tool in the further elucidation of phenanthridone chemistry will be much increased.

Experimental Part

Fluorenone.—This was prepared according to Graebe and Rateneau¹² by oxidation of fluorene with sodium dichromate in glacial acetic acid solution. The fluorene was purified by distillation from 10% of its weight of solid potassium hydroxide; yield of fluorenone, 92%.

Fluorenone Oxime (I).—We employed the procedure of Spiegler,¹³ heating 8.5 g. of pure fluorenone with 6.6 g. of hydroxylamine hydrochloride in 80 cc. of 70% alcohol for three hours. The yield was 82% of the theoretical and the melting point 192–193° (195–196° corr.).

Beckmann Rearrangement of Fluorenone Oxime to Phenanthridone.—Five g. (1 mole) of fluorenone oxime was boiled under reflux for five hours with 7.5 g. (1.4 mole) of phosphorus pentachloride dissolved in 50 cc. (21 moles) of phosphorus oxychloride. The oxime rapidly dissolved in the mixture, imparting to it a pale orange color and liberating much hydrogen chloride. On completion of the reaction the phosphorous oxychloride was removed by distillation at ordinary pressure and the residual yellowish-red viscous oil was worked with water. This treatment soon changed it to a yellow powder which weighed 5.0 g., melted at 282–289° (corr.) and contained chlorine. One-half of this powder was boiled with 100 cc. of 50% sulfuric acid for one and one-half hours. After pouring onto ice, 2.1 g. of nearly white solid separated which, like the original, also melted at 282–289° (corr.). After three recrystallizations from glacial acetic acid, using Norit decolorizing carbon in the first, the product was pure white, free from chlorine and melted at 285–286° (293–294° corr.).

Although the appearance and behavior of this material assured us that it was phenanthridone, we confirmed this by the method of mixed melting points using for comparison phenanthridone prepared from diphenic acid in a previous research.¹⁴ Samples of known pure phenanthridone, our rearrangement product and a mixture of equal weights of these two in capillary tubes attached to the same thermometer melted simultaneously at 285–286° (293–294° corr.). This value is that recorded by Graebe for phenanthridone and substantiates the identity of the rearrangement product.

2-Nitrofluorene.—This substance was prepared by nitration of fluorene according to Diels;¹⁵ yield of 2-nitro isomer, 66%; m. p. 154–154.5° (corr.).

2-Nitrofluorenone.—Continuing Diels' method, the 2-nitrofluorene so obtained

¹¹ This hydrocarbon is sold by the Eastman Kodak Company.

was dissolved in acetic acid and oxidized with sodium dichromate; yield, 91%; m. p. 214–216° (219–221° corr.).

2-Nitrofluorenone Oxime (III or V).—Six g. of pure 2-nitrofluorenone was suspended in 240 cc. of alcohol and boiled for one and one-half hours with 3.5 g. of hydroxylamine hydrochloride dissolved in the least possible volume of water. The ketone soon dissolved and a much paler yellow, curdy material began to separate. After cooling and filtering, the product was washed free from chloride with alcohol and dried at 110°; yield, 75%; m. p., with decomposition, 262.5–263 (269–270° corr.).

Repeated attempts to purify the crude product by recrystallization from benzene, alcohol, glacial acetic acid or *n*-butanol led to the discovery that the more times it was recrystallized, the lower and wider became the melting-point range. At the time this observation was regarded as highly disturbing but from the results of our later work it seems probable that the lowering of the melting point of the oxime was due to progressive rearrangement to the Beckmann product under the influence of temperature and solvent. We finally concluded that attempts at purification were futile and used directly for analysis the product obtained from carefully purified ketone and melting sharply at 262.5–263° (uncorr.) with vigorous decomposition.

Anal. Calcd. for $C_{13}H_8N_2O_3$: C, 64.97; H, 3.36; N, 11.68. Found: C, 64.69, 64.85; H, 3.40, 3.33; N, 12.21, 12.01.

Hydrolysis.—Saponification of the oxime with concentrated hydrochloric acid yielded a yellow solid, which was identified as 2-nitrofluorenone by mixed melting point, and a filtrate which gave on evaporation a solid which instantly reduced Tollens' reagent and gave Mulliken's¹⁸ color tests for hydroxylamine.

Beckmann Rearrangement of 2-Nitrofluorenone Oxime.—Twenty-three grams of 2-nitrofluorenone oxime was mixed with 34.5 g. of powdered phosphorus pentachloride and 200 cc. of phosphorus oxychloride and gently boiled under reflux for four hours. The liquid was divided into two equal portions and the solvent removed from each by distillation. The product from part A was allowed to crystallize, was then ground up in a mortar and allowed to stand in water for an hour. The residual lemon yellow solid was washed free from chloride and phosphate and after drying at 110° was found to melt at 153–173° and to contain chlorine. The residual solid from evaporation of part B was suspended in dry benzene for 39 hours; the benzene was then distilled off and the solid worked up with water as in part A. The product contained chlorine and melted at 152–193°.

Examination of Chlorine Compound from Part A.—A sample of the 153–173° product from part A was extracted with benzene, yielding a yellow solid melting at 150–185°. To remove possible nitrophenanthridone produced by hydrolysis we soaked the solid in strong alcoholic potassium hydroxide solution for a few minutes but failed to note the red color which accompanies the solution of 7-nitrophenanthridone under such circumstances. The washed solid was pale greenish-white in color and melted over the same range as before. It was analyzed for chlorine by the Carius method.

Anal. Calcd. for $C_{13}H_7ClN_2O_2$: Cl, 13.72; for $C_{13}H_7Cl_2N_2O_2$: 25.38. Found: Cl, 12.88, 13.09.

¹⁸ Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York City, 1916, Vol. II, p. 30.

A sample of the product from part B was extracted with benzene in the same way and the product obtained was twice again recrystallized from benzene dried over sodium wire. The product melted at 155–170°. No alcoholic alkali treatment was employed. After drying at 50° in a vacuum the sample was analyzed for chlorine by the Carius method as before.

Anal. Calcd. for $C_{13}H_7ClN_2O_2$: Cl, 13.72; for $C_{13}H_7Cl_2N_2O_2$: 25.38. Found: Cl, 12.90, 13.00, 12.83, 12.99.

These data indicate that the materials from parts A and B are undoubtedly identical and that the chlorine content of samples purified by entirely different methods corresponds fairly well either to 2-nitrofluorenone-9-iminochloride (VII) or its rearrangement product 7-nitro-9-mesochlorophenanthridine (VIII) but not at all to 2-nitro-9,9-dichlorofluorene. The broad fusion range and its failure to change on repeated recrystallization suggest that we have an equilibrium mixture of the oxime chloride and its rearrangement product.

Conversion of Chlorine Compounds into 7-Nitrophenanthridone

Use of Chlorobenzene.—With the idea that a solvent more closely related to the substance might facilitate isomerization of one chloride to the other, 3 g. of crude chloride was boiled with 50 cc. of chlorobenzene. Nearly all of the solid dissolved and, after filtering and cooling, 0.50 g. of yellow solid giving only a slight test for chlorine and melting at 270–274° was deposited. This was purified by recrystallization from acetic acid, reprecipitation by sulfur dioxide from alcoholic potassium hydroxide solution and four subsequent crystallizations from acetic acid. The melting point of the yellow, chlorine-free substance was now 282–284° (uncorr.) and a mixture of it with known 7-nitrophenanthridone melted at the same temperature.

Use of Acetic Acid.—On the hypothesis that the production of 7-nitrophenanthridone from the chloride mixture would be facilitated by the presence of water in a mutual solvent, a sample of crude chloride melting at 150–170° was boiled with strong acetic acid for an hour. Hydrogen chloride was evolved and the solid obtained on cooling was free from halogen and melted at 285–292°. After purification from alcoholic alkali in the usual way, a bright yellow sample resulted, melting at 286–289° (uncorr.) and subliming in short, yellow needles like 7-nitrophenanthridone. The melting point of a sample of the latter was not depressed by admixture with the rearrangement product.

Use of 50% Sulfuric Acid.—With the original intention of hydrolyzing the oxime chloride to 2-nitrofluorenone, a sample of crude chloride was boiled with 50% c. p. sulfuric acid for over an hour. Hydrogen chloride was evolved as before, and upon dilution a yellow solid melting at 275–280° and free from halogen was obtained. Three recrystallizations from acetic acid raised the melting point to 284–285° (292–293° corr.). The melting point of its mixture with known 7-nitrophenanthridone melting at 284–285° (uncorr.) was the same.

Semiquantitative Study of Oxime Rearrangement.—Three g. of 2-nitrofluorenone oxime was refluxed for six hours with 4.5 g. of phosphorus pentachloride and 25 cc. of phosphorus oxychloride. The crude chlorine material obtained in the usual way melted at 150–170° (uncorr.) and weighed 3.11 g., corresponding to 96% of the theoretical. On boiling with 100 cc. of 50% sulfuric acid for one and one-half hours, dilution yielded 2.7 g. of crude product corresponding to 95% conversion of the chloride. After reprecipitation from alcoholic alkali it melted at 282–284° (290–292° corr.).

Anal. This was carried out on the rearrangement product melting at 284–285° (uncorr.). Calcd. for $C_{13}H_8N_2O_2$: C, 64.97; H, 3.36; N, 11.67. Found: C, 64.59, 64.51; H, 3.80, 3.89; N, 11.99, 11.99.

Summary

1. Fluorenone oxime has been shown to undergo a normal Beckmann rearrangement, yielding phenanthridone.
2. Oximation of 2-nitrofluorenone has been shown to yield mainly, if not entirely, one of two possible stereo-isomers.
3. Beckmann rearrangement of this 2-nitrofluorenone oxime to 7-nitrophenanthridone has been effected in yields of 90% and the method shown to be of preparative significance.

THE REARRANGEMENT OF ISOPROPYLETHYLENE TO TRIMETHYLETHYLENE AND THE PYROGENIC DECOMPOSITION OF PENTENE-2 AND TRIMETHYLETHYLENE

BY JAMES F. NORRIS AND RAYMOND REUTER¹

RECEIVED AUGUST 3, 1927

PUBLISHED OCTOBER 5, 1927

One of the major subjects under investigation in this Laboratory is the influence of structure on the reactivity of atoms and groups in organic compounds. The problem is being studied from two points of view; in one the rates at which the members of a series of analogous compounds react with a fixed substance is being studied;² in the other the conditions are being investigated under which certain molecular rearrangements take place and under which definite bonds are severed through the influence of heat and catalytic agents. This paper contains the preliminary results obtained in the study of three amylenes from the second point of view.

A detailed study of the properties of the amylenes is of particular interest on account of the fact that certain of these hydrocarbons are formed in the cracking of petroleum and are now of importance as sources from which amyl alcohols are prepared on a large scale.

The amylenes selected for study were pentene-2, trimethylethylene, and *isopropylethylene*. These compounds can be prepared readily from easily available substances and possess structures that make possible the study of the effect of the position of the double bond on rearrangements and the severing of the molecules under the influence of heat. In *isopropylethylene* the double bond is in position 1, in pentene-2 in position

¹ From the thesis presented by Raymond Reuter in partial fulfillment of the requirements for the degree of Doctor of Philosophy, 1925. Grasselli Scholar in Chemistry 1924-1925.

² Norris and Ashdown, *THIS JOURNAL*, **47**, 837 (1925).

2 and in trimethylethylene there are two radicals in combination with one of the unsaturated carbon atoms.

The chemical reactivity of these isomers with inorganic acids varies greatly with their structure.³ The work described below shows that similar differences are observed when the isomers are subjected to the action of heat.

It was found that *isopropylethylene* rearranged to trimethylethylene to the extent of 10% when the vapor was passed through a silica tube containing alumina heated to 450° and the contact time was 1/4 minute. When aluminum sulfate was used as the catalyst 47% of the hydrocarbon underwent rearrangement. Phosphoric acid was found to facilitate the reaction but was not as efficient as aluminum sulfate.⁴

These results led to a detailed study of the influence of catalysts on the pyrogenic decomposition of *iso*-amyl alcohol, which furnishes the best method for the preparation of *isopropylethylene*. It was found that the presence of a catalyst and its nature affected markedly the product obtained. In the absence of a catalyst no rearrangement of the *isopropylethylene* produced was observed up to 450°; at higher temperatures partial rearrangement took place. When alumina was used the elimination of water took place at lower temperatures, but the catalyst did not materially alter the proportions in which the two isomers were formed. When, however, *iso*-amyl alcohol was dehydrated under the influence of aluminum sulfate or phosphoric acid, the proportion of trimethylethylene formed was largely increased. The results of three experiments are illustrations of these conclusions. At 375° with alumina (contact time 1/4 minute) 48% of the alcohol passed through the tube was decomposed and there was no rearrangement of the *isopropylethylene* formed. At the same temperature with aluminum sulfate, about 90% of the alcohol was decomposed and 70% of the product was trimethylethylene. With phosphoric acid a higher temperature was necessary to get appreciable dehydration; at 405°, 50% of the alcohol was decomposed and about 50% of the product was trimethylethylene.

The fact that catalysts of an acidic nature caused the rearrangement of *isopropylethylene* to trimethylethylene led to a detailed study of the action of sulfuric acid on the former. It was found that contrary to the behavior of other olefins of this type it could not be converted into a secondary alcohol. When the acid used was sufficiently strong to react with the hydrocarbon the chief product was a polymer. A small amount of tertiary amyl alcohol was formed from the trimethylethylene produced as the result of rearrangement.

³ Norris and Joubert, *THIS JOURNAL*, 49, 873 (1927).

⁴ Ipatiew, *Ber.*, 36, 2000 (1903), has studied the rearrangement of *isopropylethylene* at higher temperatures in the presence of alumina, but he reports no results with other catalysts.

Experiments were carried out to determine whether or not trimethylethylene would rearrange to isopropylethylene; under the conditions used by us no rearrangement was observed.

When pentene-2 was heated under a variety of conditions there was no evidence of the formation of branched-chain hydrocarbons.

The Pyrogenic Decomposition of Pentene-2 and Trimethylethylene

Pentene-2.—The hydrocarbon was passed through a silica tube at such a temperature and rate that it was not completely decomposed. These conditions were used to prevent excessive cracking of the primary products of decomposition. The reaction was studied in detail at 600° when the hydrocarbon was passed through the tube at such a rate that the contact time was 15 seconds. The interior of the silica tube was covered with a thin coating of carbon deposited from the gas before the decomposition was brought about. This was done to avoid the catalytic effect of the silica surface at the beginning of the experiment. Under these conditions about two-thirds of the hydrocarbon was decomposed.

The quantitative determination of the components of the complex mixture formed presented a difficult task. There are no satisfactory methods for the analysis of mixtures of paraffins, olefins or di-olefins. The methods used in this investigation gave results of sufficient accuracy, however, to warrant conclusions as to a probable mechanism of the decompositions studied.

The mixture of products obtained as the result of the decomposition of pentene-2 in a carefully carried out experiment at 600° consisted of ($1/3$) hydrocarbons having a molecular weight greater than pentene and ($2/3$) hydrocarbons of a lower molecular weight. The former, which appear to be unsaturated, have not yet been fully investigated.

The hydrocarbons having molecular weights lower than that of pentene were studied in some detail. The only saturated hydrocarbon found to be present was methane. There appeared to be no free hydrogen produced. The number of moles of methane was approximately equal to the sum of the number of moles of the other hydrocarbons present. This fact indicates that the decomposition consisted in the removal of a methyl group from the end of the chain of pentene-2⁵ and a similar removal in the case of the decomposition of the products formed as the cracking progressed. The carbon atom numbered 1 in pentene-2 or the one numbered 5 may be removed in this way. It is possible that the hydrocarbon decomposes in the two ways, but it is probable, for the following reasons, that in the decomposition the larger proportion of pentene loses carbon 5. In order to bring about the same percentage decomposition of trimethyl-

⁵ Gault and Altchidjian, *Ann. chim.*, [10] 2, 209 (1924), obtained a similar result with other hydrocarbons.

ethylene and pentene-2 a higher temperature is required in the case of the former. This fact indicates that it is more difficult to break the bond between a methyl radical and an unsaturated carbon atom than between the radical and a saturated atom.

If it is first assumed that the carbon atom numbered 5 is removed, the decomposition can be formulated as follows. The breaking of the bond results in the formation of two radicals

The addition of hydrogen to these radicals leads to the formation of methane and butene-2

The hydrogen necessary is produced as a result of the partial or complete decomposition of some hydrocarbon, since carbon is deposited in the tube. It is also formed during the conversion of the butylene radical into butadiene

The amounts of butene and butadiene-1,3 formed were approximately the same. The sum of the number of moles of butene and of butadiene was two-thirds of the number of moles of methane—a fact that indicates that a part of the butene radical, the primary product of decomposition, underwent subsequent cracking with the formation of methane. The presence of propylene and ethylene in the gas was demonstrated. It is possible that some propadiene was formed from the butylene, but if present its amount was too small for identification.

If a decomposition of pentene-2 takes place in which the carbon numbered 1 is split off, the reactions would be similar to those just described, with the difference that butene-1 instead of butene-2 would be formed. The method of analysis used in the work did not differentiate between these hydrocarbons. The butene present was converted into a butyl chloride by adding hydrochloric acid. Both butenes give 2-chlorobutane.

In the mixture of hydrocarbons showing molecular weights lower than the molecular weight of pentene the components were found to be present approximately in the molecular ratios: CH_4 , 100; C_4H_8 , 30; C_4H_6 , 27; C_3H_6 , 21; C_2H_4 , 15. The percentages by weight of the products obtained were approximately as follows: pentene-2 recovered, 33; hydrocarbons of higher molecular weight than that of pentene-2, 15; methane, 7.8; butadiene, 8; butene, 8; propylene, 4; ethylene, 2.

As has been noted, these conclusions are drawn from the results of the use of analytical methods which are in part but roughly quantitative. The determinations of methane were accurate as the usual combustion method was used. The determination of total unsaturated gases and of ethylene was also reasonably accurate. The butadiene was determined as the tetrabromide, which was isolated from the product formed as the result of the addition of bromine to the unsaturated compounds. The

tetrabromide was obtained in part by crystallization from the solvent used in the bromination and in part by distilling the bromides formed. The amounts of butylene and propylene were calculated from (1) the amounts of the several products formed in the fractionation of the dibromides and (2) the result of the fractionation of the chlorides produced by adding hydrochloric acid to the unsaturated hydrocarbons. The quantitative results in the case of butylene and propylene are, therefore, approximations only.

Trimethylethylene.—At 625° the extent of decomposition of trimethylethylene was about one-half that of pentene-2 at 600°, and at 650° the decomposition was slightly more. At the latter temperature about 70% of the hydrocarbon was decomposed when the contact time, as in the case of pentene-2, was 14-15 seconds. The product of decomposition as in the case of the isomer consisted of approximately $\frac{1}{3}$ hydrocarbons of higher and $\frac{2}{3}$ lower molecular weights. As before, no free hydrogen was formed and about $\frac{1}{2}$ of the gases was methane. In the examination of the products formed as a result of the decomposition of trimethylethylene, analyses were made for the proportion in which compounds

containing the grouping $\begin{array}{c} \text{CH}_3 \\ | \\ \text{C} \\ | \\ \text{CH}_3 \end{array}$ were present. Such compounds react

rapidly with 60% sulfuric acid and with concentrated hydrochloric acid. About 30% of the gas produced in the reaction was rapidly absorbed by concentrated hydrochloric acid. About 20% of the gas consisted, therefore, of straight-chain unsaturated compounds. This latter conclusion is open to question, because the behavior of gaseous di-olefins with concentrated hydrochloric acid is not known. The 30% absorbed by the acid is, accordingly, a minimum figure for the olefins containing two methyl groups attached to an unsaturated carbon atom.

The liquid condensate from the decomposition was examined with 60% sulfuric acid for hydrocarbons of the type just mentioned. About 70% dissolved in acid of this strength. This fact leads to the conclusion that the higher hydrocarbons formed contained an appreciable amount of compounds having straight chains. No butadiene was found to be present in the gases.

As in the case of pentene-2 the ethylene formed was approximately 10 molar per cent. of the methane formed; also, the amount of propylene was greater than that of ethylene.

The facts established by the work up to the present indicate that the decomposition in the case of trimethylethylene can be formulated in a way similar to that given in the case of pentene-2

The radical from *isobutene* cannot form a butadiene without the severing of a carbon-carbon bond followed by the recombination of the carbon atoms in a straight chain. As this kind of rearrangement is improbable, the fact that no butadiene-1,3 was found appears reasonable.

It is possible that the hydrocarbon may break as indicated below

The unsaturated radical could by loss of hydrogen form butadiene-1,2, which might rearrange to butadiene-1,3, although the only rearrangement yet observed is one which produces an acetylene derivative. The addition of hydrogen would produce butene-2, which by subsequent decompositions and recombinations would produce compounds with a straight chain. The butene formed would on subsequent decomposition be converted into propylene and ethylene.

The work on the two pentenes suggests that for a full understanding of the changes involved the pyrogenic decomposition of propylene, the butylenes and the dienes of low molecular weight should be studied. The investigation will be continued in this direction.

The work involved the development of analytical methods. As relatively large quantities of the hydrocarbons were made, an opportunity was offered to prepare samples in a high state of purity for the redetermination of certain physical properties. These results are given in detail in the experimental part of the paper.

Experimental Part

The Preparation of the Compounds Studied

Isopropylethylene.—A number of methods for the preparation of this hydrocarbon have been described.⁶ The directions for the method outlined briefly here are more specific than those previously given and are based on a detailed study of the effects of the various factors involved.

Isopropylethylene was prepared by passing *iso*-amyl alcohol over an alumina catalyst heated at 375–450°. When an electrically heated silica tube 4 feet long and 1 inch in internal diameter was used and the alcohol was passed through at the rate of 1.6 moles per hour (contact time 1/4 minute) about 50% of the alcohol was converted into amylene and most of the rest was recovered.

Since the *iso*-amyl alcohol used contained about 10% of active amyl alcohol it was necessary to remove from the crude amylene the unsymmetrical methylethylethylene formed and any trimethylethylene produced by rearrangement of *isopropylethylene*. This was accomplished by shaking the crude amylene for an hour at 30–35° with an equal volume of 60% sulfuric acid. The two substances were contained in a stout bottle closed by a tightly fitting rubber stopper which was wired in place and through which a thermometer passed. The bottle was attached to a shaking machine in the form of a

⁶ See Norris and Joubert, (ref. 3) for references—also Adams, Kamni and Marvel, *Univ. Ill. Bull.*, 16, No. 43, 10 (1919), and *THIS JOURNAL*, 40, 1950 (1918).

swing agitated by a motor. By placing an electric light bulb over the bottle and covering the machine with a towel the temperature could be maintained at 30–35°.

After the treatment a few cubic centimeters of the hydrocarbon should be tested by shaking at 30–35° with 4 volumes of the acid. If there is no change in volume in 15 minutes the separation of trimethylethylene and unsymmetrical methylethylethylene from the isopropylethylene is complete. If the decrease in volume is marked the treatment of the entire amount is repeated. The number of treatments is determined by the proportions in which the isomers are present.

The hydrocarbon purified in this way was washed with a dilute solution of sodium hydroxide, dried over calcium chloride, refluxed with sodium and distilled. The isopropylethylene obtained boiled at 20–21°.

After standing for four days, a hydrocarbon separated from the sulfuric acid solution used in the purification of isopropylethylene. It boiled at 153–155°, a small fraction boiled up to 160°. The main fraction was apparently the dimer of unsymmetrical methylethylethylene. Its index of refraction was n_D^{20} , 1.4382.

Trimethylethylene.—A number of methods have been given for the preparation of this hydrocarbon. The material used in this research was made by heating tertiary amyl alcohol with 46% sulfuric acid. The alcohol dissolves in acid of this strength and when the mixture is gently heated trimethylethylene separates and distills off.

One experiment gave the following results: 610 cc. (491 g.) of tertiary amyl alcohol was added to a cold mixture of 400 cc. of concentrated sulfuric acid and 800 cc. of water. On distillation 360 g. of hydrocarbon (92% of the theoretical amount) was obtained. A careful study of the product, which boiled at 36.7–38.7°, showed that it contained a small amount of unsymmetrical methylethylethylene.

Pentene-2.—This hydrocarbon was prepared by dehydrating the secondary amyl alcohol manufactured from petroleum. The alcohol is slowly dehydrated when one volume of it is heated with 1.5 volumes of 46% sulfuric acid. It is prepared most readily by using 60% acid. The yield is 90% of the hydrocarbon boiling between 36.5 and 40°.

Pentene-2 Dibromide.—This compound is described by Wagner and Saytzeff,⁷ who found that it boiled at 178° (uncorrected). It was prepared in order to ascertain its index of refraction, which was used in the examination of the material obtained as a result of the addition of bromine to the products of the cracking of pentene-2. It was made by adding to pentene-2 (b. p. 36.3–36.4°) bromine dissolved in 4 volumes of carbon tetrachloride at about –20°. The product was fractionated through a column. It was found to boil with slight decomposition at 180.2 to 180.8° (thermometer in vapor) at 754 mm. The fraction boiling at 180.2 to 180.5° had an index of refraction n_D^{10} 1.5149 and n_D^{20} 1.5098.

Trimethylethylene Dibromide.—The boiling point of this compound at atmospheric pressure and its index of refraction are not recorded. It was prepared in the way described above and was found to boil with slight decomposition at 170–173°. The fraction boiling at 170–172° had the index n_D^{20} 1.150 and the one boiling at 172–173°, n_D^{20} 1.511.

2-Chloropentane.—This compound has been prepared by Przewalski⁸ who reports the boiling point 96–97° and index $n_D^{19.5}$ 1.4062. Clough and Johns⁹ give 96° (760 mm.). It appeared advisable to examine carefully the product formed as a result of the addition of hydrogen chloride to pentene-2. The formation of two isomers is possible, 2-chloropentane and 3-chloropentane. The latter compound is reported to boil at 103–105°.

A very pure sample of pentene-2 was used, which boiled at 36.4° at 760 mm.

⁷ Wagner and Saytzeff, *Ann.*, 179, 307 (1875).

⁸ Przewalski, *Chem. Zentr.*, II, 793 (1909).

⁹ Clough and Johns, *Ind. Eng. Chem.*, 15, 1030 (1923).

When 20 cc. of the hydrocarbon was shaken with 9 volumes of concentrated hydrochloric acid for five and one-half hours at room temperature and then allowed to stand for fifteen hours, only about 40% of the hydrocarbon reacted. When a similar mixture was shaken for ten hours and left standing eight hours, almost two-thirds of the hydrocarbon was converted into chloride. The combined products were fractionated. The chloride obtained boiled at 96.87–96.96° at 759 mm.; index, n_D^{20} 1.4084. It is probable that the chloride formed in this way is in large part, or wholly, 2-chloropentane.

Determination of Physical Properties

Boiling Points.—Samples of the compounds studied, prepared in the ways just described, were subjected to fractional distillation. As the hydrocarbons boiled at low temperatures, precautions were taken to avoid superheating during distillation and efficient cooling of the vapors was secured.

Two fractionating columns were used. One, referred to as the 20-inch column, measured 18 inches from the bottom to the side neck and 1.25 inches in diameter. It was filled with pieces of 5 mm. glass tubing approximately 10 mm. long, set on end. The tower was furnished with a still head through which water could be circulated. A thermometer was so placed in the side neck that the mercury was completely immersed in vapor.

A similar column of similar construction 10 inches long and 0.5 inch in diameter was used when small amounts of liquid were fractionated.

The boiling points of the three hydrocarbons were determined with an Anschütz thermometer, graduated in fifths of a degree, which had been calibrated against a standard thermometer graduated in twentieths of a degree and calibrated at the Physikalisch-Technische Reichsanstalt. The boiling point of tertiary amyl alcohol was determined with a thermometer graduated in fifths of a degree and calibrated at the Reichsanstalt.

Melting Points.—The melting points of the hydrocarbons were determined by cooling 5cc. samples contained in 6-inch test-tubes with liquid air, and taking the temperature of the change in state with a pentane thermometer graduated in degrees.

The melting point of tertiary amyl alcohol was determined with a 125cc. sample which was frozen and then introduced into a carefully dried Dewar tube. The melting point was observed with a thermometer graduated in twentieths of a degree which had been calibrated at the Reichsanstalt.

Density.—The density determinations were made with samples contained in a 14cc. Sprengel tube or in a specific gravity bottle. Two determinations were made at 15 and at 25°. Single determinations were made at the other temperatures. A thermostat which remained constant to 0.005° was used for the measurements at 25°. A battery jar 6 by 8 inches was used as a thermostat at 15 and 20°. When the temperature of the room was within 2 degrees of that of the bath, the temperature

of the latter remained within 0.1 degree for fifteen minutes or more. The observations at 30° were made in a similar way, but the temperature of the bath remained within 0.1 degree for about five minutes only. The weights are reduced to a vacuum basis.

Index of Refraction.—An Abbé refractometer was used which was supplied with a calibrated thermometer graduated in whole degrees. Duplicate observations checked to 3 in the fourth decimal place.

Isopropylethylene.—The slow distillation of 200 cc. of the hydrocarbon prepared as described above showed that the boiling point of the pure compound lies between 20.0 and 20.2° at 759 mm. An 85cc. sample, separated between these limits, was redistilled at 759 mm. through the 10-inch column. The result was as follows: boiling point at the beginning of the distillation 20.0°; when 3 cc. had condensed 20.05°; total distillate 7 cc., 20.10°; 65 cc., 20.15°; 75 cc., 20.20°. About 80% of the hydrocarbon boiling within 0.2° distilled between 20.10 and 20.15°. It is safe to say that the boiling point of isopropylethylene at 759 mm. is $20.10 \pm 0.05^\circ$.

Pentene-2.—Two liters of the hydrocarbon boiling within 1 degree was fractionated with the 20-in. column at 771 mm. The portion measuring 500 cc. which boiled between 36.50 and 37.00° when redistilled yielded 375 cc. boiling between 36.70 and 36.90° and of this 265 cc. boiled between 36.70 and 36.75°. From these results the boiling point of pentene-2 appears to be $36.72 \pm 0.05^\circ$ at 771 mm.

The same sample was redistilled when the barometer registered 760 mm. The boiling point at this pressure was $36.39 \pm 0.03^\circ$.

Trimethylethylene.—In preparing the hydrocarbon to be used in the determination of physical properties a sample of tertiary amyl alcohol was used which boiled within 0.1° and melted within 1°. It was thought that a pure hydrocarbon might be produced in this way. The result proved that dehydration of the alcohol takes place in more than one way. The chief product is trimethylethylene but some unsymmetrical methylethylene, which is said to boil at 31–33°, is also formed. There is no way of separating the isomers by chemical means.

A sample of 1700 cc. of the mixed hydrocarbons was fractionated. The first distillation yielded 1450 cc. boiling between 36.7 and 38.7°. There was no break in the curve when volumes of the distillate were plotted against temperature. The hydrocarbon was redistilled six times, rejecting each time the lower-boiling fractions. It was only in the sixth distillation that a fraction was obtained which when redistilled boiled within the original temperature range. This fraction contained 300 cc. and boiled from 38.23 to 38.48°; 205 cc. boiled between 38.31 and 38.42°; and 145 cc. between 38.38 and 38.42°. These results indicate that trimethylethylene boils at $38.40 \pm 0.04^\circ$ at 759 mm. When redistilled at 770 mm. the hydrocarbon boiled at $38.78 \pm 0.04^\circ$.

Tertiary Amyl Alcohol.—A sample of the alcohol prepared from petroleum was used.¹⁰ The material was refluxed with barium oxide and fractionated with a 20-inch column. A fraction containing 785 cc. when refractionated at 755 mm. yielded 695 cc. boiling between 101.50 and 101.61°. Of this, 570 cc. boiled between 101.55 and 101.61°.

These results indicate that tertiary amyl alcohol boils at $101.58 \pm 0.03^\circ$ at 755 mm.

The sample when redistilled at 766 mm. boiled at $101.97 \pm 0.03^\circ$.

The results of the determination of physical properties are given in the following table.

¹⁰ We are indebted to A. D. Little, Inc., for the tertiary amyl alcohol used in this research.

The Action of Heat on Isopropylethylene, Trimethylethylene and Pentene-2

Apparatus.—The tube which was used for studying rearrangement and cracking was made of silica. It was four feet long, one inch in internal diameter, wound with No. 18 Chromel "A" resistance wire and covered with asbestos magnesia pipe covering. Three and one-half inches of the tube projected at the inlet end and 8.5 inches at the outlet end. This arrangement made possible the use of corks. The outlet end was connected with a four foot, quarter-inch spiral condenser made of copper. The receiver was a 250-cc. flask, set in ice water and connected with a gasometer.

Temperature measurements were made with two thermocouples. The junctions were so placed that they were 11 and 5 inches from the inlet and outlet ends, respectively, of the heated part of the tube. At the higher temperatures it was necessary to heat the inlet end of the tube with a flame in order to realize an even temperature throughout. In a tube of this length it is necessary to have two pyrometers in order to be sure of the temperature throughout the length of the tube.

Catalysts.—The substances used were (1) aluminum sulfate. A sample of commercial alum was heated in an iron dish until the water of crystallization was just driven off. The porous material was used in the form of small lumps. (2) Aluminum oxide. The material used was Merck's precipitated "aluminum hydroxide" powder. It was heated

for about ten minutes at 900° in the silica tube and then allowed to cool to the desired temperature in a stream of air. (3) Phosphoric acid. The catalyst was prepared by heating lumps of pumice which had been soaked in sirupy phosphoric acid.

Methods of Analysis.—In studying the rearrangement of *isopropyl*-ethylene into trimethylethylene it was necessary to devise a method for the quantitative determination of the two hydrocarbons in the presence of each other.

When no other substance is present, a determination of the index of refraction of the mixture serves as a reliable method of analysis. The index of a mixture of the two hydrocarbons in equal quantities was found to be within 0.5% of the mean of the indices of the two hydrocarbons. The same agreement was found in the case of mixtures of trimethylethylene and pentene-2.

A large number of experiments were carried out with the three hydrocarbons alone and with binary mixtures in an endeavor to develop a method of analysis based on the use of sulfuric acid. The effects of temperature, concentration of the acid, time of shaking and the relative amounts of the components in the mixtures were studied. The temperature finally selected was 33–35°. When small quantities of the materials were used they were contained in glass tubes $\frac{1}{2}$ inch in diameter and having a capacity of 20 cc. Changes in volume were measured by means of a millimeter scale. The tubes were shaken by hand in a bath, the temperature of which varied less than two degrees.

When larger quantities were used the materials were placed in oil sample bottles and shaken in a machine provided with an electric light bulb so placed that the temperature of the bottles covered with a towel measured nearly constant at 33–35°. Although the temperature is above the boiling point of *isopropylethylene*, a tightly fitting rubber stopper wired in place withstood the pressure, which at 35° was about 1.5 atmospheres. The best conditions for analysis of mixtures containing trimethylethylene are as follows. One volume of the mixture is shaken at 33–35° with 4 volumes of 60% sulfuric acid until the volume of the upper layer remains constant. When 3 to 4 cc. of the mixture of hydrocarbons is used solution of the trimethylethylene is complete in about fifteen minutes. The volume of the residual hydrocarbon layer is a measure of the amount of *isopropylethylene* or pentene-2 in the mixture.

When these conditions are used with mixtures, neither *isopropyl*-ethylene nor pentene-2 is attacked nor do they contain any polymer produced from trimethylethylene. The method was tested with mixtures containing as much as 85% of trimethylethylene and was found to be accurate within 3% at the higher concentrations and more accurate than this with lower percentages of the soluble hydrocarbon.

The great difference between the rates at which hydrochloric acid, contained in a concentrated aqueous solution, adds to olefins that yield tertiary chlorides and to those that yield secondary chlorides led to the study of the reactions with the expectation of developing a method of analyzing mixtures of these types of unsaturated hydrocarbons.

While the results did not lead to an exact analytical method, they showed that a close approximation could be obtained of the minimum amounts of trimethylethylene and *isobutene* present in mixtures of hydrocarbons which did not contain two radicals linked to an unsaturated carbon atom.

A mixture of air and the vapor of the hydrocarbons was analyzed in an apparatus for gas analysis. The mixture was treated first with concentrated hydrochloric acid and then with a solution of sodium hydroxide. The process was repeated as long as the volume of the mixture decreased appreciably. There are two sources of error in the method. The hydrocarbons that form secondary chlorides react very slowly with the acid; consequently the absorption does not come to a definite end when the hydrocarbons forming tertiary chlorides are removed. A second source of error is due to the fact that the tertiary chlorides produced have an appreciable vapor pressure at room temperature. One error tends to counteract the other; the results obtained are not exact but approximate the truth sufficiently to be useful.

The Results.—The hydrocarbons were heated at various temperatures up to that at which decomposition began. Incipient cracking was recognized by the evolution of gas. The results are given in Table II.

TABLE II

THE ACTION OF HEAT ON *ISOPROPYLETHYLENE*, *TRIMETHYLETHYLENE* AND *PENTENE-2*

No.	Hydro-carbon	Catalyst	Temp., °C.	Contact time, seconds	Rate, moles per hour	Hydro-carbon passed, moles	Hydro-carbon re-covered, %	Con-version, %	Gas, liters at 22°

7	<i>Pentene-2</i>	Aluminum sulfate	350	15	2.1	.71	77	No <i>isopropyl-ethylene</i>	0
8	<i>Pentene-2</i>	Aluminum sulfate	450	16	1.7	.38	70	No isomers formed	0.1
9	<i>Pentene-2</i>	Phosphoric acid	525	12	2.0	.47	88	No isomers formed	0

Isopropylethylene rearranged to trimethylethylene, the extent of the change varying with the catalyst used. With one passage through the tube, alumina at 450° caused 10% conversion; phosphoric acid at 500°, 29%; and aluminum sulfate at 425°, 47%. The experiments in each case were carried out at the highest temperature at which cracking did not occur.

In experiment numbered 4 a mixture of *isopropylethylene* and trimethylethylene containing 29% of the latter was passed through the tube. Fifteen per cent. conversion took place, as the hydrocarbon recovered contained 44% of trimethylethylene.

Pentene-2 was not converted into any of its isomers under the conditions used.

The Rearrangement of *Isopropylethylene* to Trimethylethylene under the Influence of Sulfuric Acid.—Up to the present no one has succeeded in preparing the corresponding secondary alcohol from *isopropylethylene*, either by the addition of hydriodic acid¹¹ and subsequent hydrolysis or by treatment with sulfuric acid.³

The action of sulfuric acid on *isopropylethylene* was studied under conditions other than those already reported. Norris and Joubert did not observe any conditions under which *isopropylethylene* dissolved in sulfuric acid. We have found that when 1 cc. of the hydrocarbon is shaken with 1 cc. of 84% sulfuric acid at 35° for about ten minutes, a clear solution is obtained which almost immediately deposits an oil. Dilution of the clear solution as soon as formed yielded only a polymer which boiled at about 150°. When 69% sulfuric acid was used, the small amount of alcohol obtained proved to be tertiary amyl alcohol formed from the trimethylethylene produced as the result of the rearrangement of the *isopropylethylene*.

The experiment which showed that rearrangement takes place under the influence of sulfuric acid was carried out as follows: 100 cc. of carefully purified *isopropylethylene* (b. p. 20.1–20.2°) was shaken at 38° with 100 cc. of 60% sulfuric acid for one hour. The layer of hydrocarbon decreased 3.3% and that of acid increased 3.6%. The acid layer was neutralized with sodium hydroxide and distilled. Three cc. of an alcohol was obtained which boiled at 94–108°, three-fourths of it at 100–104°. Tertiary amyl alcohol boils at 102°. The alcohol dissolved in concentrated hydrochloric acid and was converted into a chloride which separated from the solution in about one minute. The *isopropylethylene* recovered was fractionated and yielded 3 cc. of a polymer which boiled below 160°.

The Rearrangement of *Isopropylethylene* to Trimethylethylene during the Dehydration of *Iso*-amyl Alcohol.—The fact that *isopropylethylene* rearranged to trimethylethylene under the influence of certain

¹¹ Wischnegradsky, *Ber.*, 10, 81 (1877) and *Ann.*, 190, 328 (1878).

catalysts led to a study of the effect of these catalysts when *iso*-amyl alcohol is used to prepare "amylene." The commercial variety of pentene sold under this name varies greatly in composition. The study of the reaction was extended with the view of developing methods for the direct preparation of either *isopropylethylene* or *trimethylethylene* from *iso*-amyl alcohol.

A number of the experiments carried out are listed in Table III. The results of the experiments numbered 1 to 3 show that when no catalyst is used the silica tube affects favorably the dehydration of the alcohol. When freshly glowing, 33% of the alcohol was changed to hydrocarbon. In the third experiment when the tube contained a slight deposit of carbon from two previous runs the conversion dropped to 9%. Increase in the temperature from 515 to 555° caused appreciable cracking to gaseous hydrocarbons. Experiments 4 and 5 show the influence of the rate of passage of the alcohol; doubling the rate decreased the conversion of alcohol to hydrocarbon from 41 to 36% and decreased slightly the percentage of the rearrangement of *isopropylethylene* to *trimethylethylene*.

TABLE III
DECOMPOSITION OF *ISO*-AMYL ALCOHOL BY HEAT

The effect of alumina as a catalyst is shown in experiments 6 to 12. Up to 450° it caused no rearrangement of the *isopropylethylene* produced

as the result of the dehydration of the alcohol. The hydrocarbon obtained contained 90% of *isopropylethylene*. The fusel oil *amyl alcohol* (b. p. 130–132°) used was shown by an optical test to contain 10% of active *amyl alcohol*. The latter yields when dehydrated unsymmetrical methyl-*ethylethylene*. At 375° the catalyst appears to decrease in activity with repeated use without reactivation by heating to redness. At 450° decrease in activity was not observed. At 500° cracking to gaseous hydrocarbons and some rearrangement to trimethylethylene take place.

Aluminum sulfate is the most active of the catalysts studied. At 345° dehydration of the alcohol took place to a greater extent than when alumina was used at 375°. It also was efficient in bringing about the rearrangement of *isopropylethylene*; the product contained but 21% of the latter hydrocarbon.

Phosphoric acid closely resembled alumina in its catalytic influence on the dehydration of the alcohol. It caused, however, more rearrangement of the *isopropylethylene* produced, but at the higher temperatures did not produce the cracking to gases observed when alumina was used.

The results show clearly that if it is desired to prepare *isopropylethylene* from *iso-amyl alcohol* by catalytic dehydration by heat, alumina should be used as the catalyst and the temperature should be near 450°. If it is desired to get the largest yield of trimethylethylene by the reaction, aluminum sulfate at 345° is the best catalyst.

Comparison of the results of the study of the rearrangement of *isopropylethylene* when the pure hydrocarbon is heated and when the rearrangement takes place during the dehydration of *iso-amyl alcohol* shows that the relative effectiveness of the catalysts is the same in both cases. The extent of rearrangement was greater in all cases when the alcohol was dehydrated.

The Cracking of Pentene-2 and Trimethylethylene.—The results obtained in the study of these hydrocarbons are given in Table IV.

The gases formed were analyzed as follows: (1) Total unsaturation by means of bromine water; (2) unsaturated hydrocarbons other than ethylene by means of 87% sulfuric acid; (3) methane by explosion with air after removal of unsaturated compounds; (4) total unsaturated compounds by fractionating the dibromides obtained when the gas was treated at –20 to –10° with bromine dissolved in carbon tetrachloride; (5) fractionation of the compounds formed as the result of the addition of concentrated hydrochloric acid.

(6) The liquid condensate was treated with 60% sulfuric acid for compounds containing two radicals linked to an unsaturated carbon atom and was (7) fractionated and the part boiling below 34° was (8) treated with bromine at –17 to –10° and the product fractionated and (9) with concentrated hydrochloric acid and the products fractionated.

Summary

1. The rearrangement of *isopropylethylene* to trimethylethylene produced by heat is markedly affected by catalysts. The efficiency increases in the order alumina, phosphoric acid, aluminum sulfate.

2. The rearrangement of *isopropylethylene* to trimethylethylene which takes place when *iso*-amyl alcohol is dehydrated by heat is slightly greater than when the hydrocarbon is heated. The efficiency of the catalysts in causing rearrangement is in the same order as in (1) above.

(3) Under the conditions used trimethylethylene did not rearrange to *isopropylethylene*.

(4) When pentene-2 was heated the results showed that no branched-chain hydrocarbons were formed.

(5) The pyrogenic decomposition of pentene-2 and trimethylethylene yielded gaseous and liquid hydrocarbons which were analyzed quanti-

tatively for the following hydrocarbons: methane, butene, butadiene, propylene, ethylene, higher hydrocarbons. The results lead to an interpretation of the mechanism of the decompositions.

(6) *Isopropylethylene* is stable toward diluted sulfuric acid but can be made to rearrange to trimethylethylene to a slight extent by the action of acid of such a concentration that polymerization does not take place appreciably.

(7) The boiling point, melting point, densities at various temperatures and index of refraction of trimethylethylene, pentene-2, *isopropylethylene* and tertiary amyl alcohol were redetermined with carefully purified material.

THE REACTIVITY OF ATOMS AND GROUPS IN ORGANIC COMPOUNDS. II. SECOND CONTRIBUTION ON THE RELATIVE REACTIVITIES OF THE HYDROXYL-HYDROGEN ATOMS IN CERTAIN ALCOHOLS

BY JAMES F. NORRIS AND FRANK CORTESE¹

RECEIVED AUGUST 3, 1927

PUBLISHED OCTOBER 5, 1927

In a former paper² from this Laboratory the results were given of the study of the rates at which certain alcohols react with *p*-nitrobenzoyl chloride, and it was shown that the rates, which varied greatly, could be taken as a measure of the relative reactivities of the hydroxyl-hydrogen atoms in these alcohols. As certain striking relationships were indicated from the results obtained with the eleven alcohols investigated, the work was continued and eighteen additional compounds were studied. The alcohols were so selected that the results would show the influence of structure on the reactivity of the hydroxyl-hydrogen atom, especially as this reactivity is affected by lengthening of the carbon chain and by the position of a side chain with reference to the hydroxyl group.

Sufficient data have been obtained from the investigation of these twenty-nine alcohols to warrant definite conclusions. The results are in accord with the well-known qualitative differences in chemical behavior between the several types of alcohols; but they have, in addition, a quantitative significance, and throw some light on the change in the atomic bonding between oxygen and hydrogen produced by changes in the structure of the radical with which the hydroxyl group is combined.

¹ From the thesis of Frank Cortese, Grasselli Fellow in Chemistry, 1925-1926, presented in partial fulfillment of the requirement for the degree of Doctor of Philosophy, 1926.

² Norris and Ashdown, *THIS JOURNAL*, **47**, 837 (1925).

The effect of the substitution of a hydrogen atom by a methyl radical in a series of normal alcohols is noteworthy. For example, such replacement of an α -hydrogen atom in ethyl, propyl, butyl and amyl alcohols, respectively, caused a decrease in the reactivity of hydroxyl-hydrogen atom of the same order of magnitude in the four cases. Similar results were obtained when the methyl radical was in the beta, gamma and delta positions, although the percentage effect differed in the various positions.

Objections have been raised to the use of reaction velocities in the comparison of the chemical behavior of compounds. These objections are based upon the fact that the rate at which a reaction proceeds is markedly affected by conditions, some of which are not under control, such as, for example, the presence of unrecognized catalytic agents. The relationships indicated above were drawn from the results of the study of a large number of independent reactions and could not have been obtained if unrecognized factors that influenced the results were involved. An important deduction from the work is, therefore, that velocity constants when determined under fixed conditions can be used in the quantitative interpretation of chemical behavior.

All synthetic methods used in organic chemistry are based on the reactivities of the atoms involved in the changes which result in the desired syntheses. Quantitative measurements of these reactivities are largely lacking and any additional knowledge in this field will advance the science from the point of view of synthesis, and will be useful in enlarging our knowledge of bonding between atoms. The work described in this paper will make possible a more intelligent use of alcohols in syntheses involving the hydroxyl-hydrogen atoms of these compounds, and will be helpful in interpreting the effect of structure on the lability of the hydrogen-oxygen bond.

The methods used in the determination of the velocity constants of the alcohols were identical with those reported in the earlier communication.² The constant for *n*-butyl alcohol was redetermined in order to find out if the conditions of experimentation were identical with those used in the earlier investigation. The results checked the value previously obtained within the limit of accuracy of the work. In order to facilitate comparisons the constants of all the alcohols studied up to the present are given in Table I. The alcohols reported on in this paper are listed in Table II.

The study of the results given in Table I leads to the following conclusions.

(1) The lengthening of the carbon chain in normal primary alcohols results in a decrease in the reactivity of the hydroxyl-hydrogen in the first three members of the series; the constant increases progressively with the next three members and then decreases again.

TABLE I

SECOND ORDER VELOCITY CONSTANTS FOR THE REACTIONS BETWEEN ALCOHOLS AND *p*-NITROBENZOYL CHLORIDE

Temperature, 25°. Concentration of each reactant 1 mole in 1000 g. of ether taken as unity. Time in hours.

Normal primary alcohols	<i>k</i>	Secondary alcohols	<i>k</i>
Methanol.....	0.184	Propanol-2.....	0.010
Ethanol.....	.085	Butanol-2.....	.0074

Methyl-3-pentanol-1.....	.077	Benzyl.....	0.017
Methyl-3-hexanol-1.....	.075	β -Phenylethyl.....	.040
Methyl-4-pentanol-1.....	.068	γ -Phenylpropyl.....	.020
		α -Phenylethyl.....	.00052
		α -Phenylpropyl.....	.00050
		α -Phenylbutyl.....	.00050

In the case of the secondary alcohols with the hydroxyl group in position 2 the constant decreases with the first three members of the series and then increases.

(2) The introduction of a methyl radical as a side chain in primary alcohols has a marked effect on the constant. This effect is greatest in position 1; it decreases as we pass to positions 2 and 3 and begins to increase in position 4. The alternations in this effect are similar to, though greater than, those brought about by lengthening the chain—the periodicity is in cycles of 3.

(3) The percentage reduction in the constant brought about by the replacement of a hydrogen atom in position 1 by a methyl radical is of the same order of magnitude whatever the length of the chain. The constant of *isopropyl* alcohol is 11.7% of the constant of *ethyl* alcohol; that of secondary *butyl* alcohol is 11.2% of the constant of *n-propyl* alcohol; the constant of *pentanol-2* is 8% that of *n-butyl* alcohol; and the constant of *hexanol-2* is 8.2% that of *amyl* alcohol.

(4) When a methyl radical replaces a hydrogen atom in position 2 its effect on the constant is much less. The constant of *isobutyl* alcohol is 46.9% of that of *n-propyl* alcohol; the constant of *methyl-2-butanol-1* is 48.6% that of *n-butyl* alcohol; and the constant of *methyl-2-pentanol-1* is 44.3% that of *n-amyl* alcohol.

(5) When a methyl radical replaces a hydrogen atom in position 3 the effect almost disappears. The constant of *iso-amyl* alcohol is 98%

that of *n*-butyl alcohol; and the constant of methyl-3-pentanol-1 is 97% that of *n*-amyl alcohol.

(6) When a methyl radical replaces a hydrogen atom in position 4 the effect now begins to increase. The constant of methyl-4-pentanol-1 is 86% that of *n*-amyl alcohol.

(7) The relationships between the constants of primary and secondary alcohols containing the same number of carbon atoms are as follows. The constant of the secondary alcohols containing 3, 4, 5 and 6 carbon atoms are, respectively, 15.8, 10.0, 7.5 and 7.6% those of the corresponding primary alcohols. In this case the effect increases with increasing molecular weight in the case of the first three members of the series.

(8) The relationships between the constants of tertiary and primary alcohols containing four and five carbon atoms are, respectively, 3.7 and 3.2%.

(9) The effect of the position of the hydroxyl group in a straight chain of carbon atoms is great. The constants of pentanol-1, pentanol-2 and pentanol-3 are in the ratio 1 to 0.075 to 0.045.

(10) In the case of the aromatic alcohols there is an alternation in the value of the constant as the phenyl radical is removed from the hydroxyl group. The depression of reactivity produced by the replacement of a hydrogen atom by phenyl is so great that the secondary alcohols containing this group in position 1 had the smallest constants measured.

The striking relationships between the constants of alcohols of similar structure indicate clearly that the results are significant in regard to the effect of the position of a substituent on the hydrogen bond in alcohols. It is hoped to interpret later the results in terms of the electronic theory of the bonding of atoms in organic compounds. Further work must be done, however, before this is attempted. The relationships indicated hold when the hydroxyl-hydrogen is replaced by the *p*-nitrobenzoyl radical. It is possible that they may be found to be different when another atom or group replaces this hydrogen atom. The speed with which two molecules interact depends at least in part on the tendency of the atoms eliminated to unite and the tendency of the radicals formed to combine with each other. It is interesting to note in this connection that the velocity constant of *isopropyl* alcohol is 11.7% of that of ethyl alcohol when measured by *p*-nitrobenzoyl chloride as a second order reaction in ethereal solution, and that the velocity constant of *isopropyl* alcohol is 9.4% of that of ethyl alcohol when measured as first order reactions by diphenyl-chloromethane dissolved in a large excess of the respective alcohols.

Work is now in progress on the study of rates at which alcohols react with sodium and with potassium. As the result of this type of reaction, hydrogen is eliminated and the hydroxyl-hydrogen is replaced by a strongly electropositive metal.

* Note: The extent to which the reactions had proceeded at any time was determined by the titration of the hydrochloric acid produced. The values given above for the per cent. conversion have been corrected for the small amount of hydrochloric acid formed by hydrolysis from the acyl chloride during the titration.

It was found with these alcohols, as was the case with those studied earlier, that the velocity constant decreased slowly in value after a certain percentage of the alcohol had been converted into ester. The values given in Table III are calculated from the results obtained up to the time when the decrease in the constant began. It can be seen from the table that in the case of primary alcohols the reaction fulfilled the requirements of one of the second order up to from 20 to 35% conversion to ester. In the case of secondary alcohols the decrease in the constant began when from 4 to 7% conversion had taken place; and in the case of tertiary alcohols the change occurred at a lower conversion.

It is probable that the reaction may not be one of the second order—that a more complex mechanism is involved—but the results show that at the beginning of the reaction the requirements of the equation for a reaction of this type are fulfilled; and comparisons under these circumstances are justified. It should be noted that the method of calculating second-order velocity constants has been shown in the past to give real constants only when reactions are carried out at very low concentrations—

in certain cases as low as 0.02 normal. Further, constants calculated from results obtained at different concentrations do not agree except when the concentrations used are very small.

It was impossible to determine with a reasonable degree of accuracy the velocity constants of the reactions reported in this paper at lower concentrations than 0.2 *N*. The degree of accuracy of the analytical methods used and the sources of error that could not be eliminated made work at lower concentrations inadvisable.

In order to study the influence of change in concentration in the constants, experiments were carried out with four alcohols with solutions made by dissolving, respectively, 1, 0.5 and 0.2 moles of the alcohols in 1000 g. of ether. The values are given in Table IV.

TABLE IV

EFFECT OF CONCENTRATION ON THE VELOCITY CONSTANT OF THE REACTION BETWEEN ALCOHOLS AND *p*-NITROBENZOYL CHLORIDE DISSOLVED IN ETHER

Alcohol	Moles of each reactant in 1000 g of ether	<i>k</i>
Methyl-2-butanol-1	1.0	0.036
Methyl-2-butanol-1	0.5	.019
Methyl-3-butanol-1	1.0	.073
Methyl-3-butanol-1	0.5	.032
Methyl-3-butanol-1	.2	.011
<i>n</i> -Amyl	1.1	.079
<i>n</i> -Amyl	0.5	.048
<i>n</i> -Amyl	.2	.034
<i>n</i> -Hexyl	1	.085
<i>n</i> -Hexyl	0.5	.054
<i>n</i> -Hexyl	.2	.035

The constants tabulated show in all cases that the values decrease rapidly with decreasing concentration. It is important to note, however, that the order in which the alcohols stand, as measured by the reactivity of their hydroxyl-hydrogen atoms, is the same irrespective of the concentration at which they are compared. The earlier results with methyl and ethyl alcohols led to the same conclusion.

The cause of the progressive change in velocity constant is being studied with the hope of elucidating the mechanism of the reactions involved. It is possible that the reactions are reversible or that the ester and hydrochloric acid formed react. If either is the case, the use of the usual expression for calculating a second-order velocity constant is warranted only in the early stages of the reaction before the secondary reaction becomes significant. The constants given are based on this assumption.

Summary

1. The second order velocity constants for the reaction between *p*-nitrobenzoyl chloride and the following alcohols have been determined:

pentanol-1, hexanol-1, heptanol-1, methyl-2-butanol-1, methyl-2-pentanol-1, methyl-3-butanol-1, methyl-3-pentanol-1, methyl-3-hexanol-1, methyl-4-pentanol-1, pentanol-2, hexanol-2, pentanol-3, heptanol-4, methyl-2-butanol-2, methyl-3-pentanol-3, α -phenylethyl, α -phenylpropyl and α -phenylbutyl alcohols.

2. The results obtained, together with those from an earlier investigation of the lower fatty alcohols, make possible definite conclusions as to the effect of structure on the reactivity of the hydroxyl-hydrogen atoms of alcohols.

RESEARCHES ON QUINAZOLINES. XXXVIII. THE SYNTHESIS OF SOME NEW ANALOGS OF CINCHOPHEN AND INTERMEDIATE PRODUCTS

BY MARSTON TAYLOR BOGERT AND EUGENE MILLER MCCOLM¹

RECEIVED AUGUST 3, 1927

PUBLISHED OCTOBER 5, 1927

Our knowledge of the pharmacodynamics of the quinazoline group is scattering, fragmentary and meager. It, therefore, seems to us worth while to endeavor to contribute something to this field, not only with the object of throwing additional light upon the connection between chemical constitution and physiological effects, but also in the hope of discovering new compounds of therapeutic value. In this undertaking we have been so fortunate as to enlist the valuable coöperation of two distinguished pharmacologists, Professors Arthur D. Hirschfelder, of the University of Minnesota, and Elbert W. Rockwood, of the State University of Iowa, whose investigations will be published in appropriate journals.

The syntheses recorded in this paper were for the purpose of obtaining quinazoline derivatives of cinchophen (atophan) type, carrying a carboxyl group in Position 4 and hydroxylated phenyls in Position 2, since the preliminary pharmacological examination of the di-ammonium salt of 2-phenylquinazoline-4,2'-dicarboxylic acid, synthesized by Bogert and Nabenhauer,² had given results which looked both interesting and promising.

From these carboxylic acids, ethyl esters also were prepared, giving compounds analogous to acitrin; while the 2-hydroxyphenyl-4-carboxylic acids are intermediate between our 4,2'-dicarboxylic acid and the well-known hexophan of the cinchophen series.

These 2-hydroxyphenylquinazolines were synthesized because Kalle and

¹ This research was made possible by a generous grant from the Sigma Xi Foundation, for whose assistance we are most grateful.—M. T. B. and E. M. McC.

² Bogert and Nabenhauer, *THIS JOURNAL*, **46**, 1702 (1924).

Company took out a patent³ in 1915 for the manufacture of 2-hydroxy-phenylquinoline-4-carboxylic acids, in which they claimed that their action was similar to that of cinchophen, but without its bitter taste or irritating action upon the stomach, that the hydroxyl groups endowed them with pronounced antiseptic and antipyretic properties, that they exhibited a definite beneficial action against the plasmodia of malaria similar to that of quinine and that they were also of value in the treatment of pertussis.

The plan of synthesis followed that developed by Bogert and Nabenhauer,² and consisted in the preparation of the substituted *o*-amino-acetophenone, oxidation of this to the corresponding isatinic acid and the conversion of the latter into the quinazoline derivative by heating it with alcoholic ammonia under pressure.

Experimental Part

Quinazoline itself, required for an investigation which will be reported later, was prepared from *o*-nitrobenzaldiformamide by a modification of the excellent method of Riedel.⁴ The yield of pure *o*-nitrobenzaldiformamide (m. p. 178°, corr.) was 70%. It was converted into quinazoline as follows.

To a mixture of 20 g. of finely pulverized diformamide with 60 g. of zinc dust, there were slowly added 240 g. of cracked ice and then 80 g. of glacial acetic acid, while the mixture was being well shaken. When a 25% solution of acetic acid was employed, with external cooling instead of using cracked ice in the mixture, local superheating occurred and the yield of quinazoline was much less. After the reduction had been completed by shaking the mixture for about an hour, with frequent additions of small amounts of zinc dust, the acid solution was filtered from the excess of zinc dust. Sufficient caustic alkali (400 cc. of 50% sodium hydroxide solution) was added to this filtrate to redissolve the zinc hydroxide precipitated, the alkaline solution was extracted repeatedly with ether, the ethereal extracts dried over sodium sulfate, the solvent evaporated and the residual quinazoline purified by crystallization from petroleum ether or by distillation; yield of pure product, m. p. 48°, 10 g. or 93%.

Attempts were made to use a crude *o*-nitrobenzaldehyde, containing some of the *m*-nitro isomer, in place of the pure *o*-compound, but it was found that this necessitated a laborious separation of the formamide condensation products and it was, therefore, abandoned.

Salicyl Chloride was prepared from sodium salicylate and thionyl chloride by the process of Kopetschni and Karczag,⁵ which was found preferable to that of Wolfenstein.⁶ *o*-(*o*-Nitrobenzoylamino)-acetophenone, $\text{O}_2\text{NC}_6\text{H}_4\text{CONHC}_6\text{H}_4\text{COCH}_3$.—To a vigor-

ously agitated dispersion of 8 g. of *o*-amino-acetophenone in 100 cc. of a 10% aqueous sodium hydroxide solution, there was added 20 g. of *o*-nitrobenzoyl chloride. The mixture was thoroughly shaken while the flask was well cooled externally. When the odor of the acid chloride was no longer perceptible, the precipitate was collected and crystallized from alcohol. Colorless needles were obtained, m. p. 156° (corr.); yield, 13 g. or 78%.

Anal. Calcd. for $C_{15}H_{11}O_4N_2$: C, 63.37; H, 4.26. Found: C, 63.75; H, 4.45.

o-(*m*-Nitrobenzoylamino)-acetophenone, prepared in a similar manner and in approximately the same yield, formed colorless needles, m. p. 170° (corr.).

Anal. Calcd. for $C_{15}H_{11}O_4N_2$: C, 63.37; H, 4.26. Found: C, 63.32; H, 4.30.

o-Salicylamino-acetophenone, $HOC_6H_4CONHC_6H_4COCH_3$.—A benzene solution of 20 g. of salicyl chloride and 15 g. of *o*-amino-acetophenone was refluxed until the evolution of HCl ceased. The solution gradually darkened during this heating and, when finally permitted to cool, a mass of brown needles separated which when decolorized and crystallized from alcohol appeared in colorless needles, m. p. 135° (corr.); yield, 17 g. or 59%.

Anal. Calcd. for $C_{15}H_{11}O_3N$: C, 70.58; H, 5.14. Found: C, 70.62; H, 4.90.

Attempts to condense salicyl chloride with the amino-acetophenone in the presence of either alkali or pyridine were unsuccessful.

o-(*p*-Acetoxybenzoylamino)-acetophenone, $CH_3COOC_6H_4CONHC_6H_4COCH_3$.—To a vigorously shaken dispersion of 8 g. of *o*-amino-acetophenone in 200 cc. of 5% aqueous sodium hydroxide solution, there was added 20 g. of *p*-acetoxybenzoyl chloride, while the flask was cooled under tap water and the shaking was continued until the odor of the acid chloride had disappeared (long continued contact of the acetate so formed with excess of dilute caustic alkali solution gradually causes hydrolysis of this ester). The precipitate, when collected and dried, melted at 95°; yield, 15.2 g. or 89%. Recrystallized from alcohol to the constant melting-point of 97.5° (corr.), it formed colorless plates; yield, about 75%.

Anal. Calcd. for $C_{17}H_{15}O_4N$: C, 68.66; H, 5.09. Found: C, 68.60; H, 5.12.

Dilute aqueous solutions of caustic soda, hydrochloric or acetic acid, when warm, hydrolyzed both the ester and amide unions, giving *p*-hydroxybenzoic acid.

o-(*p*-Hydroxybenzoylamino)-acetophenone was obtained from the foregoing aceto derivative. The problem was to hydrolyze the ester grouping without simultaneous hydrolysis of the amide union, and two methods of accomplishing this were found. One was based upon the greater sensitiveness of the ester grouping to the continued action of cold dilute caustic alkali, and the other upon the greater stability of ethyl acetate.

In the former case, 15.2 g. of unrecrystallized acetate was shaken with 200 cc. of 5% sodium hydroxide solution until the solid was dissolved completely (three hours). Then the solution was acidified and the precipitate removed, dried and crystallized from 95% alcohol. Colorless needles were obtained, m. p. 219° (corr.); yield, 11.8 g. or 90%.

By the other method, 1 g. of the acetate was dissolved in 20 cc. of ethyl alcohol, 1 cc. of concd. sulfuric acid added, the solution warmed for 30 minutes at 50°, then diluted largely with water, the precipitate collected, dissolved in dilute caustic soda, the solution filtered from a small quantity of unhydrolyzed initial material, acidified, the precipitate removed and crystallized from alcohol; yield, 0.65 g.; m. p. 219° (corr.).

Of these two methods, the former proved the more satisfactory. This product could not be obtained by the method used for the isomeric salicyl derivative.

Anal. Calcd. for $C_{15}H_{11}O_4N$: C, 70.58; H, 5.14. Found: C, 70.04; H, 5.14.

All efforts to prepare the isomeric *o*-(*m*-hydroxybenzoylamino) derivative proved futile.

***o*-Nitrobenzoyl Isatinic Acid**, $O_2NC_6H_4CONHC_6H_4COCOOH$.—To a suspension of 11 g. of *o*-(*o*-nitrobenzoylamino)-acetophenone in 200 cc. of cold water, there was added a solution of 12.2 g. of potassium permanganate and 4 g. of potassium hydroxide in 100 cc. of water, and the mixture was allowed to stand at laboratory temperature for 48 hours with occasional stirring, the color gradually changing from the purple of the permanganate to the dirty green of the manganate. The manganese in solution was precipitated by the addition of 12 g. of ferrous sulfate dissolved in 100 cc. of water. The filtrate from the manganese oxides was acidified and the brownish nitrobenzoyl isatinic acid which separated was collected and dried; yield, 5 g. By repeated extraction of the manganese dioxide sludge with hot alcohol, 3.5 g. of the initial unoxidized acetophenone was recovered. Based upon the 7.5 g. of acetophenone actually oxidized, the yield of isatinic acid was approximately 60%. Because of the instability of these *o*-substituted isatinic acids, as found by Bogert and Nabenhauer,² further purification or analysis was not attempted. Hydrolyzed by caustic alkali, the compound formed isatin and *o*-nitrobenzoic acid.

Salicyl Isatinic Acid, $HOC_6H_4CONHC_6H_4COCOOH$.—To a solution of 2.5 g. of *o*-salicylamino-acetophenone in 10 cc. of 10% caustic soda solution, 40 g. of cracked ice was added and then a solution of 2.75 g. of potassium permanganate in 25 cc. of water. The color of the solution changed rapidly to green and, after standing for an hour at laboratory temperature, to a clear yellow. When it had stood for two hours longer at room temperature, the solution was removed from the dioxide sludge, acidified, the light-yellow precipitated isatinic acid collected, dissolved in 25 cc. of hot alcohol, the solution cooled and filtered from a small amount of unoxidized initial ketone, the filtrate heated to boiling and boiling water added carefully until the acid began to separate. As the solution cooled, the acid precipitated in yellowish, fluffy needles; yield, 2.5 g. or 90%. After several crystallizations, it melted with decomposition at about 209–210°, the melting point varying considerably with the rate of heating. Hydrolyzed by dilute sodium hydroxide solution, it yielded isatin and salicylic acid.

Anal. Calcd. for $C_{16}H_{11}O_5N$: C, 63.16; H, 3.86. Found: C, 64.28; H, 4.15.

These analytical figures indicate the difficulty experienced in the purification of the product.

***p*-Hydroxybenzoyl Isatinic Acid** was prepared in the same way as the analogous *o*-isomer, in similar yields and of approximately the same melting point. When hydrolyzed, it formed isatin and *p*-hydroxybenzoic acid.

Anal. Calcd. for $C_{16}H_{11}O_5N$: C, 63.16; H, 3.86. Found: C, 63.96; H, 3.93.

2-(*o*-Nitrophenyl)-quinazoline-4-carboxylic Acid, $O_2NC_6H_4C_8H_4N_2COOH$.—A solution of 5 g. of *o*-nitrobenzoyl isatinic acid and 7 g. of dry ammonia in 70 cc. of absolute methanol was heated in a sealed tube for ten hours at 140°, and the reaction product isolated as described beyond for the *o*-hydroxyphenyl derivative. After recrystallizing this crude product seven times from 50% alcohol, it melted at 235° (corr.) but was still impure, as shown by the following analysis.

Anal. Calcd. for $C_{18}H_9O_3N_3$: C, 61.01; H, 3.07. Found: C, 59.37; H, 3.64.

Not enough material was available for further purification, and the experiment was not repeated.

2-(*o*-Hydroxyphenyl)-quinazoline-4-carboxylic Acid, $HOC_6H_4C_8H_4N_2COOH$.—A solution of salicyl isatinic acid in absolute methanol, containing one to three g. of dry ammonia per g. of the isatinic acid, was heated in a sealed tube for 20 hours at 110°, after which the solvent was evaporated, the residue dissolved in hot water, the filtered solution decolorized and acidified carefully, and the yellow flocculent precipitate dried; yield, 99%. After five recrystallizations from dilute alcohol, the fine, yellow needles obtained melted constantly at 171° (corr.).

Anal. Calcd. for $C_{18}H_{10}O_2N_2$: C, 67.66; H, 3.79. Found: C, 67.84; H, 3.90.

ETHYL ESTER.—A solution of 1 g. of the acid in a little absolute alcohol was added to 20 cc. of absolute alcohol containing 5 g. of dry hydrogen chloride and after this solution had stood for 13 hours at laboratory temperature, it was heated for an hour and a half at 60° , then concentrated to small volume, about 50 cc. of water added, sodium carbonate added in excess and the cloudy suspension allowed to settle. The ester separated as a yellow solid; yield, 0.76 g. or 70%. After two recrystallizations from dilute alcohol it formed yellow, glistening plates, m. p. 115° (corr.).

Anal. Calcd. for $C_{17}H_{14}O_2N_2$: C, 69.37; H, 4.80. Found: C, 69.72; H, 4.89.

2-(*p*-Hydroxyphenyl)-quinazoline-4-carboxylic Acid, prepared in a similar manner from the corresponding isatinic acid and methanol solution of dry ammonia heated together in a sealed tube for 24 hours at 110° , was purified by crystallization from dilute acid until its melting point remained constant at 251° (corr.). It formed fine, yellow needles of somewhat more orange shade than its *o*-hydroxy isomer; yield, 95%.

ETHYL ESTER.—As only a small amount of the free acid was prepared, it was not analyzed but was all utilized for the production of its ethyl ester, by the method described above for its *o*-hydroxy isomer. After repeated crystallization from dilute acetone, it appeared in yellow plates, m. p. 159° (corr.); yield, 75%.

Anal. Calcd. for $C_{17}H_{14}O_2N_2$: C, 69.37; H, 4.80. Found: C, 69.11; H, 4.85.

2-Phenylquinazoline-4,2'-dicarboxylic Acid, $HOOC-C_6H_4-C_8H_4N_2-COOH$, was synthesized as described by Bogert and Nabenhauer.¹ Inasmuch as the pharmacological tests hitherto carried out had been with the di-ammonium salt, it was thought desirable to examine also the disodium salt, which was obtained as follows.

A saturated solution of 18.5 g. of the acid in hot absolute alcohol (760 cc.) was treated with a sodium ethylate solution prepared from 70 cc. of absolute alcohol and 2.65 g. of metallic sodium. The sodium salt separated rapidly as the solution was stirred. It was collected, washed with absolute alcohol until the washings were neutral to litmus, and it then formed fine colorless needles, easily soluble in water. The solution was neutral to phenolphthalein and to methyl orange and had a saline, slightly bitter taste. In the free flame it melted with decomposition and charring. Its pharmacological properties are now being studied by Professor Rockwood.

Summary

1. Various new acylated *o*-amino-acetophenones have been prepared.
2. These ketones have been oxidized to the corresponding isatinic acids.
3. From the isatinic acids, quinazoline derivatives of cinchophen type have been obtained and are being tested pharmacologically.

REACTIONS OF ANESTHETIC ETHERS WITH POTASSIUM HYDROXIDE AND WITH MERCURY AND THE TEST FOR FOREIGN ODORS

BY EDWARD MALLINCKRODT, JR.

RECEIVED SEPTEMBER 10, 1927

PUBLISHED OCTOBER 5, 1927

Experience over a long period of years in the testing of ether has enabled us to interpret, with at least a fair degree of accuracy, the meaning of the various appearances that arise when ethers of different compositions and purity are tested for aldehyde with potassium hydroxide. In the hope of establishing a more complete understanding of this test, our conclusions and a few typical experiments are given in the following pages, together with some remarks on the action of mercury on ether containing peroxides and the results obtained by the application of the test for foreign odors to many cans of old anesthetic ether.

The U. S. Pharmacopœia (X edition) requires that no coloration shall develop within two hours when 10 cc. of ether is mixed with 1 cc. of potassium hydroxide test solution and occasionally shaken.

By breaking weighed, sealed glass bulbs of pure aldehyde under pure ether, three ethers were prepared containing, respectively, 0.025 g., 0.05 g. and 0.075 g. of aldehyde per 100 g. of ether.

By holding the test-tubes before a sheet of white paper, one observer detected a pale yellow color with ether containing 0.05% of aldehyde but could find no color with 0.02%. An observer making the test for the first time detected 0.1% of aldehyde but could detect no color with 0.05% after one hour. After several hours, however, he could detect the color. Another observer was able to detect 0.025% of aldehyde readily if care was used, but got no reaction with 0.0125%. A 5% potassium hydroxide solution was used as directed in U. S. P. VIII. Recently another trial has been made by entirely different observers using 5.6% potassium hydroxide (N) as directed by U. S. P. X. A solution of acetaldehyde in pure aldehyde-free ether was prepared and its aldehyde content accurately determined by titration. This solution was then diluted with pure aldehyde-free ether, making known aldehyde solutions of 0.005, 0.01, 0.02, 0.04 and 0.06% acetaldehyde. It was found that the temperature at which the test was made had quite a pronounced effect upon the minimum amount which could be detected. By holding the tubes in a good light, using a white paper background and comparing the color with a blank, using pure distilled water in the place of potassium hydroxide solution, and covering this with a layer of ether, the minimum amount which could be detected was 0.02% at 35°, while at 15° it required 0.04% to give a corresponding color. This places the maximum sensibility of the test under ideal conditions at 0.03%, making the observation at average laboratory temperature of 25°. It is safe to say that under average conditions the limit of sensibility of this test would be in the neighborhood of 0.05 to 0.06%.

This test appears to be much less sensitive than the test of the German and Austrian Pharmacopœias employing solid potassium hydrate. The use of solid potassium hydrate is to be preferred to the solution as a reagent for aldehyde, both on account of greater sensitiveness and because, as will

appear later, the various appearances around and on the surface of the lumps of potash give valuable indications as to the presence of alcohol and peroxides in the ether. We have never employed this test except to determine its sensitiveness in the above experiments.

The German Pharmacopœia (Ph. G. VI) requires that anesthetic ether (*aether pro narcosi*), when placed in a glass-stoppered bottle protected from the light, shall not become colored itself and shall not impart any color, after six hours, to freshly broken lumps of potassium hydroxide the size of a pea. Following the German procedure, 30 cc. of ether and 5 g. of fresh pure potassium hydroxide sticks were used in each test.

Baskerville¹ states that anhydrous ether should give no response in this test for twenty-four hours. It should be noted, however, that this reaction in the complete absence of water is not to be depended upon to indicate aldehyde, as the following experiments indicate.

Aldehyde Can Produce No Color in the Absence of Water

It was soon observed in applying this test to pure anhydrous ether containing 0.1% of pure acetaldehyde that the characteristic brown coloration tended to make its appearance on the curved surfaces of the fragments of potassium hydroxide sticks and not on the freshly broken surfaces. By sandpapering off the cylindrical surface, that surface lost its property of acquiring the brown color, behaving then like the freshly broken surfaces. By holding the sandpapered stick of potassium hydroxide in a steam jet for a few seconds and making the test with it, the coloration reappeared on the sandpapered surface, showing that the presence of a slight amount of moisture in the potash is necessary for the proper formation of the color.

It was thought that a trace of carbonate in the crust on the caustic sticks might be one of the causes of the coloration appearing on the cylindrical surfaces. Accordingly, a test was made using instead of potassium hydroxide, potassium carbonate containing about one and one-half molecules of water, and another test after drying the potassium carbonate at 120°. The ether used contained, besides traces of alcohol and water, sufficient aldehyde to color potassium hydroxide a good brown. After thirty-six hours under this ether, the potassium carbonate, both dried and undried, was uncolored. The ether was then poured from the potassium carbonate into bottles containing the usual 5g. portions of potassium hydroxide. The ether from the dried salt became strongly turbid at once and the pieces of potassium hydroxide after several hours acquired a pale yellowish-brown tint, whereas the ether from the undried potassium carbonate colored the potassium hydroxide a deep brown.

Evidently potassium carbonate, while it plays no part in the production of the color on the lumps of potassium hydroxide, is able to dry ether containing considerable aldehyde to the point where the potassium hydroxide test fails to indicate the presence of aldehyde by the production of the usual brown color.

Sensitiveness of the Solid Potassium Hydroxide Test

Pure anhydrous ether free of aldehyde was prepared and determinate amounts of pure aldehyde were added corresponding to 0.025 g., 0.05 g. and 0.075 g. per 100 g. of

¹ Baskerville and Hamor, *J. Ind. Eng. Chem.*, 3, 396 (1911).

ether. The best way to prepare such determinate solutions is by weighing pure aldehyde in small, sealed glass bulbs and breaking them under ether. Our solutions were prepared in this manner. Thirty cc. of these ethers were poured upon 5 g. of freshly-broken sticks of potassium hydroxide in glass-stoppered bottles. Duplicate bottles were made and placed in light-tight cases to test the effect of excluding the light as required in the above mentioned Pharmacopoeia. It was found necessary to reject the first set of tests, for there was so little moisture present that at the end of three hours the potash was still white, even in the ether containing 0.075 % of aldehyde. A large drop of water was now added to the bottle containing the ether with 0.075% of aldehyde and in twenty-five minutes the potash became distinctly brown, thus showing the remarkable part played by water in facilitating the reaction between aldehyde and alkali. Four fresh tests were prepared, one with the pure ether and three with the ether containing the aldehyde, and to each test was added one drop (about 0.04 cc.) of water. A set of four duplicates was placed in the dark. The ethers containing 0.075% and 0.05% of aldehyde began to show perceptible color in about fifteen minutes, the tests protected from the light showing a slightly deeper tint. At the end of two hours, the ether containing 0.02% of aldehyde had produced a good brown on the potash and the ether itself was a pale amber color. This sample was overlooked at the end of the first hour, but had it been observed, it is probable that the color could easily have been detected. However, the full depth of the brown does not appear until from two to four hours have elapsed and, with very small amounts of aldehyde, twelve hours may be required for maximum color. The pure ether used for making these solutions gave absolutely no reaction even after several days.² A comparison of the tests which had been protected from the light with those exposed to the ordinary daylight showed no marked difference. At the end of five hours, however, it was just possible to distinguish by their slightly darker tints the bottles which had been kept in the dark. It would seem that the importance of protecting the tests from light has been overestimated. We have observed some slight influence from light in other experiments, but we have not ascertained the exact nature of the effect. For extreme delicacy the exclusion of light is perhaps desirable.

Further experiments showed that this test will detect 0.01% of aldehyde in pure ether. The observer should familiarize himself with the indications of the test by comparing pure ether with ether containing known amounts of pure aldehyde. The test fails absolutely to give reliable indications at dilutions of 0.001% of aldehyde, although we made many attempts to increase its sensitiveness. Possibly some indications may be obtained with less than 0.01% of aldehyde, but below this limit we prefer to employ other reagents of greater sensitiveness. As will appear later, this sensitiveness (0.01%), representing the limit for pure aldehyde in pure ether, cannot be attained in applying this test to ordinary ethers unless the proper amount of water is present to overcome the interference produced by the alcohol normally present in such ethers.

The Significance of Turbidity and Effect of Alcohol

Baskerville and others appear to regard the appearance of a turbidity in the potassium hydroxide test as indicative of the presence of aldehyde.

"On covering 5 g. of solid potassium hydroxide in freshly broken pieces

² This degree of purity is not difficult to obtain by laboratory methods. Compare Wobbe, *Apoth. Ztg.*, 18, 466 (1903).

about 5 mm. in diameter with 30 cc. of the sample and allowing to stand for six hours tightly closed and protected from light and occasionally shaking, the potassium hydroxide should not acquire a yellowish color, no yellowish or brownish-colored substance should separate and *the ether should not become turbid or assume any color.*"³

The quotation appears ambiguous as to whether an ether which becomes turbid immediately and then clears up after several hours would be construed to have passed or to have failed. Presumably it would be held to have failed.

The absence of a turbidity, that is, the ether remaining water-clear in the potassium hydroxide test, seems to depend upon too many factors to be relied upon as a proof of the purity of ether. As the following tests indicate, the amount of alcohol present influences this largely, ethers rich in alcohol but perfectly pure and normal otherwise generally produce a turbidity which clears up more or less after several hours.

Twenty cubic centimeters of ether free from aldehyde and dehydrated over metallic sodium, to which had been added 0.72 cc. of absolute alcohol and 0.08 cc. of water to imitate the composition of anesthetic ether required by the U. S. Pharmacopœia (9th Edition now superseded by 10th), produced an immediate turbidity when poured upon the caustic. The aldehyde introduced by the alcohol is trifling. We have seen many specimens of ether of 0.711 sp. gr. (water and ether at 25°) which were sufficiently free from aldehyde to give to potassium hydroxide no color for eighteen hours and yet if several per cent. of "Cologne Spirits," which contains less aldehyde than the ordinary grain alcohol, were added to the ether, an immediate turbidity, when poured on the potash, would result.

To further demonstrate the influence of alcohol on the reaction, two aldehyde tests were made on a pure aldehyde-free ether containing about 3% of cologne spirits and to one of the test bottles two drops of water were added. After standing some twenty hours, the test without water was still slightly turbid and the potash showed a yellowish coloration, whereas the test containing water showed no turbidity and the potash remained white. It is evident that the turbidity and also the formation of a coloration which might easily be mistaken for a trace of aldehyde in the ether, is due to the alcohol. That the presence of alcohol interferes with the detection of aldehyde was known to Vulpus⁴ and confirmed by Schobig,⁵ who pointed out that ether containing several per cent. of alcohol dissolved 40 mg.⁶ of potassium hydroxide in 10 cc. and likewise tended to dissolve aldehyde resin, as shown by the yellow color of the ether.

We have repeated many times the experiment of adding several per cent. of cologne spirits to ethers in which the potassium hydroxide would remain almost, but not absolutely, snow-white for several days and always with the same general result, namely, more or less coloration at the end of about twenty-four hours upon the caustic and the production of a yellowish or brownish sediment. This deposit sometimes takes the form of

³ Ref. 1, p. 393.

⁴ Vulpus, *Apoth. Ztg.*, 9, 7 (1894).

⁵ Schobig, *ibid.*, 22, 210 (1894).

⁶ We found similar amounts dissolved by ether containing 4% of absolute alcohol.

feathery crystals several millimeters in length adhering to the lumps of potassium hydroxide. Whether or not one is prepared to admit the similarity between the shade of color produced by alcohol and that produced by aldehyde, the fact remains that alcohol greatly modifies the appearance of the test. The disturbance increases with increase in the amount of alcohol in the ether and the time of standing. When several per cent. of alcohol is present, twenty-four hours is too long to allow to stand before observation. Six hours is usually a safe time to allow for the aldehyde color to develop before the alcohol produces its yellow discoloration or feathery crystals, although tests will occasionally remain unharmed by the alcohol for twelve to eighteen hours.

We have stated that the presence of a certain amount of water in an ether containing several per cent. of alcohol helps to overcome the effect produced by alcohol in the potassium hydroxide test. In order to determine whether the sensitiveness of the test is diminished by the presence of water, and also the proper way to add the water, tests were made with fresh potassium hydroxide unexposed to moisture and with the same after it had stood overnight over water in a desiccator, and by a third procedure which consisted in adding a few drops of water to 30 cc. of the ether to be tested, shaking vigorously and then pouring the moistened ether over fresh potassium hydroxide. Four ethers of different composition were used, as follows.

Ether (1) was pure anhydrous ether containing 0.01% of aldehyde. It produced absolutely no color on unmoistened potassium hydroxide even for forty-eight hours, but the potassium hydroxide exposed to moist air showed a distinct brown in six hours. Ether (1) shaken with three drops of water did not produce as distinct a brown as the potassium hydroxide exposed to moist air, but it was still detectable.

Ether (2) was pure anhydrous ether containing 1.42% of absolute alcohol and was intended to show the disturbing effect of alcohol. With *unmoistened* potassium hydroxide, after six hours, this ether became turbid and yellowish and some precipitate formed, although the potassium hydroxide remained white. After twenty-four hours the color deepened and the potassium hydroxide appeared partially dissolved. Test valueless. In sharp contrast to the above, the *moistened* potassium hydroxide showed only a slight haziness after six hours. Ether (2) shaken with three drops of water remained clear for twenty-four hours and the potassium hydroxide was white except for a few minute, brownish crystals starting to form, indicating that the alcohol was beginning to show its effect.

Ether (3) was pure anhydrous ether containing 1.28% of absolute alcohol and 0.01% of aldehyde, and was designed to show the combined influence of alcohol and the least amount of aldehyde that can be detected by this test. With *unmoistened* potassium hydroxide, the ether was yellow after six hours, but the potassium hydroxide showed no true brown color. Test valueless. *Moistened* potassium hydroxide, however, after six hours, showed a faint true brown color, but after twenty-four hours the test was valueless, due to the effect of the alcohol. When ether (3) was shaken with three drops of water, the potassium hydroxide showed a trace of true brown after six hours, and after twenty-four hours the potassium hydroxide showed a distinct true brown and the test was still free from alcoholic effect.

Ether (4) was a pure anesthetic ether containing about 0.25% of water and 0.33% of alcohol to which 0.01% of aldehyde was added. This was intended to represent ordinary anesthetic ether such as might be met with on the market. It was of special interest, therefore, to show whether the potassium hydroxide test would detect the aldehyde in it. Both unmoistened and moistened potassium hydroxide showed a true brown in six hours. When ether (4) was shaken with three drops of water, the color after six hours' standing upon the potassium hydroxide was not so strong, but after twenty-four hours the color was practically normal.

Reaction of Mercury with Ether Containing Peroxides

Before considering certain abnormal indications which arise when the potassium hydroxide test is applied to ether containing peroxides, we will refer to the following chance observation made thirteen years ago.

Four or five samples of an excellent grade of anesthetic ether, originally free from aldehyde, which had been kept in glass-stoppered bottles for about a year in a laboratory closet (only occasionally exposed to daylight), were found to be rich in peroxides, but when tested for aldehyde in the usual manner with potassium hydroxide, produced only a slight brown color.

Copious precipitates, some black and some light gray, resulted on shaking these samples with mercury and the aldehyde test applied as above now quickly showed the characteristic dark brown color on the potash. One sample became almost black, indicating the presence of aldehyde far in excess of that generally present even in commercial ethers. No intensified reaction could be obtained by shaking with mercury an ether rich in aldehyde (containing over 0.1%) but free from peroxides and no reaction whatever could be obtained from pure ether by such shaking. The reaction is very sensitive and an ether which gives an easily recognizable yellow with cadmium potassium iodide will also show, when carefully observed, a slight tarnishing or production of a skin on the bright surface of a globule of clean mercury. Ether which has been in contact with rubber will blacken mercury, although containing no peroxides. The color of the precipitate due to peroxides is generally grayish-black but may be light gray or, if water is present, it may be yellowish.

Although the peroxides present in the ether were completely destroyed after five hours shaking with mercury on a vigorous mechanical shaker, the weight of the powder, because of its variable composition, even after allowing for the finely-divided metallic mercury in it, cannot be taken as a measure of the active oxygen present. We were forced to abandon the idea of a quantitative method based upon this reaction. The precipitate is non-explosive, contains considerable acetic acid and the color can be made to vary by digestion with water.

The use of mercury for removing traces of peroxides in ether is well known,⁷ but we have seen no reference to the simultaneous liberation of aldehyde. This reaction agrees with the results of Clover,⁸ who proved that acetaldehyde was one of the main decomposition products of the organic peroxides in many old ethers. Warming ether containing peroxides with a few drops of 50% sulfuric acid will often liberate sufficient aldehyde to indicate itself by the potassium hydroxide test.

⁷ Bein, "Ausdehnung des Aethyläthers, etc.," *Wissenschaftliche Abhandlung der Kaiserlichen Normal-Eichungs Kommission*, Heft VII, Metronom. Beiträge, p. 42.

⁸ Clover, *THIS JOURNAL*, 44, 1107 (1922).

Referring to the tarnishing of mercury by impure ether, Baskerville⁹ says "that only the presence of free sulfur or hydrogen sulfide can produce the reaction generally ascribed to organic sulfur, excepting, of course, hydrogen dioxide which produces a gray precipitate even when present in mere traces." It is true that mercury is very easily corroded even by 0.001% of the *organic* peroxides naturally occurring in ether, but by pure hydrogen dioxide it appears to be but little attacked, as the following experiments show.

To two portions of pure ether showing no reaction either with cadmium potassium iodide or ammoniacal silver nitrate, aqueous hydrogen peroxide was added equivalent to 0.01% of H_2O_2 and 0.1% of H_2O_2 , respectively. After shaking these two samples and also a comparison sample of pure ether for one hour with mercury, the mercury in the pure ether was only very slightly tarnished, the surface remaining bright except for a few separate specks; the ether containing 0.01% of H_2O_2 differed very slightly from the pure ether, the mercury containing a few more specks. The total tarnishing was insignificant in either. The ether containing 0.1% produced barely sufficient grayish powder to conceal the surface of the mercury, whereas ether containing 0.1% of the natural organic peroxides gives, as already stated, a copious precipitate. Other portions of each ether were allowed to stand for six days before shaking with mercury to test whether the mercury would then be greatly attacked, but the results were substantially the same. No hydrogen peroxide could be found in any of the samples after the shaking with mercury. Mercury is not very readily converted into the finely-divided metallic state by shaking with ether. After shaking the ether containing 0.1% of H_2O_2 with a weighed amount of mercury on a mechanical shaker for five hours, the loss of weight due to the formation of the powder which was separated from the globule before weighing amounted to less than 0.2 g. Another sample of ether containing 0.09% of H_2O_2 , when shaken for five hours with 2 cc. of mercury, produced a small amount of yellowish powder insufficient to cover its surface.¹⁰ After long contact with hydrogen peroxide, however, ether does acquire the property of readily corroding mercury, presumably because of the formation of organic peroxides as explained by Wieland and Wingler.¹¹

The Effect of the Presence of Peroxides

Baskerville⁹ states, as the result of his experiments, that "peroxides may cause a turbidity, but no coloration or colored separate." This is true, but this statement and the preceding paragraph should not be taken to mean that neither hydrogen peroxide nor the natural peroxides interferes with the detection of aldehyde by means of the potassium hydroxide test, as the following experiments indicate.

Ether containing about 0.15% of aldehyde was exposed to an ordinary glass mercury vapor light for sixty hours. A portion of the light-treated ether, which now gave a strong test for peroxides with the cadmium potassium iodide reagent, was shaken for five hours with metallic mercury to liberate the aldehyde. Comparative aldehyde tests

⁹ Ref. 1, p. 308.

¹⁰ The well-known catalysis of hydrogen peroxide by mercury (Bredig and Weinmayr, *Z. physik. Chem.*, **42**, 601 (1903)) would lead one to expect some such results with ether.

¹¹ Wieland and Wingler, *Ann.*, **431**, 301 (1923).

were next made using both fresh caustic and caustic exposed to moist air on the original ether, on the light-treated ether and on the latter after shaking with mercury. The caustic in the light-treated ether was almost white, showing less color than is produced by 0.01% of aldehyde, and there was only a slight increase even after twenty-four hours' standing. The portion of light-treated ether shaken with mercury produced in four hours a notably darker color estimated to be at least equal to the presence of 0.03% of aldehyde and the color increased considerably after twenty hours. With original ether, the aldehyde was evident in five minutes and after four hours the caustic was strongly colored rusty brown and considerably darker than the ether which was shaken with mercury. Evidently the liberation of the aldehyde is not quantitative. Sunlight produced similar results. Exposure to ordinary daylight for several hours seems to be without injurious influence, but a half day's exposure has produced the effect.

Aqueous hydrogen peroxide was added to ether containing 0.1% of aldehyde in the proportion of two molecules for one of aldehyde and the solution was kept in the dark for three days and occasionally shaken.¹² An aldehyde test now showed a scarcely perceptible yellow color after one-half hour. The color deepened somewhat on long standing but the caustic assumed a yellowish color and powdery appearance. A portion of the original ether treated with peroxide was shaken with mercury and the test then showed a strong reaction after twenty minutes, thus proving that the aldehyde was not destroyed. These experiments suggest a possible explanation for the fact frequently observed by us that ether rich in the naturally occurring peroxides gives only a feeble aldehyde reaction (or even none at all) with potassium hydroxide, although the ether when fresh may have contained sufficient aldehyde to give a dark brown coloration. It is clear that hydrogen dioxide and likewise the peroxide naturally occurring in ether interfere greatly with the production of the characteristic dark brown color, rendering the test far less sensitive and indeed practically useless for indicating small traces of aldehyde.

Potassium Hydroxide Test Applied to Peroxidized Ethers

Most specimens of ether containing several per cent. of alcohol will give, when they have acquired sufficient peroxide, a marked turbidity which persists for many hours and finally settles out as a yellowish or brownish precipitate after from eight to twelve hours. The lumps of potassium hydroxide then appear to have been pitted or partially dissolved and the test has a characteristic appearance.

In the case of peroxidized ether which originally contained little or no alcohol, no turbidity is produced, the ether remaining water-clear and the lumps of caustic frequently exhibit a sort of blistered appearance and are only slightly colored, due presumably to the liberation of a little aldehyde from the peroxides. The following examination is intended to illustrate these conclusions and gives the results obtained by applying the potassium hydroxide test to a number of samples of ether which had stood in amber bottles tightly stoppered with corks on the laboratory shelf for about six months, including the heat of the summer. The ether was originally of good quality, sp. gr. 0.711^{25°} and practically free from aldehyde, and to a portion of it several per cent. of pure cologne spirits had been added. Almost all of the bottles had partially evaporated, many having lost one-

¹² From Wieland and Winkler's work this result might be expected. Ref. 11.

quarter of their contents. For purposes of comparison, samples which were free of peroxides were also tested.

Of thirteen samples of alcoholic ether giving marked peroxide tests, all gave a *marked turbidity* when poured upon the potassium hydroxide. After about five hours' standing, six of the tests were still turbid, resembling a solution containing freshly precipitated aluminum hydrate. Four were yellowish and the precipitate had settled. Of six comparison samples (free of peroxides) five gave a slight turbidity upon pouring upon the potassium hydroxide, and after about five hours five were *slightly* turbid, but *none showed a marked turbidity* resembling aluminum hydrate. After standing overnight, eleven of the tests on the peroxidized ether were brownish and the potassium hydroxide lumps appeared partially dissolved, while five of the peroxide-free ethers showed only pale yellowish sediments and no dissolving of the potassium hydroxide. Of seventeen samples of the non-alcoholic ether giving marked peroxide reactions, four showed a turbidity after the test had stood for five hours, the balance being clear; but in eleven of these the potassium hydroxide was yellowish and in eight the potassium hydroxide had a blistered appearance in addition to being colored. Four comparison samples (peroxide free) were all clear and the potassium hydroxide white in three and almost white in the fourth.

Anyone using the test with solid potassium hydroxide day in and day out on ethers of varying composition will be struck by the variations in the phenomena attending the test, and herein lies its chief defect, for the observer must make allowances for the disturbing influences caused by the presence in the ether of such common impurities as alcohol and peroxides. The pure brown coloration on the lumps of potash normally produced by pure aldehyde in pure ether may be obscured or replaced more or less by the other appearances which, while difficult to describe in an adequate manner, are readily recognized after having once been seen.

We may sum up briefly the results of all experiments with the potassium hydroxide test as ordinarily employed, using lumps of potash, as follows.

As a means of detecting aldehyde it is unreliable in the presence of peroxides unless these are present only in very small traces. Before applying the test, such ether may be shaken with mercury to liberate the aldehyde combined with the organic peroxides. However, what evidence we have indicates that this decomposition is not quantitative.

The appearance of a turbidity which remains undiminished in intensity for some hours points to an alcoholic ether containing considerable peroxides. Alcohol itself produces a turbidity which is not easy to distinguish from that due to peroxides. Contrary to the prevailing opinion, the appearance of a turbidity is in no way indicative of the presence of aldehyde and is an indication from which no positive conclusions can be drawn unless substantiated by other tests.

The test will not indicate aldehyde in the complete absence of water. The presence of several per cent. of alcohol in ether, especially if not accompanied by the usual amount of water, produces a coloration which resembles the aldehyde color. The use of potassium hydroxide which has

been exposed to moist air will avoid the first difficulty, but to avoid the second it may be necessary to moisten the ether with water, three drops to 20 cc. If this is done, the effect of the alcohol which otherwise may manifest itself in several different appearances on the lumps of caustic is delayed for at least twelve to eighteen hours, amply sufficient to allow the aldehyde color to attain its maximum. While it is easy to detect 0.01% of aldehyde in pure ether, it requires some experience and the proper use of water to detect this amount in an alcoholic ether. Since many anesthetic ethers contain from 0.5 to 1% of water,¹³ the use of potassium hydroxide exposed to moist air will suffice if fresh caustic fails to indicate aldehyde, but in the absence of any information concerning a given specimen three tests should be made: namely, with fresh caustic, with caustic which has been exposed to moist air and by using water in the ether itself.

When ether contains both alcohol, to the extent of several per cent., and considerable aldehyde, say 0.1%, there is generally formed a precipitate which resembles ferric hydrate both in form and color.

We have occasionally noticed a transient yellow color which appeared on the potassium hydroxide in some of the tests and then disappeared at the end of about twelve hours. This was finally traced to test bottles which were rinsed with alcohol, then with ether, and the caustic put in before the bottles were fully dry. Various kinds of potassium hydroxide were investigated before the cause of the color was discovered and it may be remarked that the test is not much influenced by the purity of the alkali. Obviously, however, the pure white sticks are the best to use in this test.

Acrolein and furfural, if added in small quantities to ether, impart a color to potash similar to the aldehyde color. Paraldehyde in traces produces no color in this test unless the ether containing it is previously warmed with a drop of sulfuric acid, which suffices to liberate the aldehyde. These substances, however, are not known to occur in ethers of modern manufacture. A more likely source of trouble lies in the use of ordinary corks for, as pointed out by Baskerville,³ ether may dissolve substances from cork which cause the potash to discolor in the absence of aldehyde.

Test for Foreign Odors

The usual practice is to evaporate slowly on a steam-bath, without rapid boiling, 30 cc. of the ether to be tested in a small beaker covered with a watch glass. When the ether has evaporated to a residue of one or two cubic centimeters, the residue is poured drop by drop on the center of a clean piece of filter paper; four inches square is a convenient size. The evaporation keeps up with the dropping and a spot about the size of a half dollar is formed. Practice enables one to judge when the ether has almost disappeared and at this instant the wet spot, which now contains the

¹³ Mallinckrodt and Alt, *J. Ind. Eng. Chem.*, 8, 807 (1916).

substances less volatile than ether, should be placed close to the nostrils and smelled. With pure ether containing little or no odor, the damp spot at the center of the paper may be laid over the nostrils and air drawn into the nose. This test is so sensitive that an aroma different from the smell of ether itself may be detected with nearly every ether, no matter how prepared, and good judgment should be used in interpreting the results. The value of such a sensitive test lies in concentrating any traces of irritating substances present in the ether, which are masked more or less by the smell of the ether itself, and presenting them to the nostrils in such a way that their pungency or irritating effect cannot be mistaken. The appearance of the spot is very characteristic and should be carefully noted. The presence of several per cent. of alcohol may be detected by the appearance and smell of the spot. Water shows plainly by the slowness with which the spot evaporates from the paper. One drop of acetic or formic acid or one drop of oil of wine in 30 cc. of ether is easily recognized. Frequently the spot at the center of the paper on which the ether has been poured shows an oily appearance, or an oily margin about the circumference of the spot. This occurs in the case of ethers containing peroxides, due to the concentration of the latter being only slightly volatile. When such a spot is placed to the nostrils and air drawn into the nose, a very characteristic irritating odor, somewhat like pepper, is noticed which, after a few moments, becomes still more irritating to the lining of the nostrils. If a few drops of the cadmium potassium iodide reagent, as used for the peroxide test, is applied to the oily line, iodine is immediately liberated and stains the paper brown or bluish. The pure oil, on the other hand, rich in organic peroxides,¹⁴ which we obtained by fractionation of old ether, had of itself very little odor, but if several drops are added to 30 cc. of pure ether and the odor test applied, the characteristic irritating odor of peroxidized ether appears.¹⁵

The odor test is of little value for detecting volatile impurities which distil with the ether vapor itself. Fortunately there are none such likely to occur in ether. A few drops of aqueous sulfurous acid in 30 cc. of ether could neither be detected by the odor test nor could it be detected by pouring the ether directly on filter paper and smelling.

In one experiment, sixty-five sealed cans of ether, averaging about one year old and ranging from about seven months to a year and a half, were found to contain fifteen cans which had pronounced bad odors. Of the fifteen bad cans, nine gave pronounced reactions for peroxides and each of the nine, when subjected to the odor test, gave the pungent, peppery

¹⁴ Clover (Ref. 8, p. 1112), on the other hand, found that his pure "ether peroxide" had an irritating odor.

¹⁵ This interesting fact was noted by Dr. W. N. Stull in our Laboratory fifteen years ago and has been confirmed by later experience.

odor characteristic of peroxides. There were only two cans in the lot which gave affirmative test for peroxides which failed to give the characteristic odor, but these cans showed only a very slight reaction with the cadmium potassium iodide reagent. The close relation between the presence of peroxides and a certain kind of odor is evident.

Summary

1. Under average conditions, if ether contains less than about 0.05% of aldehyde it will probably not be detected by the official aldehyde test in U.S.P. X, whereas the test employing solid potassium hydroxide will, by employing the precautions given in this paper, detect 0.01%.

2. Peroxides and alcohol, if present in the ether, produce characteristic appearances in this test and their effects are described.

3. Shaking with metallic mercury provides a convenient means of decomposing the organic peroxides naturally occurring in old ether with liberation of acetaldehyde in accordance with the work of Clover and of Wieland and Winger on the constitution of these peroxides.

4. The presence of more than minute traces of peroxides in ether can be detected by a characteristic odor when the ether is evaporated to small volume and smelled after pouring upon paper.

ST. LOUIS, MISSOURI

NOTE

Reduction of Benzophenone by Magnesium Amalgam. Correction.—In a recent paper¹ we reported that magnesium amalgam did not reduce benzophenone, contrary to statements of others.² Because of the positive results obtained in the case of benzil³ with magnesium amalgam, the experiments on benzophenone were repeated. We again experienced the same difficulty as before with amalgam that had been prepared as previously by heating together magnesium and mercury. However, in several instances of a number of experiments it was observed that a simple mixture of magnesium metal and mercury at room temperature effected reduction of benzophenone. We are at present at a loss to explain the differences in the results obtained.

NEW BOOKS

Periodic Table. Reprinted and enlarged from General Chemistry by HORACE G. DEMING. 95 X 155 cm. John Wiley and Sons, Inc., 440 Fourth Avenue, New York. Price, \$3.50.

In general principle this chart is similar to one in Nernst's Theoretical Chemistry and still more closely related to the chart of Antropoff, reviewed in *THIS JOURNAL*, 49, 888 (1927). While it does not have the colors of the Antropoff chart, the same relations are brought out by connecting lines. It contains a number of valuable features not found in the other chart, especially the successive shells of electrons for the inert gases and the radioactive disintegration relations. The chart will be very useful for recitation rooms and offices.

WILLIAM A. NOYES

Theorie der Adsorption von Gasen (Theory of Gas Adsorption). By EMANUEL JAQUET. Gebrüder Borntraeger, W 35 Schöneberger Ufer 12a, Berlin, 1925. 56 pp. 17 figs. 25.5 X 16.5 cm. Price, unbound, 4.80 M.

The theory of adsorption is developed by considering the adsorbed molecules as systems of electric charges (dipoles or quadrupoles) in thermal equilibrium in a variable electric field due to the contiguity of an adsorbing surface, regarded as a perfect conductor or dielectric. First, the form of the isotherm is investigated, and several methods are suggested for allowing for the intermolecular action which causes departures from Henry's law. The equation best fitting the experiments is one which is essentially the same as that given by Langmuir,¹ although the author does not mention this. Next, a method is derived for estimating the maximum adsorption energy from the observed temperature coefficient of the initial slopes of the isotherms, having regard to the fact that at high temperatures the adsorbed molecules do not occupy positions of minimum potential energy, so that the mean energy, as given by the temperature coefficient, must be multiplied by a factor. Expressions for the electrostatic energy of dipoles and quadrupoles in the vicinity of a conducting wall are derived, and found to involve the molecular diameter, the electrical moment or moment of inertia and, to a secondary degree, the polarization constant. In the case of dipoles, the energy should show a marked temperature variation owing to changes in molecular orientation.

The conclusions are tested by comparison with experiment, and tolerably verified, the values of the constants obtained being of the same order of magnitude as those derived by other means.

A Text-Book of Organic Chemistry. By Dr. JULIUS SCHMIDT, Professor of Chemistry in the Technical High School, Stuttgart. English Edition by H. GORDON RULE, Ph.D., D.Sc., Lecturer in Organic Chemistry, University of Edinburgh. D. Van Nostrand Company, 8 Warren Street, New York City, 1926. xxiv + 798 pp. 24.5 × 17 cm. Price \$9.00.

The author intended to write "a book which stimulates the reader to think for himself." There is every reason to believe that he has been successful in this endeavor. This text is remarkably free from errors in spelling and in punctuation. On page 143, footnote numbers are omitted. This is all the more evident because of the notable freedom from such slips in the book as a whole. In general, the print work indicates that the book has been carefully made up and proof-read. It is characterized by an abundance of references to the original literature.

The material included in the first part of the volume is too elementary for the remainder of the work. It is, for example, useless to indicate the mode of calculating empirical formulas in a book which subsequently deals at some length with such a subject as osotriazoles. No endeavor is made to avoid the use of such terms as normal and iso before these are explained. It is, at least, debatable whether or not the book might not really benefit by the elimination of all material on analyses, and thus do away with the first sixteen pages. This specialized branch of organic chemistry might preferably be covered in a separate volume.

The statements in this book are concise and clear, and characterized by a feature almost unique, namely, the designation of the specific reagents utilized in various reactions, instead of the all too common and very unsatisfactory remarks to the effect that this or that change is produced by oxidation, reduction, etc., found in so many other books. It is pleasing to note the translator's conformity with the rules for numbering organic ring systems, recently published by a Committee of the International Union of Pure and Applied Chemistry.

In the discussion of the determination of molecular weights by the Victor Meyer method, references to air as a standard are superfluous and simply make the computations unnecessarily involved. Certain of the statements dealing with 1,4 addition are surprising, especially when consideration is given to the well-known work on conjugated systems in alpha, beta unsaturated ketones with the Grignard reagent. In the description of melting-point determinations, there is altogether too much detail, quite unnecessary if it is assumed that the reader is capable of appreciating most of the material in the book.

The slowness with which facts in the periodical literature get into texts is nowhere more evident than in the neglect to correct the hoary statement that $C_{60}H_{122}$ is the highest known member of the saturated hydrocarbon series; this despite Gascard's publication dealing with $C_{64}H_{130}$, which ap-

peared in 1921. The residents of Seminole County, Oklahoma, might be excused some righteous indignation if they took violent exception to the statement that Pennsylvania is the most important source of petroleum in North America.

Occasionally the rather loose use of the term "solution" instead of the more exact "colloidal suspension" may be noted. In the description of the purification of crude ether, the recommendation that quicklime be used to remove alcohol hardly seems reasonable. The designation of certain compounds as isonitriles might advantageously be changed to isocyanides. The more desirable pinacol and pinacolone for pinacone and pinacolone have not been utilized. In dealing with the formation of glycol chlorohydrin, the use of hypochlorous acid and ethylene is not mentioned. Sufficient years have elapsed since the World War so that this process, of no mean importance, might be expected to be found in a book of such scope as this. Almost invariably textbooks indicate that dynamite is made of kieselguhr, whereas generally, and certainly uniformly in the United States, wood pulp or wood powder is used.

In the section on monosaccharides, these compounds are classed according to the number of carbons in the molecule without reference to the modern tendency to use the number of oxygens instead. When this method is used, rhamnose and similar compounds are, quite as a matter of course, regarded as pentoses, which is in accordance with their chemical behavior. The formula for lactose is incorrect, but it is too much to expect anything else. The formula most recently suggested by Haworth, wherein both parts have amylenoxide rings and the bioc attachment is on carbon 4 in the glucose part, is, however, more acceptable than that given. The formulas for the uric acid syntheses in one case indicate potassium cyanate, whereas cyanic acid would be in accord with what is subsequently given. In naming saturated alicyclic compounds, both the polymethylene and the more preferable cyclo systems are employed. In one instance, both designations appear in the same sentence. In the conversions of aromatic to aliphatic compounds, no mention is made of the very important industrial preparation of maleic anhydride by the catalytic oxidation of benzene. In the portion dealing with furane derivatives, instead of the more desirable furane, furfuran designations are employed. It would seem advantageous to indicate the possibility of the furfuran scheme, and thereafter to employ consistently the more modern furane naming.

In the section on proteins, it is stated that "most of it (nitrogen) is present in peptide groups." This is certainly debatable in the light of recent information concerning the possible occurrence of dioxopiperazines, pyrrole and even ureide complexes in this extraordinarily important group of substances. It is, of course, impossible to have any text absolutely up-to-date in all matters, and this is doubly true of a translation, but it

seems that an inkling of something other than the classical peptide structure for proteins might have been included. Certainly that "it may be stated with confidence that most of the constituent parts of proteins have now been identified" requires clarification, at least to the extent of the author's meaning of the term "constituent parts." It must be admitted that a dioxopiperazine derivative is mentioned as a protein degradation product, but not in such a manner that even by intimation can one conclude that dioxopiperazines may be present as such in the protein molecules.

The special sections on the various classes of ring compounds are unusually numerous and seem to have been especially well treated.

It has been stated that it is an American characteristic never to praise anything without immediately qualifying the approval. In this instance the procedure will be reversed. Despite the criticisms of this volume, it should be recognized as one of the most stimulating, lucid and useful of the larger organic chemistry texts, and an eminently worth while production.

G. ALBERT HILL

Textbook of Biological Chemistry. By JAMES SUMNER, Ph.D., Assistant Professor of Biological Chemistry, Cornell University. The Macmillan Company, 60 Fifth Avenue, New York City, 1927. xxiii + 283 pp. 6 figs. 22.5 × 14.5 cm. Price \$3.50.

Five chapters on the subjects of fats, carbohydrates, proteins, urine and blood make up about two-thirds of this book. The chemistry of digestion is treated in short sections under the chapters on fats, carbohydrates and proteins. The chemistry of muscle, nerve and bone is almost entirely neglected as is also that of the mineral constituents of the tissues. The book is intended for elementary students and, presumably for that reason, no references are cited. The somewhat frequent use of workers' names is hardly in line with the same principle. Typographical errors occur on pages xxii and 91. The names Macleod and Schafer are misspelt on page 68.

PRIMARY DECOMPOSITION OF MOLECULES IN PHOTOCHEMICAL REACTIONS

BY ROSCOE H. GERKE

RECEIVED OCTOBER 27, 1926

PUBLISHED NOVEMBER 5, 1927

Introduction

Excited atoms and molecules produced by the primary action of the absorbed light have been found to be effective in stimulating photochemical changes in a number of photochemical reactions. When excited atoms or molecules are produced by the absorption of light, the absorption spectrum of the gas consists of lines or bands, respectively.

Recently it has been found that not all absorbers in photochemical reactions have line or band spectra. In fact some exhibit continuous absorption. Some writers have concluded that if the absorption spectrum of a diatomic molecule is truly continuous, the molecule is disrupted or decomposed into atoms when the frequency of the absorbed radiation is not great enough to produce ionization. Those photochemical reactions in which the absorber molecule has a continuous spectrum in the region of the spectrum under investigation, and consequently those in which the primary action of the light decomposes the molecule into atoms, have been called primary decomposition photochemical reactions in contrast to the excited atom or molecule types.

It is pointed out in this paper that a given photochemical reaction may belong to the excited molecule type in one region of the spectrum and to the primary decomposition type in another region of the spectrum; also that the quantum efficiency of the primary decomposition type is independent of the wave length and pressure, whereas it is not independent in the excited atom or molecule types.

Historical

Einstein's Law of Photochemical Equivalence, when tested by comparing the number of molecules which react with the quanta of radiation

absorbed, appears to have been violated¹ in the majority of reactions which have been quantitatively studied. In the abnormally low yields the absorbed light energy may lose its effectiveness by fluorescence or ineffective collisions. Abnormally high yields may be attributed to chain reactions. While secondary reactions are of fundamental importance, it is wished to restrict the discussion primarily to the primary action of the light.

It is now accepted as fact that band spectra are attributed to change in rotational or vibrational or electronic energy levels or a combination of these changes in the molecules. On this basis Stern and Volmer² have taken issue with Warburg's³ assumption that gaseous hydrogen bromide and hydrogen iodide are decomposed into atoms as a primary action of ultraviolet light. Moreover, they suggested that the hydrogen halide molecule is first excited by the ultraviolet light and that a collision of the excited molecule with a normal molecule produces a hydrogen and a halide molecule. More recently Franck⁴ and Bodenstein¹ have also postulated that in general the primary action of light in photochemical reactions produces an excited molecule. Mulliken⁵ assumed that iodine vapor in the visible spectrum is dissociated into atoms by the absorption of light in a region of continuous absorption. The reason given for this assumption is that in its absorption spectrum the vibration frequency of the atoms in the molecule approaches zero and that the band absorption spectrum in this region of the spectrum merges into a region of continuous absorption. In addition Franck⁴ and Dymond⁶ have observed that the absorption of light by the iodine molecule in the region of continuous absorption produces no fluorescence. With this additional evidence, Franck⁴ asserts that the halogens are dissociated into atoms by the absorption of light in the region of continuous absorption. He also states that one of the dissociated atoms must be excited, inasmuch as the threshold value for the spectroscopic energy of dissociation is greater than the thermochemical value. Birge⁷ and his associates have found that the absorption spectrum of oxygen is similar to that of iodine. In addition they have been able to calculate heats of dissociation of molecules from vibrational energy terms of band spectra data.

Tingey and Gerke⁸ have made observations on the ultraviolet absorption spectra of hydrogen bromide and hydrogen iodide during photochemical

decomposition. These spectra were found to be continuous. It was concluded that these molecules were dissociated into atoms by the primary action of the light.

Additional examples of photochemical reactions will be found in Table I, in which the absorption spectra indicate that the primary action of the light is the dissociation of the molecules. Examples of the excited molecule class for which the spectroscopic data exist also will be listed in Table I.

The first class listed in Table I is called the "excited reactant" class, in which molecules are excited by the primary action of light absorption. Then by a collision the excited reactant molecule produces a photochemical reaction. The second class is called the "excited sensitizer" class, in which the radiation is absorbed by the sensitizer or catalyzer. This excited sensitizer then by a collision with the reactants utilizes this absorbed energy in producing photochemical change between reactants. The third class listed in Table I is called the "primary decomposition" class, in which the primary action of the absorbed light by the reactant is to produce decomposition of the reactant or sensitizer. It is stated whether great care was taken to remove traces of moisture. In those reactions in which heat is absorbed, the photochemical efficiency is usually low. In the exothermal reactions it is possible that the photochemical efficiency may become very great, especially in those reactions where traces of water are present. In this table it is noticed that there are very few exothermal reactions which are listed as reactions with secondary spontaneous chain reactions. This is due to the absence of data on the photochemical efficiency of these reactions in which water has been excluded.

It is possible to have a complex reaction in which the rate of the reaction is the sum of the separate rates which correspond to the classes listed above. Thus in Table I the decomposition of ozone in the presence of chlorine

as a sensitizer is the sum of the rate of decomposition of ozone caused by its own absorption of light and the rate of decomposition caused by the absorption of light by the catalyzer, chlorine. The decomposition of ozone in the presence of chlorine or bromine, as listed in Table I, is principally sensitization by primary decomposition. When more reactions of this type are investigated, it may be convenient to subdivide primary decomposition photochemical reactions into the reactant and sensitizer classes.³⁸

Einstein's Law of Photochemical Equivalence

Einstein's law of photochemical equivalence appears to have been found wanting in all of the "excited reactant" and "excited sensitizer" photochemical reactions in Table I. The reason which has been given for the failure of this law lies in the possibility that the excited reactant or sensitizer may re-radiate the absorbed radiation as fluorescent radiation or lose it by collisions which are ineffective in producing photochemical reactions. (On the other hand the examples of the "primary decomposition" class in Table I which have been quantitatively investigated are in complete harmony with Einstein's law. The photolyses of hydrogen bromide and hydrogen iodide have been quantitatively investigated as a function of temperature, wave length, pressure, inert gas and in the liquid state with the universal result that two molecules are decomposed per quantum of absorbed radiation.^{1,39}

While the data are very complete for these two reactions, data on other reactions should be available before it would be certain that only "primary decomposition" photochemical reactions obey Einstein's law. Moreover, it would seem reasonable that every quantum of absorbed light which decomposes a molecule into atoms has a better chance of producing secondary reactions than one which produces an excited molecule in which one of the electrons is temporarily lifted to a higher energy level.

The Halogens.—In the band absorption spectra of the halogens the vibration frequency approaches zero and a region of continuous absorption sets in. Mulliken⁶ has assumed that it was possible that the halogens were decomposed into atoms in the region of continuous absorption. Franck⁴ and Dymond⁶ have assumed that the halogens are decomposed into a normal atom and an excited atom because the radiant energy is greater than the thermochemical heat of decomposition. They also state that the iodine fluorescence cannot be excited by absorption of the light

³⁸ The writer is indebted to Professor S. C. Lind for this suggestion.

³⁹ It is not to be expected that all reactions of this class should have the same photochemical efficiency since, in general, secondary reactions are to be expected which may be different for different reactions. Investigation of other photochemical reactions with continuous absorption spectra will be interesting from this point of view. It seems possible that the photolysis of hydrogen bromide and hydrogen iodide should be very useful for the counting of quanta in a given beam in ultraviolet light.

in the continuous region. Accordingly, the class to which a photochemical reaction in which the halogen is the absorber belongs depends upon whether the wave length of light is in the region of band or continuous absorption.

The Halogen Hydrides.—The photographs of the absorption spectra of hydrogen chloride, bromide and iodide have been found to be continuous in structure.^{14,8} Tingey and Gerke⁸ have discussed the possibility as to whether the structure is apparently or actually continuous. It was concluded that the structure must be actually continuous if the spacing of the vibrational energy levels for the hypothetical electronic excited molecules would be approximately equal to those of the normal molecule. If it is granted that these absorption spectra are actually continuous, then it seems necessary that the primary action of the light produces a splitting of the molecule into two parts, which are presumably atoms. This assumption has in its support that no emission band spectra⁴⁰ corresponding to uni-univalent polar molecules have ever been observed.

With respect to the photochemical formation of the hydrogen chloride by the absorption of light by chlorine it is necessary to mention that the absorption of light in the continuous region and beginning with 3000 Å.³³ has been found to be effective when the gases are dry. In the presence of traces of water vapor wave lengths in the region of band absorption in the visible are also effective. Consequently the photochemical formation of hydrogen chloride in the absence of impurities is listed in the primary decomposition class. Moreover, this reaction in the presence of water vapor is not listed at all because the facts are not clear as to the role of the water vapor. For example, it has been found that in the case of the formation of hydrogen chloride one quantum of visible light would produce about a million molecules of hydrogen chloride,⁴¹ whereas it^{12,33} has been found that the reaction hardly proceeded at all in the visible region where the reaction mixture was carefully freed from water.

Oxygen.—The absorption spectrum of oxygen has been found to be similar to those of the halogens by the recent measurements of Leifson.¹⁴ In the far quartz and the near fluorite ultraviolet regions are the absorption bands of oxygen which at shorter wave lengths merge into a region of continuous absorption. Birge and Spomer⁷ attribute this continuous absorption to a dissociation of the molecule. It will be interesting to compare the photochemical activity of oxygen in the region of band and continuous absorption. Born and Gerlach³⁶ observed that the production of ozone was very great in the region of continuous absorption and that it seemed to fall off abruptly at greater wave lengths where band absorption began. The careful quantitative experiments of Warburg¹¹ in the region of band absorption show that oxygen forms ozone, but that 1.04 to 3.04

⁴⁰ Mulliken, *Phys. Rev.*, **26**, 1 (1925).

⁴¹ Bodenstein, *Z. physik. Chem.*, **85**, 351 (1913).

quanta are necessary to decompose one molecule of oxygen. This efficiency depends upon the wave length and the pressure. The formation of ozone is an example of both the "excited reactant" and "primary decomposition" types of photochemical reaction, depending upon whether the absorption spectrum consists of bands or is continuous in structure.

Ammonia.—The nature of the photochemical decomposition of ammonia has been uncertain, due to the fact that no definite conclusion could be drawn as to whether the absorption spectra were bands or continuous in structure. Examination of Leibson's recent data,¹⁴ however, shows that the structure consists of bands throughout the whole region of absorption. The decomposition of ammonia, therefore, belongs to the "excited reactant" type. It is interesting to note that the photochemical efficiency, which was quantitatively studied by Warburg¹⁵ and by Kuhn¹⁷ with monochromatic light depends upon the wave length of light.

Summary

The recent data on absorption spectra of gases entering into photochemical reaction, together with the older data, have made possible an extended study of the nature of the primary action of the absorbed light. In several cases band or line spectra have been observed for the absorbers which definitely classify these photochemical reactions into two widely known types of photochemical action which have been called in this paper the "excited reactant" and "excited sensitizer" types. In other cases not band spectra but continuous spectra were observed. Some authors have concluded as a necessary consequence of the most recent developments of the quantum theory of molecular spectra that the primary action of light in these cases is a dissociation of the molecule. Several examples of this class, which have been called the "primary decomposition" type in this paper, have been collected and compared with examples of the "excited reactant" and "excited sensitizer" types of photochemical reaction.

The quantum efficiencies of photochemical reactions as measured by the number of molecules which react per quantum of light absorbed are in accord with the suggestion; the chance for stimulation of photochemical action by excited molecules or atoms is not as great as by atoms produced from molecules by the primary action of the absorbed radiation.⁴²

FOREST HILLS, LONG ISLAND

⁴² Since the manuscript was first written the writer has noted the interesting articles by Bonhoeffer and Steiner, *Z. physik. Chem.*, **122**, 287 (1926), on the continuous absorption in hydrogen iodide vapor and by Lewis, *Nature*, **119**, 493 (1927), on the constancy of the quantum yields on the photolysis of hydrogen iodide at very low pressures, which support the primary decomposition mechanism for those photochemical reactions with continuous absorption spectra.

THE ACTIVITY OF WEAK ACIDS IN AQUEOUS SULFATE SOLUTIONS

BY MERLE RANDALL AND CRAWFORD F. FAILEY

RECEIVED APRIL 4, 1927

PUBLISHED NOVEMBER 5, 1927

It was shown in another place¹ that sulfates cause a marked rise in the activity coefficient of aqueous solutions of non-electrolytes. It was also shown in the previous article that the effect of salts was in general the same upon the activity coefficient of the undissociated part of weak acids and moderately strong acids as that upon non-electrolytes.

When we consider the total effect of sulfates upon the escaping tendency of acids of intermediate strength, the salting-out effect is greatly overshadowed by the removal of hydrogen ion to form hydrosulfate ion. Thus, in two solutions of a weak acid at a fixed activity, we have $(m_+ 'm_- ')/(m_+ m_-) = \gamma_{\pm}^2 / \gamma_{\pm}^{\prime 2}$, where m and m' are the molalities of the two solutions. If one of the solutions contains sulfate, there is formation of hydrosulfate ion with the removal of hydrogen ion from the solution. Consequently a larger molality of acid anion must be present to maintain equilibrium and the total molality will be increased.

Partially neutralizing this effect will be an increase in the activity coefficient of the undissociated molecules $m_u' / m_u = \gamma_u / \gamma_u'$. This effect will decrease the concentration of undissociated molecules, and the observed change in the molality of the acid, whose activity is held constant on adding sulfate, will be the algebraic sum of the change in the molality of acid anion and of undissociated molecules. The increase in total acid molality will be greater the larger the dissociation constant of the weak acid being studied.

Activity of Monochloro- and Dichloro-acetic Acids in Sulfate Solutions from Distribution Measurements

The same materials and methods were used as in the previous measurements.¹ The results are shown in Tables I, II and III. The first column gives the density of the aqueous phase, the second the ionic strength

.2029	.02796	.999	.2000	.009126	.962	.4000	.05490	.804
.4008	.02723	1.026	.6400	.009015	.974	.6400	.05633	.784
.7580	.02578	1.083	.9836	.008653	1.015	.9836	.05679	.777

Discussion.—The values of m°/m are plotted in Fig. 1 against the square root of the ionic strength of the added sulfate. Because of the number of variables and the complexity of the equilibria it is not practical to attempt to determine the activity coefficient of the various molecular

² Rørdam, *Thesis*, Copenhagen, 1925.

species in the solutions. If we define the activity as equal to the stoichiometric molality, m° , of a given solution of a weak acid in pure water, then m°/m will be analogous to the activity coefficient for a solution of the same activity in another solvent when the molality of the acid in equilibrium is m .

We note that the "activity coefficient" of the acid is lowered by a larger amount the larger the dissociation constant of the acid. This is in agreement with the assumption of a larger amount of hydrosulfate ion formed with the stronger acid. The salting-out effect is more noticeable with the

Fig. 1.—"Activity coefficients" at constant activity of weak acids in aqueous sulfate solutions at 25°.

weaker acids. The order of the effect of the potassium sulfate and magnesium sulfate upon dichloro-acetic acid is the same as the order of the effect of these salts on the activity coefficient of sulfuric acid,³ which must be considered a moderately weak acid. The activity coefficient of hydrobromic acid, a typical strong electrolyte, is greatly lowered by sulfates.⁴ This effect is almost wholly due to the formation of hydrosulfate ion. If we were to draw a curve for hydrobromic acid similar to that of Fig. 1, we should find that it lies lower than that of dichloroacetic acid for the same added sulfate.

³ See (a) Harned and Sturgis, *THIS JOURNAL*, **47**, 945 (1925). (b) Randall and Langford, *ibid.*, **49**, 1445 (1927).

⁴ See Livingston, *ibid.*, **48**, 45 (1926).

Summary

The distribution of monochloro- and dichloro-acetic acids between aqueous sulfate solutions and normal dibutyl ether has been measured.

The "activity coefficient" as measured by the ratio of the molality in pure water to that in a salt solution at a constant activity is determined by the salting-out effect of the sulfate on the undissociated part of a weak acid, and the amount of formation of hydrosulfate ion.

At constant ionic strength the "activity coefficient" is lower the greater the dissociation constant of the weak acid.

The "activity coefficient" is lowered to a greater extent by potassium sulfate than by magnesium sulfate.

THE EFFECT OF SHAKING ON THE EVOLUTION OF GASES FROM SUPERSATURATED SOLUTIONS AND ITS IMPORTANCE FOR THE MEASUREMENT OF THE VELOCITY OF CERTAIN CHEMICAL REACTIONS

BY KAI JULIUS PEDERSEN

RECEIVED APRIL 13, 1927

PUBLISHED NOVEMBER 5, 1927

Introduction

During the examination of the rate of decomposition of nitro-acetic acid in aqueous solution

by means of an apparatus described by J. N. Brønsted^{1,2} in which the pressure of the gas is measured during the reaction, it was found necessary to examine whether the gas was evolved sufficiently quickly to prevent a supersaturation effect. In order to get a quick evolution of the carbon dioxide the reaction flask was shaken horizontally. It was found that the supersaturation is very much less at a certain rate of shaking than with slower or quicker shaking. When the rate of shaking is not kept very constant, the supersaturation may, even when it is only small, as a consequence of this variability, cause a considerable error. The author thinks that this examination of the influence of the supersaturation may have some interest for other investigators who study the velocity of chemical reactions by measurement of the rate of gas evolution. Part 1 of this paper is an examination of the velocity of the evolution of carbon dioxide from supersaturated solution and its dependence upon the length and number per minute of the horizontal shakings of the reaction vessel. Part

¹ Brønsted and King, *THIS JOURNAL*, 47, 2523 (1925).

² Brønsted and Duus, *Z. physik. Chem.*, 117, 299 (1925).

2 is a mathematical treatment of the influence of supersaturation on the measurement of the velocity of a unimolecular reaction.

Part 1

The experiments were made at 18° in the Brönsted apparatus. The volume of the spherical part of the flask was 210 cc. Usually 100 cc. of solution was used; in one series of experiments only 60 cc. In each experiment 0.08–0.10 g. of sodium bicarbonate (about 0.001 mole) was weighed roughly in a little platinum bucket which was suspended at the top inside the apparatus so that it could be dropped into the solution after evacuation of the apparatus. The solution was usually 0.1 *M* hydrochloric acid; in some experiments a buffer solution: 0.06 *M* acetic acid + 0.04 *M* sodium acetate (*P_H* about 4.5).

Fig. 1.—The velocity of the evolution of carbon dioxide from supersaturated solution.

In all the experiments (about 100) the rate of evolution of carbon dioxide followed the unimolecular law. Although the reaction in most cases was very quick, the agreement with the formula for the unimolecular reaction

$$kt = \text{constant} - \log P \quad (1)$$

(*k* being the velocity constant; *t*, the time in minutes; *P* = *p_∞* − *p*, the difference between the pressure *p_∞* above the solution after the reaction has finished and the pressure *p* at the time *t*) was very good; *k* was computed graphically by plotting log *P* against *t*. As seen from (1) it is not necessary to know the exact weight of the sodium bicarbonate nor the

time when it is dissolved. The shaking was stopped before the bucket was dropped and the reaction flask was kept quiet for some minutes until the first vigorous evolution of carbon dioxide had ceased, after which the pressure remained almost constant. Then the shaker was started and the rate of evolution from the supersaturated solution determined.

The finite velocity of the reaction in the aqueous phase, $\text{H}_2\text{CO}_3 \rightarrow \text{H}_2\text{O} + \text{CO}_2$ (dissolved), was found to be without importance even in the quickest experiments with acetate buffer solutions. This is in agreement with the measurements of C. Faurholt,³ who has determined the velocity of the above reaction. At $P_{\text{H}} = 5$ he finds at 18° the velocity constant $k = 9$ (min.^{-1} , decad. logs) for the unimolecular reaction. In $0.1 M$ hydrochloric acid the reaction is practically instantaneous. Thus the velocity of the formation of dissolved carbon dioxide from the bicarbonate is, even at $P_{\text{H}} = 5$, ten times greater than the greatest velocity found for the evolution of gaseous carbon dioxide from the solution.

The evolution of carbon dioxide from its supersaturated solution is a limited reaction consisting of two opposing reactions: CO_2 (dissolved) $\rightleftharpoons \text{CO}_2$ (gas). As is well known, the constant h which has been measured is really the sum of the constants for the velocities of the two opposing reactions.

The experimental results are given in Fig. 1 and in Tables I-VI; h is the velocity constant (min.^{-1} , decad. logs), t is the time in minutes, n is the number of horizontal movements forwards and backwards of the reaction flask and l is the length in mm. of the single movement.

In Table I an experiment is given in full to give an idea of the accuracy of the measurements; $t = 0$ is the time when the shaker is started some time after the bicarbonate has been dissolved.

When n is about 160, h has a maximum. It falls quickly when n is increased or diminished, especially rapidly when n is diminished. In Curve

III it falls to half its value when n is diminished from 159 to 158 per minute. At greater values of n , h will pass through a minimum, as seen in the figure. The shape of the curves is similar to that of an ordinary curve of resonance. The maxima can be explained as due to resonance. When n has about that value corresponding with the maximum of h , the solution reaches the neck of the flask and falls down again. When it is shaken more quickly, it does not reach so far before it is stopped in its movement. It behaves like a pendulum, which prefers a certain number of oscillations per minute. If it is pushed at other intervals than its own time of oscillation it does not move so well.

Part 2

Let us consider the reactions (I) $A \rightarrow B + C$ (dissolved), velocity constant k (decad. logs) or k_n (natural logs), $k = k_n \log e$; (II) C (dissolved) $\rightleftharpoons C$ (gas), velocity constant h (decad. logs) or h_n (natural logs), h is the sum of the velocity constants for the two opposing reactions.

Let p denote the observed pressure of C (gas) at the time t . π is the pressure we would have obtained if there were no supersaturation. $\pi - p = \delta$ is a measure for the supersaturation. The subscripts 0 or ∞ denote that the pressures correspond with $t = 0$ or $t = \infty$. We put $P = p_\infty - p$ and $P_0 = p_\infty - p_0$.

We have the following two differential equations

$$\frac{d(P - \delta)}{dt} = k_n (P - \delta) \quad (2)$$

and

$$\frac{dp}{dt} = h_n \delta \quad (3)$$

They express, respectively, that Reaction (I) would give the unimolecular constant k_n in the experiment if there were no supersaturation, and that reaction (II) approaches the equilibrium as if it were a unimolecular complete reaction with the constant h_n . (2) and (3) are the exact mathematical expressions for the velocities of Reactions (I) and (II); (3) can also be written

$$-\frac{dP}{dt} = h_n \delta \quad (4)$$

By integration of (2) we have

$$P - \delta = (P_0 - \delta_0) e^{-k_n t} \quad (5)$$

which, together with (4), gives

$$\frac{dP}{dt} + h_n P = h_n (P_0 - \delta_0) e^{-k_n t} \quad (6)$$

By integration we obtain

$$P = (P_0 - \delta_0) \cdot \left[\frac{h_n}{h_n - k_n} e^{-k_n t} - \left(\frac{k_n}{h_n - k_n} - \frac{\delta_0}{P_0 - \delta_0} \right) e^{-h_n t} \right] \quad (7)$$

From (5) and (7) by subtraction

$$\delta = (P_0 - \delta_0) \cdot \left[\frac{k_n}{h_n - k_n} \cdot e^{-k_n t} - \left(\frac{k_n}{h_n - k_n} - \frac{\delta_0}{P_0 - \delta_0} \right) e^{-h t} \right] \quad (8)$$

Using decadic logarithms, (7) and (8) can be written as follows

$$P = (P_0 - \delta_0) \cdot \left[\frac{h}{h - k} 10^{-kt} - \left(\frac{k}{h - k} - \frac{\delta_0}{P_0 - \delta_0} \right) 10^{-ht} \right] \quad (9)$$

$$\delta = (P_0 - \delta_0) \left[\frac{k}{h - k} 10^{-kt} - \left(\frac{k}{h - k} - \frac{\delta_0}{P_0 - \delta_0} \right) 10^{-ht} \right] \quad (10)$$

(9) can be written as

$$kt = \log (P_0 - \delta_0) + \log \frac{h}{h - k} - \log \left[P + (P_0 - \delta_0) \left(\frac{k}{h - k} - \frac{\delta_0}{P_0 - \delta_0} \right) 10^{-ht} \right] \quad (11)$$

If $t = 0$ is the time when the reaction is started, and if we assume that there is no C present at $t = 0$, we have $\delta = 0$, in which case (11) simplifies to

$$kt = \log P_0 + \log \frac{h}{h - k} - \log \left[P + P_0 \frac{k}{h - k} \cdot 10^{-ht} \right] \quad (12)$$

If we ignore the supersaturation, the following simple formula would hold

$$kt = \log P_0 - \log P \quad (13)$$

When the shaking is kept uniform, and accordingly h is a constant, $\log \frac{h}{h - k}$ in (12) is constant and without importance for the determination of k . The other correction $\Delta = P_0 \frac{k}{h - k} 10^{-ht}$ decreases rapidly as t increases. If we require $\Delta < 0.01$ cm., before we take readings of p , we are sure to attain this by waiting until the time t determined by

$$\Delta < 10 \cdot 10^{-ht} < 10^{-2}. \quad ht > 3. \quad t > 3/h$$

(we assume $P_0 < 10$ cm. and $h > 2k$).

In Fig. 2, AB is the straight line we should get by plotting $\log P$ against t if there were no supersaturation ($P_0 = 8$ cm., $k = 0.03$, $h = \infty$). With supersaturation, say $h = 0.3$, we get the curve AB_1 by plotting $\log P$ against t . AB_1 very quickly fuses into the straight line A_1B_1 . Thus the supersaturation only causes a parallel displacement of the straight line. The magnitude of this displacement is determined by the term $\log h/(h - k)$. Δ determines how quickly the curve AB_1 fuses into the straight line A_1B_1 .

If Reaction II had taken place in a homogeneous phase, h would be constant at constant temperature. In the present case Reaction II is a heterogeneous reaction and h varies with the rate of shaking. We shall find what influence it will have if h changes to h' at the time t_1 during the reaction. From (11) we get

$$k(t - t_1) = \log(P_1 - \delta_1) + \log \frac{h'}{h' - k} - \log \left[P + (P_1 - \delta_1) \left(\frac{k}{h' - k} - \frac{\delta_1}{P_1 - \delta_1} \right) 10^{-h(t-t_1)} \right] \quad (14)$$

From (5) we get, putting $\delta_0 = 0$,

$$\log(P_1 - \delta_1) = \log P_0 - kt_1 \quad (15)$$

and from (5) and (10)

$$\frac{\delta_1}{P_1 - \delta_1} = \frac{k}{h - k} - \frac{k}{h' - k} 10^{-(h-k)t_1} \quad (16)$$

If we substitute (15) and (16) in (14) we get

$$kt = \log P_0 + \log \frac{h'}{h' - k} - \log \left[P + P_0 \frac{k}{h - k} \left(10^{-(h'(t-t_1) + ht_1)} - \frac{h' - h}{h' - k} 10^{-(h'(t-t_1) + ht_1)} \right) \right] \quad (17)$$

which gives an expression for k when $t \geq t_1$. It shows that the change in supersaturation due to the change in h at $t = t_1$ causes a new parallel displacement of the straight line whose slope determines k . If $P_0 = 8$ cm., $k = 0.03$, $h = 0.3$, when $t < 5$ min., but $h = 0.6$ when $t > 5$ min., we get the curve ACB₂ in Fig. 2. CB₂ fuses into the straight line A₂B₂ parallel to AB. The magnitude of the extra displacement is determined by the change in the constant term of equation (17) compared with that of (12) which holds for $t \leq t_1$. The

Fig. 2.--The effect of supersaturation on a uni-molecular reaction.

$$\Delta_2 = -P_0 \frac{k}{h - k} \frac{h' - h}{h_1 - k} 10^{-(h'(t-t_1) + ht_1)}$$

shows how quickly this second displacement takes place, while

$$\Delta_1 = P_0 \frac{k}{h - k} 10^{-(h'(t-t_1) + ht_1)}$$

expresses the changed velocity for the first displacement for $t > t_1$. Of course Δ_1 will only play a part when the change in h to h' occurs very soon after the start, that is, before the first displacement has finished.

If we wish to calculate how great a change in h we can allow during the reaction, it is obviously sufficient to consider the corrections in the

constant term. We, therefore, put $\Delta_1 = \Delta_2 = \Delta = 0$. We get inste, of (12) and (17) the simpler formulas

$$0 < t < t_1: kt = \log P_0 + \log \frac{h}{h-k} - \log P \quad (18)$$

$$t_1 < t: kt = \log P_0 + \log \frac{h'}{h'-k} - \log P \quad (19)$$

(19) can be written as follows

$$t_1 < t: kt = \log P_0 + \log \frac{h}{h-k} - \log \left(P \frac{h}{h-k} \frac{h'-k}{h'} \right)$$

which by comparison with (18) gives

$$\frac{\Delta P}{P} = \frac{h}{h-k} \frac{h'-k}{h'} - 1 = \frac{k}{h-k} \frac{h'-h}{h'}$$

$$\frac{\Delta h}{h} = \left(\frac{h}{k} - 1 \right) \frac{\Delta P}{P}$$

If we require that $\Delta P/P < 0.2\%$, the permissible variation in h is determined by

$$\frac{\Delta h}{h} < \left(\frac{h}{k} - 1 \right) 0.2\%$$

Examples

While the free undissociated nitro-acetic acid is stable in aqueous solution, the decomposition of the nitro-acetate ion follows the unimolecular law.⁴ The constants are at 18° 0.0241 and at 20° 0.0316 (min.⁻¹, decad. logs).

1. In an experiment on the decomposition of the nitro-acetate ion we have $k < 0.03$. $P_0 < 10$ cm. We use 100 cc. of solution. We shake so that we get as little supersaturation as possible: $l = 18$ mm., $n = 158$ (the maximum of Curve I in Fig. 1). From the figure we find $h = 0.94$. We have $\Delta < 10 (0.03/0.9) 10^{-0.94t}$. $t = 1$, gives $\Delta < 0.04$, $t \geq 2$, gives $\Delta < 0.005$. If we allow an error of 0.01 cm. in P , we can start the readings two minutes after the dissolution of the nitro-acetic acid.

In h we can allow a variation of $((0.94/0.03) - 1) 0.2 = 6\%$. From Curve I we find that n must be kept within the limits $152 < n < 163$.

2. If we shake more rapidly, say $n = 190$, $l = 12$ mm., the conditions become much less favorable for a good result, as seen from the following calculations. From Curve II in Fig. 1 we find $h = 0.43$; $\Delta < 10 (0.03/0.40) 10^{-0.43t}$.

The induction period is much longer

t	1	2	3	4	5
Δ	0.28	0.10	0.04	0.014	0.006

We must wait five minutes for the first reading. The permissible variation in h is $((0.43/0.03) - 1) 0.2 = 2.6\%$. From the curve we find that n

⁴ Pedersen, *Trans. Faraday Soc.*, 23, 316 (1927).

must be kept within the limits $189 < n < 191$. A comparison of the two examples makes clear of how great importance it may be to know how to do the shaking in order to get the best effect.

In conclusion I wish to thank Professor Dr. Niels Bjerrum, whose advice and helpful criticism of my work have been of great value.

Summary

The supersaturation error in measurements of velocity of chemical reactions by rate of gas evolution has been examined.

The velocity of the evolution of carbon dioxide from supersaturated solution follows the unimolecular law. The dependence of its velocity constant h on the number of horizontal shakings n per minute has been determined. h has a maximum and falls rapidly when n is diminished or increased.

A mathematical expression for the velocity of the evolution of gas in the course of the reaction $A \rightarrow B + C$ (dissolved), followed by the reaction C (dissolved) $\rightleftharpoons C$ (gas), has been derived.

The importance of the results for the measurement of a fairly quick unimolecular reaction has been discussed.

SILVER ION CATALYSIS OF PERSULFATE OXIDATIONS. I SALT EFFECT ON THE VELOCITY OF OXIDATION OF AMMONIA. II. COMPARISON OF THE VELOCITY WITH VARIOUS REDUCING AGENTS

By CECIL V. KING

RECEIVED MAY 16, 1927

PUBLISHED NOVEMBER 5, 1927

I. Introduction

It has been shown that persulfates react with ammonia, in alkaline solutions, in the presence of silver salts, with a measurable velocity,¹ and Yost has represented the reaction as taking place in two steps, as follows (the silver ion, however, being in an ammonia complex):

There seems to be no question that trivalent silver is formed, as indicated by two things: the analysis of the insoluble compound formed when persulfates and silver salts are mixed, and the fact that the reaction rate, when ammonia or chromic salts are oxidized, is proportional to the *first* power of the silver-ion concentration.

¹ (a) Marshall, *Proc. Roy. Soc. Edinburgh*, 23, 163 (1900). (b) Yost, *This Journal*, 48, 374 (1926).

Yost found that when this reaction was carried out in alkaline solution increase in ammonia concentration increased the velocity of reaction, while increase in hydroxide concentration decreased it. Since in any one experiment ammonia and hydroxyl ions both disappear and the silver-ion concentration remains constant, rather good "pseudo-unimolecular" rate constants can be obtained. Since Yost attributes the measurable velocity entirely to reaction (1), he concludes that the effect of increased ammonia concentration is to increase the concentration of a silver ion with more ammonia groups attached than in $\text{Ag}(\text{NH}_3)_2^+$, and that this higher complex makes reaction (1) faster. The effect of hydroxide he treats rather as a specific effect than a general salt effect, though he suggests that perhaps "a decrease in the activity coefficient of peroxysulfate ion is superposed upon the effect of producing a less reactive substance" $[\text{Ag}(\text{NH}_3)_2\text{OH}]$. It is the purpose of this paper to show that the effect of hydroxides is not a specific but is a perfectly general salt effect; to show that the reaction is "pseudo-unimolecular" only in a certain range of salt concentration (that is, where change in ionic concentration during the course of the reaction counteracts the loss of ammonia); and to discuss the question of possible dependency of the velocity of the reaction on the nature of the reducing agent.

Theoretical

If the velocity-determining reaction is $\text{S}_2\text{O}_8^{--} + \text{Ag}^+ \longrightarrow \text{Ag}^{+++} + 2\text{SO}_4^{--}$, then, according to Brönsted's theory of kinetic salt effect,² the expression for the velocity should be

$$V = k' C_{\text{S}_2\text{O}_8^{--}} \cdot C_{\text{Ag}^+} \cdot \frac{f_{\text{S}_2\text{O}_8^{--}} \cdot f_{\text{Ag}^+}}{f_{(\text{S}_2\text{O}_8, \text{Ag})^{--}}}$$

where f represents activity coefficient; and we may consider that $f_{(\text{S}_2\text{O}_8, \text{Ag})^{--}}$ (the activity coefficient of the first complex formed between Ag^+ and $\text{S}_2\text{O}_8^{--}$) is approximately equal to f_{Ag^+} , since both are univalent ions, thus reducing the velocity expression to

$$V = k' C_{\text{S}_2\text{O}_8^{--}} \cdot C_{\text{Ag}^+} \cdot f_2$$

where $f_{\text{S}_2\text{O}_8^{--}} = f_2$ if $f_{\text{S}_2\text{O}_8^{--}}$ approximates the activity coefficient of any bivalent ion. Then

$$k = k' f_2$$

where k = the observed rate constant and k' = the theoretical rate constant in a solution containing no ions; and k as measured and plotted later in this paper is directly proportional to the activity coefficient of a bivalent ion, provided that Brönsted's theory is correct and that the velocity is actually determined by the reaction assumed.

Even if the second reaction

² Brönsted, *Z. physik. Chem.*, **102**, 169 (1922); *ibid.*, **115**, 337 (1925); Lecture, Columbia University, Columbia University Press, New York City, 1926.

were slow, according to Brönsted's theory the salt effect would be small and linear and the total salt effect would be nearly the same; but if this were true it should be evidenced by accumulation of the trivalent silver and precipitation of the insoluble black compound, and this is not the case.

Experimental

Method of Measuring Velocity.—Since in a closed system the pressure of nitrogen above the solution is directly proportional to the amount of persulfate decomposed (provided thorough shaking of the reaction vessel insures equilibrium at all times), the velocity can be measured by following this pressure. The same type of apparatus described before for measurements of this sort was used.³ The space above the solution in the velocity apparatus was evacuated to practically the vapor pressure of the solution; evacuation was continued for as short a time as possible in order to avoid undue volatilization of ammonia. The volume of solution used was 100 cc. and the space above the solution was about 100 cc. It can be shown from the vapor pressure of ammonia from the solutions used that the amount of ammonia in the gas phase was always considerably less than 1% of the total amount present, so this factor is unimportant.

In making the measurements, suitable amounts of standard persulfate, ammonia, hydroxide and salt solutions were mixed and made up to 98 cc., put in the reaction flask and allowed to come to temperature. A 2 cc. portion of standard silver nitrate solution was carefully measured into a glass capsule with a small glass hook near its open end, and this capsule suspended from a platinum loop fused into the side of the neck of the reaction flask. The flask was closed and the apparatus evacuated with shaking to aid evolution of dissolved air in the solution, the apparatus closed, the pressure read and the capsule with the silver nitrate dropped into the solution and thoroughly mixed by the shaking. The time was noted from the time the silver nitrate solution became thoroughly mixed with the other solution.

The rate constants were calculated in the same way as Yost's, that is, from the integrated form of the equation

$$\frac{dC_{\text{SO}_4^{--}}}{dt} = k \cdot C_{\text{SO}_4^{--}} \cdot C_{\text{Ag}^+}$$

Solutions Used.—Potassium persulfate was prepared by recrystallizing the c. p. salt two or more times from water between 50 and 0°; the crystals were drained on a cotton plug in a funnel, washed with cold water, dried by sucking dried, dust-free air through them for two or three hours and further allowed to stand several days in a desiccator over sulfuric acid before use. Standard solutions were made by direct weighing of the salt, and were made fresh every four or five days.

C. p. ammonia water was diluted to the desired strength and standardized by running a sample from a pipet into excess of standard hydrochloric acid, titrating back with standard potassium hydroxide with methyl red as indicator.

Potassium and sodium hydroxides were made from saturated solutions that had stood for some time to allow the insoluble carbonates to settle out, and standardized

³ (a) Brönsted and Daus, *Z. physik. Chem.*, 117, 299 (1925); (b) Brönsted and King, *THIS JOURNAL*, 47, 2523 (1925).

against resublimed benzoic acid. The solutions were made in carbon dioxide-free, distilled water and protected from the air.

Potassium and sodium nitrates were recrystallized from the c. p. salts, dried at 100°, pulverized and dried again at 100° and allowed to stand in a desiccator over sulfuric acid for several days before use; the standard solutions were made by weighing the salts.

Silver nitrate was made by recrystallizing the c. p. salt. A 0.15 *M* solution was made by weighing the salt, and a 2 cc. portion was pipetted out of this same solution for every experiment. The solution was kept in a dark closet. The 2cc. pipet used could easily deliver the same amount with a maximum error of less than 0.5%, well within the error of measurement of the reaction-velocity constants.

In all experiments the concentration of the catalyst was the same; the concentration of ammonia was the same (within 0.5%) and was much higher than that of the persulfate; and the concentration of persulfate was the same (except in two experiments which are noted later). The concentration of persulfate used was chosen to give a suitable increase in pressure in the apparatus, and the concentration of ammonia was chosen so that the proportion oxidized was not too great, and the change in ionic concentration during the reaction would practically balance the loss in ammonia, except in a few experiments noted later. All measurements were made at $20^\circ \pm 0.01^\circ$.

Results of the Measurements.—Experiment 40 in Table I shows the results of a typical experiment with a solution containing sufficient potassium hydroxide so that no NH_4^+ ion was formed during the reaction, that is, so that the solution did not become much less alkaline. In some experiments such a small amount of potassium hydroxide was used that it would all be neutralized before the reaction was over; NH_4^+ is then formed and the ammonia disappears much more rapidly. In these cases the velocity constants fell off towards the end of the reaction and only those over the first half of the reaction were used for the averages. Experiments 28 and 26, Table I, show how the "constants" fall off when no potassium hydroxide is used and so ammonia disappears both from the oxidation and neutralization of H^+ ion formed—even though sufficient inert salt (potassium nitrate) is present so that the change in ionic concentration is small.

In Table II are given the mean constants for a number of experiments in which varying amounts of potassium hydroxide, sodium hydroxide, potassium nitrate and sodium nitrate were added. When potassium nitrate and sodium nitrate were used, it was, as stated, necessary to start with some alkali present, if the "pseudo-unimolecular" constants were to be obtained; and so 0.02 *N* potassium hydroxide was present in all these experiments, this being about the minimum amount possible. It is unfortunate for the comparison between the effect of sodium and potassium ions that sodium ion could not constitute the entire positive ion present in those experiments with sodium ion; but due to the difficulty of preparing pure sodium persulfate this was not attempted. It would also have been possible to prepare pure ammonium persulfate and then have

included the ammonia formed in the alkaline solution from this in the total ammonia concentration. This was also not attempted, chiefly because a qualitative, not a quantitative, comparison between the potassium and sodium ions was desired. Of course, only a qualitative comparison between the hydroxide and nitrate ions can be made, as these must both be present in all solutions.

It was feared that when a solution became low in hydroxyl-ion concentration, some nitrate might be formed—that is, not all the oxidation resulted in nitrogen gas.⁴ But in no case was there evidence that less nitrogen was evolved than in the most alkaline solutions.

In Table III are given full data for experiments made with the lowest possible salt concentrations. No ionic substances were present except those actually necessary; and in Experiments 45 and 46 the persulfate concentration was reduced to the minimum necessary for accurate measurements by the method used. It was known that ammonia would disappear rapidly, and that the ionic concentration would increase, as indicated in the equation

(ions whose concentrations are unchanged being enclosed in the parentheses). Since both these effects would decrease the velocity, it is to be expected that the "constants" would fall off very rapidly, and that this happened is shown in the table. Only the very first "constants" can give a measure of the true velocity for the ionic concentrations specified for these solutions in Table II; and these values, due to the difficulty of accurate measurement, are less accurate than those in Table II. Never-

theless, they show the order of magnitude of the velocity and indicate very clearly how different it is in these solutions of lowest ionic concentration.

It is evident that in solutions of very low ionic concentration the salt effect due to changing ionic concentration during the course of the reaction entirely masks the character of the reaction. It is necessary, of course, to determine the character of such a reaction in high concentrations of some neutral salt, where the change will have little influence.

Fig. 1.—Effect of added salts on the persulfate-ammonia reaction.

Discussion of Results

The results given in Tables II and III are plotted in Fig. 1. A glance at this figure shows again how useless it is to record a velocity constant

for a reaction between ions unless not only their concentration but the total ionic concentration of the solution is given. This is especially true for very low salt concentrations where the velocity changes very rapidly with changing salt concentration.

The curves make it plain that the effect is not a specific one for hydroxides, since the effect of the salts used is of the same character and magnitude. Both positive and negative ions show an effect, since changing either one changes the salt effect. Sodium ion shows less effect than potassium ion, and this is in agreement with the measurements of the effect of sodium and potassium salts on activity coefficients of ions by other means, for example, from solubility measurements. Slightly soluble salts are as a rule less soluble in sodium salts than in potassium salts at corresponding concentrations,⁵ and this means that the activity coefficient of the saturating salt is greater in the sodium salt than in the potassium salt solution. Here, since k is proportional to f_2 , it is seen that f_2 is greater in the presence of the sodium salt than in the presence of the potassium salt.

There are in the literature no direct comparisons available between the effects of hydroxides and nitrates on the activity coefficients of other ions. However, as a rule hydroxides have a greater "salting out effect" than other ionic substances, both on non-electrolytes and electrolytes.⁶ This would indicate that the activity coefficients of other ions should be lower in the presence of nitrates than in the presence of hydroxides, and this is in accordance with the data here presented and shown in Fig. 1.

It is impossible to extrapolate the curves to zero concentration and so get any accurate measure of the absolute magnitude of the salt effect, but the sign, general character and magnitude agree with the Brönsted theory. It is sufficient to say that in this solution, containing some bivalent and some monovalent ion, at a concentration of 0.04 N , f_2 = about 0.40, the velocity of the reaction should be only about four-tenths its value in a solution of zero ionic concentration.

In the inserted figure some of Yost's measurements have been replotted on the same scale as the others. The data are given in Table IV. The first two measurements were with ammonium persulfate, with no addition of potassium hydroxide, and, as noted before, these "constants" fall off rapidly during the reaction. Consequently the first "constants" only are taken and these are recalculated to the same concentration of ammonia as the other measurements, using Yost's curve for the effect of ammonia on the reaction rate to make this correction. The values obtained are,

⁵ See, for example, (a) Brönsted, *THIS JOURNAL*, **44**, 877 (1922); (b) *Kgl. Danske Videnskab. Selskab., Math.-fys. Medd.*, **4**, No. 4 (1921).

of course, not very accurate but it is evident that the curve as a whole is of exactly the same type and the salt effect of the same magnitude as found in the present investigation. It is difficult to make a direct comparison due to the difference in ammonia concentration and difference in temperature (Yost's measurements were at 25°).

II. Comparison of the Velocity with Various Reducing Agents

According to the assumptions made, any substance oxidized by persulfate in the presence of silver ion (at negligible speed otherwise) should be oxidized at the same rate, the total salt concentration being the same, provided the second reaction is very rapid, and in case the persulfate and silver ions are in the same condition of solvation, etc. At least, no such oxidation should be faster than the oxidation of Ag^+ to Ag^{++} . Now Marshall and Inglis have measured the velocity of oxidation of NH_4^+ to NO_3^- by persulfate in the presence of silver ion at 25°, ^{4b} with only NH_4^+ , $S_2O_8^{--}$ and $AgNO_3$ present, and also in the presence of other salts. Yost has measured the velocity of oxidation of chromic ion by persulfate in the presence of silver ion.⁷ Some typical total salt concentrations and rate constants (those of Marshall and Inglis recalculated in the same manner as those in this paper) are given in Table VI. From these figures it seems quite possible that the velocities of the NH_4^+ and the Cr^{+++} oxidations are controlled in exactly the same way, the small differences being due to salt effect. But the ammonia oxidation is 10 times as fast; Yost concludes that this is due to the fact that not Ag^+ but $Ag(NH_3)_2^+$ is reacting. This appears to be a plausible explanation.

The author has also carried out some experiments involving silver ion as the catalyst for the reaction

In these solutions the Ag^+ was expected to be in the same state of solvation as in the Cr^{+++} and NH_4^+ solutions and, consequently, the velocity of reaction should be about the same. But the experiments indicated that it was about 4000 times as fast as in the Cr^{+++} and NH_4^+ oxidations,

⁷ Yost, *THIS JOURNAL*, 48, 152 (1926).

and 300 to 400 times as fast as in the ammonia oxidation. The results of one experiment are given in Table V and also in Table VI.

TABLE V
EXPERIMENTAL RESULTS

0.02 <i>N</i> Na ₂ C ₂ O ₄	}	Total salt concentration, 0.03 <i>N</i>

TABLE VI
TYPICAL VALUES

Total salt equiv. concn.	<i>k</i>	
1.0	0.218	Marshall and Inglis, NH ⁺ oxidation (25°)
0.5	.267	
0.2-0.36	0.30-0.36	Yost, Cr ⁺⁺⁺ oxidation (25°)
.2	2.25-3.25	King, NH ₃ oxidation (20°)
.03	7.0	King, NH ₃ oxidation (20°)
.03	1100-1200	King, C ₂ O ₄ ⁼ oxidation (20°)

These experiments were not continued, as it was difficult to reproduce results within less than 10 to 15%, and only with certain concentrations of reactants was the reaction as nearly "pseudo-unimolecular" as the above example. Nevertheless, it seems that the mechanism of the silver ion catalysis may not be altogether explained yet. It is possible that the nature of the reducing agent influences the velocity, in spite of the other evidence to the contrary.

Summary

I. The effect of various salts on the velocity of oxidation of ammonia by persulfate, catalyzed by silver ion, has been measured, and the following conclusions have been reached.

1. The effect of hydroxides, as measured by Yost, is not specific, but a general salt effect (except in so far as the equilibrium $\text{NH}_3 + \text{H}_2\text{O} \rightleftharpoons \text{NH}_4^+ + \text{OH}^-$ is concerned).

2. The salt effect is of the sign, general character and magnitude predicted by the Brönsted theory of salt effect, assuming the velocity-determining reaction to be that deduced by Yost.

3. The specific effect of the ions K⁺, Na⁺, OH⁻ and NO₃⁻ is in accord with their effect on the activity coefficient of other ions as indicated by solubility and other measurements.

4. It is pointed out again that the magnitude of the salt effect on velocity of reaction between ions is very great in dilute solutions, and that at low concentrations changing salt concentration during the course of a reaction may mask the true character of the reaction.

II. Finally, it is shown that in the case of the reaction $\text{S}_2\text{O}_8^{--} + \text{C}_2\text{O}_4^{--} \xrightarrow{\text{Ag}^+} 2\text{SO}_4^{--} + 2\text{CO}_2$, the velocity is not as predicted from the other reactions.

FLUORESCENCE IN MIXTURES OF AMMONIA AND MERCURY VAPOR

By ALLAN C. G. MITCHELL

RECEIVED MAY 23, 1927

PUBLISHED NOVEMBER 5, 1927

Introduction

While making experiments on the decomposition of ammonia by optically excited mercury vapor, Dickinson and Mitchell¹ observed a greenish fluorescence which appeared when a mixture of ammonia at a few millimeters' pressure and mercury vapor at room temperature was illuminated by the radiation from a cooled quartz mercury arc; they showed that the resonance radiation 2537 Å. was necessary to the production of this fluorescence. Observations with a direct vision spectroscope showed the fluorescence to be a diffuse band with a maximum around 5100 Å. Photographs with a quartz prism spectrograph showed an additional diffuse band in the ultraviolet with a maximum around 3370 Å. The green fluorescence was also observed visually when nitrogen was used instead of ammonia.

In the present experiments the ultraviolet fluorescence and the conditions under which it is excited were examined further.

Experimental Arrangement

A spherical resonance vessel (volume about 500 cc.) with a plane quartz window sealed to one end with sealing wax was connected to a vacuum system. About 2 cc. of mercury was placed in the resonance vessel to give a partial pressure of mercury corresponding to its vapor pressure at room temperature. Ammonia, nitrogen, hydrogen and argon could be admitted to the apparatus in the desired amounts and their pressures read on a McLeod gage. The method of purifying and admitting the gases to the resonance vessel was the same as that described by Mitchell

¹ Dickinson and Mitchell, *Proc. Nat. Acad. Sci.*, 12, 692 (1926).

and Dickinson.² Light from a quartz mercury arc, cooled by water at a definite temperature, was allowed to shine on the quartz window of the resonance vessel. In some cases a light filter consisting of a quartz cell containing 3 mm. thickness of a 25% solution of acetic acid was used. This filter was found to cut out radiation below 2400 Å., which was shown¹ to decompose ammonia photochemically, giving rise to hydrogen as a product. As the amount of hydrogen formed per unit time in the direct photochemical decomposition was known to be several times as great as the amount formed in the sensitized decomposition, it was thought necessary to use the filter. However, on account of the intensity of the light (distance from the window 10 cm.) and the short time of exposure, very little decomposition took place. One experiment made using no filter (see Fig. 2) gave substantially the same results as when the filter was used. The filter was only used in cases where relative intensities were desired, except in the above-mentioned case. A small Hilger quartz prism spectrograph was used for photographing the ultraviolet band.

In cases where intensity measurements were desired, calibration spots were placed on the plate by exposing portions of it to light from a small flash light bulb at different distances for the same length of time used in the fluorescence exposures (1 minute). The plates were measured on a microphotometer and the galvanometer deflections plotted against the square of the distance to the light. The relative intensities of the bands were obtained by recording the minimum galvanometer deflections (corresponding to the maximum of intensity of the band) and reading off the intensities from the plot. A small correction for the blackening of the plate in the region from 3180 to 3650 Å., due to scattered light from the window, was made by subtracting the intensity at zero ammonia pressure from each of the intensities at higher pressures.

Experimental Results

With 7 mm. of ammonia in the vessel, the green fluorescence was observed and photographs showed the diffuse bands stretching from 3170 to 3650 Å., with a maximum around 3370 Å.

Experiments made with the same pressure of nitrogen showed green fluorescence but photographs showed no ultraviolet band. The plate showed, incidentally, a line or perhaps a band-head at about 3370 Å., near the mercury line 3342 Å. which was reflected from the quartz window.

Experiments made with 7 mm. of argon, 40 mm. of argon and 7 mm. of hydrogen showed neither green nor ultraviolet bands. Indeed nothing was visible on the plate except the mercury lines reflected from the window, the fluorescent band of quartz between 4046 and 4358 Å., and the 2537 Å. resonance line of mercury.

² Mitchell and Dickinson, *THIS JOURNAL*, **49**, 1478 (1927).

Photographs with an uncooled arc and ammonia showed neither green nor ultraviolet bands.

Photographs were taken with different ammonia pressures in the vessel, using the cooled arc, and the plates were photometered. The relative intensities of the ultraviolet band were plotted against the pressures of ammonia as shown in Fig. 1. On Fig. 1 are also plotted rates of decomposition of ammonia, in arbitrary units, as a function of the ammonia pressure.

Fig. 1.

Finally, experiments were made in which a constant pressure of ammonia was kept in the vessel and various amounts of hydrogen were added. Small amounts of hydrogen were found to decrease the intensity of the ultraviolet band to a marked degree. The plates were photometered and the results are shown in Fig. 2. Relative intensities are plotted as ordinates against pressure of hydrogen as abscissas for three different ammonia pressures, namely, 5.04 mm., 3.00 mm. and 2.82 mm. Fig. 2 also contains results of experiments on the effect of hydrogen on the rate of sensitized decomposition of ammonia.²

Discussion of Results

The above experiments show that mercury atoms, excited by the absorption of the resonance line 2537 Å. of mercury, are necessary for the production of the ultraviolet and green bands, since no bands were observable when the lamp was run hot so that the center of the line was reversed. Confining our attention to the ultraviolet band for the moment,

the experiments show that this band occurs when ammonia is present. Hence, ammonia and mercury atoms in the 2^3P_1 or 2^3P_0 states are necessary for the production of the band.

It will be seen from Fig. 1 that the dependence of the intensity of fluorescence on the pressure of ammonia agrees quite well with the dependence of the rate of sensitized decomposition on ammonia pressure. The possibility of so adjusting the scale of ordinates that the fluorescence and the rate curves coincide shows that there is a proportionality between the intensity of fluorescence and the rate of decomposition of ammonia. The proportionality between the intensity of fluorescence and the rate of sensi-

+ Quenching of fluorescence, $P_{\text{NH}_3} = 5.04$ mm.; \circ Quenching of fluorescence, $P_{\text{NH}_3} = 2.82$ mm.; \times Quenching of fluorescence (no filter), $P_{\text{NH}_3} = 3.0$ mm.; \triangle Rate of decomposition, $P_{\text{NH}_3} = 5.06$ mm.; \square Rate of decomposition, $P_{\text{NH}_3} = 3.22$ mm.

Fig. 2.

tized decomposition can be accounted for on the assumption that excited ammonia molecules are responsible for both the fluorescence and the decomposition.

From Fig. 2 it will be seen that small amounts of hydrogen have a marked effect in decreasing the fluorescence and that the relative effect is greater, the smaller the ammonia pressure. If the sole role of the hydrogen were to take activation from the mercury atoms, we should expect that at very low pressures of ammonia the amount of hydrogen necessary to decrease the intensity of fluorescence to one-half would be the same as that necessary to decrease the resonance radiation of mercury by the same amount. This pressure of hydrogen was shown by Stuart³ to be 0.2 mm. However, from Fig. 2 it is to be noticed that at pressures of ammonia as high as 3 mm. only 0.05 mm. of hydrogen is necessary to decrease the intensity of the

³ Stuart, *Z. Physik*, **32**, 262 (1925).

fluorescence to one-half. The proportionality between the intensity of fluorescence and the rate of sensitized decomposition is even more striking in Fig. 2, since the curves there show considerably more curvature than those of Fig. 1. The explanation of the large effect of hydrogen on the rate of decomposition, that hydrogen can take activation from excited ammonia molecules by collision of the second kind, is applicable to the intensity of fluorescence if ammonia be assumed to be the emitter.

Rayleigh⁴ and Houtermans⁵ have found that diffuse bands are emitted by distilling mercury vapor which has been radiated by the light from a cooled quartz mercury arc. One band, with a maximum at 3370 Å., bears a striking similarity to the band described in this paper; however, another band occurs at 2539 Å., which is not observed in mixtures of ammonia and mercury. If it is assumed that the 3370 Å. band from boiling mercury is identical with that from mercury-ammonia mixtures it becomes difficult to explain the above facts, since it is not easy to see how the fluorescence would then depend on the pressures of ammonia and hydrogen in the way it does. In particular it is difficult to see how the explanation given by Houtermans for the bands in distilling mercury vapor could be made to fit the facts observed in the case of the fluorescence of mercury and ammonia at room temperature. However, the dependence of the intensity of fluorescence on the pressure of ammonia and hydrogen is readily explained on the assumption that the emitter is an ammonia molecule which has been activated by collision of the second kind with an excited mercury atom.

The writer wishes to express his thanks to Dr. R. G. Dickinson for his advice and interest in this work, and to Mr. F. Petit of the Mount Wilson Observatory for the use of a microphotometer. Financial assistance has been received from the Carnegie Institution of Washington through a grant to Professor A. A. Noyes.

Summary

The intensity of the diffuse band, with a maximum at 3370 Å., emitted when mixtures of ammonia and mercury vapor at room temperature are irradiated with mercury resonance radiation 2537 Å., has been found to vary with ammonia and hydrogen pressures in the same manner as the rate of sensitized decomposition of ammonia. It is suggested that excited ammonia molecules are responsible for both emission and decomposition.

THE SURFACE TENSION OF LIQUID CARBON DIOXIDE

BY ELTON L. QUINN

RECEIVED JUNE 4, 1927

PUBLISHED NOVEMBER 5, 1927

Interest in the question of solubility led the author a few years ago to inquire whether liquids which exist only under very high pressures behave in the same manner towards solutes as those with which we are most familiar. The answer to this inquiry was not easy to obtain from the literature because of the small amount of quantitative work which has been done on such liquids. It seemed worth while, therefore, to attempt to determine some of the important properties of a liquid of this type and, if possible, to fit it into the solubility theory of Hildebrand.¹ As carbon dioxide exists as a liquid at ordinary temperatures only under very high pressures and under these conditions is but slightly removed from its critical temperature, it may well be used for determinations of this kind.

One of the most useful properties of a liquid, which can be used for calculating its internal pressure and therefore its position in a solubility table, is its surface tension. Although a few surface tension measurements have been made on liquid carbon dioxide² it cannot be said that these values are reliable enough or extensive enough to be used as a basis for such a calculation. The work described in this paper was carried out in an attempt to obtain enough data to predict some of the solubility relations of this compound. Later, if possible, these results will be checked against some actual solubility determinations.

On account of the extremely high vapor pressure of carbon dioxide at ordinary temperatures, the capillary tube method is the only one that can be readily applied to the solution of this problem. The pressure of its saturated vapor at 20° is about 56 atmospheres and therefore the apparatus must be designed for strength, which will, of course, render it difficult to apply all the refinements which are usually applied to measurements of this kind.³

Preparation of Tubes

Capillary tubes were made by drawing down ordinary soft glass tubes to a diameter of about 0.2 to 0.5 mm. Selected pieces from a very large number of these tubes were inspected with a microscope for uniformity of bore and circular cross section. The tubes which passed this inspection were then placed in carefully cleaned Pyrex glass tubes of 1 cm. internal diameter which had been sealed at one end. They were fitted with small platinum wires placed in such a way that the capillary was held firmly in the center of the tube. The Pyrex tubes were then constricted just above the end of the

¹ Hildebrand, "Solubility," The Chemical Catalog Co., Inc., New York City, 1924.

² Verschaefelt, *Verhandel, Akad. Wetenschappen Amsterdam*, 4, 74 (1895).

³ Richards and Coombs, *THIS JOURNAL*, 37, 1656 (1915).

capillary to facilitate the final sealing. The tubes when finished were about 15 cm. in length.

The carbon dioxide used for filling the Pyrex tubes as well as that used for making the freezing mixtures was furnished through the courtesy of the Carbo Chemical Company of Salt Lake City. The analysis of the gas from the top of the cylinder showed it to be 99.8% carbon dioxide; this value increased somewhat as the gas was drawn from the cylinder. There was no evidence of oil but there was a small amount of water vapor in the gas. A long drying tube filled with calcium chloride was connected at one end with the carbon dioxide cylinder and at the other with the Pyrex tube containing the capillary. These connections were made with small copper tubing and the joint between the copper tube and the glass tube was made with de Khotinsky cement. The glass tube was placed in a freezing mixture of carbon dioxide snow and ether and the liquid carbon dioxide distilled from the standard carbon dioxide cylinder into it. The freezing mixture was easily kept at -100° by reducing the pressure of the carbon dioxide above it with a vacuum pump. After the glass tube had been purged several times with carbon dioxide to remove all of the air, it was partly filled with liquid and allowed to stand until the carbon dioxide had frozen to a transparent mass. It was then sealed in an oxy-gas flame at the constriction and the contents were allowed to melt.

Eight tubes were prepared in the above manner and used for several months without breaking. This was quite remarkable as several tubes of much thicker sodium glass exploded in the preliminary trials.

Temperature Control

Fig. 1 is a drawing of the thermostat in which the tubes were placed for measurement. *A* is an inverted standard 20-lb. carbon dioxide cylinder containing the liquid carbon dioxide. It was connected through the needle valve *B* with the coil of copper tubing placed in the unsilvered vacuum tube *C*. This vacuum tube was about 9 cm. in diameter by about 30 cm. high. It was

Fig. 1.

placed in a wooden box in which it just fitted. This box was then placed in a larger one, leaving a space of about two inches all around which was then packed with mineral wool. Two windows, indicated in the drawing by the dotted lines, were placed opposite each other in order to make it possible to observe the contents of the tube. The bath liquid was alcohol and this was kept in constant agitation by means of the brass pump *E*. This pump was essentially an air-lift pump and the com-

pressed air, which had been pre-cooled, forced the alcohol up the tube and forced it out at the top of the bath. The cooling of the air took place in the apparatus marked *D*, which in this case was a coiled glass tube around which the escaping carbon dioxide from the bath was allowed to pass. With this apparatus it was possible to lower the temperature of the bath to -50° and with close attention to keep it constant to within $\pm 0.2^{\circ}$. The temperature was changed by manipulating the needle valve *B*, and as one temperature was not needed longer than about three hours at a time this did not prove to be very troublesome.

Temperatures were measured with a pentane thermometer which had been calibrated by the Bureau of Standards and was checked again just before this work was started. The freezing points of water and mercury and the sublimation temperature of solid carbon dioxide were taken as the fixed points.

The capillary rise of the carbon dioxide was measured with a cathetometer. It so happened that the micrometer screw of this cathetometer was long enough to measure the greatest height of the liquid without making necessary any other adjustments of the instrument. Four tubes were used at each temperature and at least five readings of the cathetometer were made on each tube, the observed heights h_0 given in Table II being the average of these readings.

At each temperature where readings were taken the height of the meniscus in the capillary tube was measured with a meter stick. This was done to determine the point at which the capillary should be cut for measuring its diameter. This point was very nearly constant for all temperatures, in no case varying more than 5 mm. The capillary was cut at the average of these heights, each piece set in a paraffin block, the cut ends colored with drawing ink and the diameter measured with a microscope fitted with a micrometer attachment with movable cross hairs. One graduation mark on this micrometer screw head was equal to 0.0006 mm. but probably the error of setting the cross hairs was great enough so that the individual measurements were not accurate to within ± 0.005 mm. Five measurements were made on each piece of the capillary in each of two directions, which were at right angles to each other, and the average of these twenty measurements was taken as the inner diameter of the tube.

Calculations

The observed height h_0 was corrected for the quantity of liquid in the meniscus by means of the equation $h_1 = h_0 + r/3$, where h_1 is the corrected height and r the radius of the capillary. Although this equation is not exact, it was found by Richards and Carver⁴ to apply with sufficient accuracy where the value of r is small, as it is in this case.

⁴ Richards and Carver, *THIS JOURNAL*, 43, 828 (1921).

The surface tension was calculated by means of the equation $\gamma = \frac{1}{2} rhg(D - d)$, where γ is the surface tension in dynes per centimeter, g the acceleration due to gravity, which at Salt Lake City is 979.8 cm./sec.²; D is the density of the liquid carbon dioxide, and d the density of the saturated vapor. The values for these gas densities between 0° and the critical temperature (31.35°) were taken from Amagat's table.⁵ By plotting the values for the density of liquid carbon dioxide obtained by Behn⁶ and those obtained by Jenkin⁷ on large scale cross-section paper, a curve was obtained which served very well to indicate the liquid densities down to -60°. The values obtained by Amagat above 0° gave a satisfactory agreement with those read from this curve. The only determinations we have of the density of the saturated vapor of carbon dioxide below 0° were made by Cailletet and Mathias.⁸ We have in addition to these determinations some calculated values by Jenkin⁹ and some extrapolated values calculated by Mollier by means of Amagat's values above 0°.¹⁰ On account of the general acceptance of Amagat's values above 0°, it seemed best to make a new extrapolation of his curve to temperatures below zero in order to obtain the data necessary for making the surface tension calculations. This extrapolation was carried out by first plotting the experimental values of Amagat against the temperature and drawing the curve. The equation of this curve was found to be $Td = 1.936 P^n$, which can be readily derived from the gas laws if we keep in mind that in the case of an actual gas $P^n V = K$.¹¹ In this equation, d is the density of the saturated vapor, T the temperature in degrees absolute, 1.936 is a constant, P is the vapor pressure in atmospheres and the exponent n is equal to $0.737 + 0.0048t$, where t is the temperature in degrees centigrade. The values for P for the vapor pressure of liquid carbon dioxide were taken from the tables in Landolt-Börnstein.¹² Table I shows the agreement between the densities calculated by means of this equation and the observed experimental results.

Richards and Coombs showed that a considerable error is introduced when a capillary tube is set in a narrow outer jacket. They found that in the case of water the outside tube must be greater than 38 mm. in order to make this correction negligible. From the experience the author has had using large quantities of liquid carbon dioxide in glass tubes it seemed quite unsafe to use an outer jacket larger than 1 cm. in internal

-29.8	.035	Cailletet	.032	- .003

diameter. It became necessary, therefore, to apply a correction to each reading for the capillary effect of the outside tube. The internal diameter of the eight outer jackets used averaged 0.96 cm., with a variation of only 0.01 cm. All of the capillary tubes had an outside diameter of 0.1 cm. The effect of this capillary was to decrease the diameter of the outside tube, so this value was subtracted from 0.96, giving 0.43 as the value of the radius of the outside jacket. The corrections were calculated by means of the equation $h = h_1 r / 0.43$, where h is the correction to be added to the observed height, h_1 the observed height and r the radius of the capillary. While the correction for each tube is indicated in the table, only the average of these values at each temperature was added to the observed height.

The results of these measurements and calculations are tabulated in Table II.

Discussion of Results

It is interesting to apply the above results to the equation of de Block¹³ which he writes in the following form, $\gamma = K(t_c - t)^n$; where t_c is the critical temperature of the liquid; γ is the surface tension at the temperature t in degrees centigrade; $K = \gamma_0/(t)^n$; γ_0 is the surface tension at 0° ; and the exponent n is approximately 1.2 for all non-polar liquids. The average value for n , which is not exactly constant over the range of temperatures used, is 1.24 for carbon dioxide. In order to get this value for n it is necessary to take 4.68 for the surface tension at 0° instead of 4.62 as given in Table II. This is justified by the fact that 4.68 at 0° falls exactly on the surface-tension curve made by plotting the above values on cross-section paper; also if we do not include the lowest value obtained at 0° in our average we get a value of 4.68 dynes per centimeter.

¹³ De Block, *Bull. sci. acad. roy. Belg.*, [5] 11, 292-300, 353-60 (1925).

We can now rewrite the de Block equation so that in the case of carbon dioxide it becomes $\gamma = .0653(31.35 - t)^{1.24}$. Table III shows the agreement between the observed and calculated values for the surface tension at various temperatures. The calculated values were obtained from the above equation. The values of n in the second column were obtained by substituting the experimental surface-tension values in the de Block equation and solving for n .

TABLE III

SHOWING THE AGREEMENT BETWEEN THE OBSERVED AND CALCULATED VALUES FOR THE SURFACE TENSION OF LIQUID CARBON DIOXIDE

Temp., °C.	n	γ , obs.	γ , calcd.	Diff.

10	1.21	2.94	2.90	- .04
5	1.27	3.75	3.77	+ .02
- 6	1.21	5.79	5.81	+ .02
-11.3	1.22	6.81	6.85	+ .04
-21.7	1.25	9.05	8.99	- .06
-32.3	1.24	11.25	11.26	+ .01
-42.7	1.26	13.88	13.59	- .29
-52.2	1.29	16.54	15.77	- .77

There are several ways of treating surface tension measurements to determine the internal pressure of a liquid.¹⁴ Perhaps one of the most convenient methods in this case is to calculate its total energy of surface formation E_s by means of the Thomson equation, $E_s = \gamma - Td\gamma/dT$. At 20° E_s becomes 61.9 when $d\gamma/dT$ is taken over the whole temperature range studied. This places carbon dioxide with carbon tetrachloride, toluene and chloroform in the Hildebrand series and indicates that it should behave as a solvent much as these liquids do. This cannot be confirmed by experimental evidence, as no measurements have been made on the solubility of these substances in liquid carbon dioxide. We know, however, that carbon dioxide in the solid state is readily soluble in ethyl ether¹⁵ and must have, therefore, nearly the same internal pressure. As ethyl ether is only slightly removed from these compounds in the internal pressure series, we may safely assume that they would behave in much the same manner towards carbon dioxide.

The author expects to treat this question of solubility more fully in a later communication.

The author wishes to acknowledge with gratitude the suggestions which Dr. J. H. Hildebrand made at the beginning of this work.

Summary

1. An equation has been derived for calculating the density of the saturated vapor of carbon dioxide from 25 to 0°. This equation gives

¹⁴ Ref. 1, p. 111.

¹⁵ Thiel and Schulte, *Z. physik. Chem.*, **96**, 312 (1920).

values which agree very well with the observed densities over this range. Use was made of this equation to calculate densities down to -52.2° .

2. Surface-tension measurements of liquid carbon dioxide have been made from 25 to -52.2° .

3. The equation of de Block when put into the form $\gamma = .0653(31.35 - t)^{1.24}$ was found to fit the experimental results for the surface tension of carbon dioxide very well except at lower temperatures.

4. From its total energy of surface formation it was found that carbon dioxide had an internal pressure about the same as carbon tetrachloride, toluene and chloroform.

THE EFFECT OF IRON AND OXYGEN ON THE ELECTRICAL CONDUCTIVITY OF COPPER¹

BY RUSSELL P. HEUER

RECEIVED JUNE 18, 1927

PUBLISHED NOVEMBER 5, 1927

The electrical conductivity of dilute solid solutions of metallic elements in copper has been the subject of many investigations. The data presented treat the binary systems of copper and practically every metal which may occur as an impurity in commercial copper, namely, silver, gold, zinc, cadmium, aluminum, tin, phosphorus, arsenic, antimony, iron, cobalt and nickel.² Unfortunately much discordance is evident in the published results.

In illustration, the solute element iron may be considered. Addicks³ in his pioneer work upon the impurities of copper attempted to evaluate the effect of the 0.002 to 0.005% of iron present in electrolytic copper. From measurements upon alloys of 0.042, 0.046 and 0.068% of iron and upon pure copper, he interpolated for intermediate iron concentrations and concluded that the conductivity was lowered at the rate of 140% of the International Standard value for each 1% of iron present.

Hanson and Ford⁴ at the National Physical Laboratory in England, under Rosenhain's direction, have recently repeated Addicks' work, extending the data to higher iron concentrations. Using the observed conductivity of an alloy of 0.2% of iron, they project a curve to pure copper and suggest a lowering in conductivity at the rate of 235% for 1% of iron.

¹ A thesis for the degree of Doctor of Philosophy, presented to the Graduate Faculty of the University of Pennsylvania.

² Guertler, "Handbuch der Metallographic," Berlin, 1925; Circular No. 73, Copper, U. S. Bureau of Standards, 1922.

³ Addicks, *Trans. Am. Inst. Min. Eng.*, **36**, 18 (1906).

⁴ Hanson and Ford, *J. Inst. Metals*, **32**, 335 (1924).

They measured one alloy in this interpolated range. It contained 0.06% of iron. Curiously its conductivity was only about 1% lower than their value for pure copper. Such high conductivity is a considerable deviation from the established behavior of solid solutions. It indicates that the iron in the 0.06% alloy was not present in solid solution.

In an effort, perhaps, to simulate commercial copper, Addicks' and Hanson's alloys all contained cuprous oxide as a soluble component of the liquid phase. The assumption is made in their work that the effect of this oxide is negligible or at least is constant while they perform the interpolation between iron of zero concentration and iron at the measured concentration.

Thermodynamic consideration of the ternary system copper-iron-oxygen shows such assumption to be incorrect. Cuprous oxide is thermally dissociated. Roberts and Smyth⁵ measured the equilibrium pressure of liquid copper saturated with cuprous oxide. For the reaction

they record the data: 1392.3°K. = 0.028 mm. of Hg, 1423.5°K. = 0.035 mm. of Hg; 1457.1°K. = 0.041 mm. of Hg. Selecting solid cuprous oxide and pure liquid copper as the states of unit activity and assuming the activity of copper to equal its mole fraction, the above reaction can be evaluated for ΔF° at 1398°K. and 1336°K. These temperatures are chosen to be, respectively, the temperature of formation of the liquid alloy and the eutectic temperature of the copper-cuprous oxide system. $\Delta F^\circ_{1398} = +17,490$ cal.; $\Delta F^\circ_{1336} = +17,430$ cal.

Eastman⁶ has examined critically the recorded data for equilibrium in the reaction

Using Lewis and Randall's⁷ value of ΔF° for the reaction

he evaluates ΔF° for the reaction

for temperatures of 100° intervals from 873 to 1273°K. Extrapolating slightly, $\Delta F^\circ_{1398} = +41,295$ cal.; $\Delta F^\circ_{1336} = +42,260$ cal.

Combining Equations (1) and (2) to obtain the reaction

$\Delta F^\circ_{1398} = -23,805$ cal.; $\Delta F^\circ_{1336} = -24,830$ cal.

Assuming the insolubility of ferrous oxide in molten copper and utilizing

⁵ Roberts and Smyth, *THIS JOURNAL*, **43**, 1061 (1921).

⁶ Eastman, *ibid.*, **44**, 875 (1922).

⁷ Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., New York, 1923.

the fact that at the eutectic temperature the activity of cuprous oxide becomes unity, the equilibria are expressed

$$\text{at } 1336^{\circ}\text{K. } a_{\text{Fe}} = 8 \times 10^{-5} \quad (3)$$

$$\text{at } 1398^{\circ}\text{K. } a_{\text{Fe}} \times a_{\text{Cu}_2\text{O}} = 19 \times 10^{-5} \quad (4)$$

Equation (4) defines a curve, abc, in Fig. 1 which limits the composition of the ternary alloys which can exist at 1125° . Alloys of composition *M* react to eliminate FeO and arrive at the composition *R*, with very small oxygen content. Alloys of composition *N* react similarly to reach *S*, the equilibrium composition containing little residual iron.

Fig. 1.

Equation (3) defines a line of constant activity, such as TU in Fig. 2, which at 1063° divides the ternary diagram into two areas. Within TUV, iron and eutectic cuprous oxide react, forming ferrous oxide until the iron is reduced to the equilibrium activity 8×10^{-5} or the cuprous oxide phase is consumed. Only within the small area TUVZ can iron and cuprous oxide pass through the eutectic temperature without reacting.

In the absence of data relating the activity of iron and cuprous oxide in copper solutions to the mole fractions, these equilibrium concentrations cannot be calculated. We know, however, that these solutes exhibit quite low solubility in copper. The iron activity in such case doubtless exceeds its mole fraction. The line TU lies, therefore, at or less than 0.008% of iron.

This indicates the presence of indefinite amounts of ferrous oxide in Addicks' and Hanson's alloys. The application of their data to the conductivity of the system copper-iron is thus open to objection.

The present work is planned to take the effect of oxygen into consideration. The alloys are based upon the ternary system copper-iron-oxygen. The copper-rich alloys of the binary systems copper-iron and copper-oxygen are measured. The ternary alloys are then investigated and the lines abc and TU located.

Fig. 2.

Experimental

Pure copper for the alloys was prepared by two successive electrolytic depositions of the metal. Pure electrolyte free of metallic impurities was used in the final deposition. The cathodes analyzed: Ag, 0.0003%; As, 0.0000%; Sb, 0.0001%; Bi, 0.0000%; Fe, 0.0001%; Co, 0.0000%; Ni, 0.0001%; Zn, 0.0000%; Pb, 0.0000%; S, 0.0004%; Se + Te, 0.0000%.

The melts were prepared in a platinum resistance furnace having a vertical heating chamber 12 inches high and 3 inches in diameter. The furnace was evacuated and filled with dry, oxygen-free nitrogen. The system of crucibles and feeders used is shown in Fig. 3. For the binary series copper-iron, electrolytic iron chips to form the desired alloy were placed in the thimble (b). The feeder (a) contained 375 g. of copper and 300 g. of anhydrous barium chloride. Seven hours were required for making each

melt, three and one-fourth hours for heating to 1125° , three-fourths of an hour at that temperature and four hours for slow cooling. Practically all the cuprous oxide was removed from the liquid metal by the solvent action of the molten barium chloride.

The solidified melts were sampled for metallographic specimens and forged hot to a $\frac{5}{8}$ -inch octagon section. Scale and surface defects were removed by machining to $\frac{9}{16}$ -inch diameter, whereupon the samples were annealed to 950° for fifty hours in carbon dioxide and cooled slowly to equalize any cored structure present in the original dendrites. The forgings were then drawn cold to 12 gage (0.080 inch diameter) wire and annealed at 500° by passing an electric current through the wire. The conductivity was measured at 20° with an accuracy of 0.1%, using the standard bridge; 0.15328 ohms per meter gram was considered 100% conductivity.

Chemical analyses for copper, oxygen, sulfur and iron were made on each melt. Copper was determined on turnings removed from the cast piece. Two 10g. electrolytic assays were made, checking within 0.003%. Oxygen and sulfur were determined by ignition in hydrogen at 900° to convert these elements to water and hydrogen sulfide.* The sulfide evolved was absorbed in ammoniacal cadmium chloride solution and evaluated by iodine titration. The loss in weight of the sample upon this ignition was attributed to oxygen and sulfur. Knowing the sulfur value, oxygen was determined by difference.

Sixty g. of wire samples from the conductivity measurements were used in this analysis. After cleaning the metal surface, as recommended, with abrasive, dilute alcoholic potassium hydrate, dilute potassium cyanide, distilled water, alcohol and ether, there was no assurance that upon drying at 80° the surface would be free of oxide or adsorbed substances. That adsorbed substances were present seemed proved when metal so prepared was ignited in carbon dioxide and lost 0.0008% in weight. Since all material volatile in carbon dioxide from within the copper had been removed by previous annealing at 950° for fifty hours, this loss must have been a surface effect. Upon further ignition in hydrogen at 900° for five hours, this piece lost 0.0006% as oxygen. Some of this might have been surface oxygen. To overcome these surface effects, a similar sample was given a rapid preliminary heating in hydrogen to 550° , held for three minutes and cooled rapidly. This freed the adsorbed material and removed surface oxygen. Upon further treatment at 900° for five hours, 0.0004% of oxygen was lost. From this the preliminary hydrogen heating was considered more satisfactory than ether drying and carbon dioxide ignition, where such small amounts of oxygen were involved. Iron was determined on the conductivity samples, after electrolytically removing the copper, by double precipitation with gaseous ammonia and weighing as ferric oxide.

It was found impossible to use the crucible assembly shown in Fig. 3 for making copper free of iron, due to a considerable "pick-up" of iron from the crucible. To overcome this, a silica tube ten inches long and seven-eighths of an inch inside diameter, sealed at one end, was substituted for the crucibles. Two hundred g. of copper and 75 g. of barium chloride were charged. The copper used was specially freed from sulfur

Fig. 3.—Crucible assembly.

by ignition in hydrogen. The melt piped badly but sufficient metal for one conductivity measurement was obtained.

For the binary series copper-cuprous oxide, methods similar to those employed for the copper-iron series were used. The charge, of course, contained no iron addition and no barium chloride. The oxygen addition was made by allowing the desired amount of oxygen gas to be present in the nitrogen atmosphere of the furnace. No annealing of the forged pieces for fifty hours at 950° was required. In the oxygen determination, ether drying at 80° was used for the preparation of the sample.

For the ternary alloys, the methods of the copper-cuprous oxide series were adopted. A copper-iron alloy containing 2.2% of iron was used for the iron addition. The amount desired was charged in the feeder crucible.

Results

The data for the binary system copper-iron are assembled in Table I. Fig. 4 expresses the relation of conductivity to atomic per cent. of

Addicks and Hanson are plotted. The displacement of their values at low iron concentration confirms the original premise of this paper that ferrous oxide is present in their alloys.

The effect of small additions of iron upon the conductivity is shown to be considerable. For the first 0.0071% of iron present, the conductivity is lowered 4.5%, a rate of 634% for 1% iron. This great depression tends toward agreement with Norbury's⁹ generalization that solute elements far removed in the periodic system from the solvent metal cause the greater lowering in conductivity. Comparison, however, with Norbury's data for nickel solid solutions shows at once the more rapid lowering caused by iron. Norbury's idea seems to neglect the effect of the small solid solubility of iron.

The conductivity data confirm the expression of Hanson that the iron solid solubility at 750° is much less than the 3% originally reported by Ruer and Goerens.¹⁰

Hanson's suggestion that the solubility is less than 0.2% is not checked by the conductivity values. They seem to indicate between 0.3 and 0.4% as the limiting value.

Sample 22, the purest copper obtained in these experiments, had a conductivity of 102.1%. This can be compared with the values assembled by Wolff and Dellinger¹¹ for several samples of "pure" copper. Their highest value is 101.88%, obtained for electrolytic copper melted in a vacuum in an Acheson graphite crucible, drawn and tested as annealed wire. A piece of native Lake copper formed into wire without melting and tested in the annealed state yielded 101.87% conductivity. Their best value of several samples of electrolytic copper drawn to wire without melting and annealed is 101.60%. Meissner¹² observed 102.2% conductivity in a piece of electrolytically deposited wire which was carefully filed and ground to circular cross section and tested without drawing or annealing. This sample, however, cannot be regarded as statistically equivalent to the poly-crystalline aggregate obtained in wires which have been drawn and annealed. The electrolytic crystals may exhibit some preferred orientation and tend thereby to increase the conductivity toward the higher value of the copper single crystal.

The data for the binary system copper-cuprous oxide are assembled in Table II. The curve in Fig. 5 represents the relation of conductivity to volume per cent. of cuprous oxide calculated for a density of the oxide 6.0. Comparison is made to conductivity values calculated from the law of Le Chatelier, which requires that in systems whose components are

In Fig. 6, the conductivity is plotted against weight per cent. of oxygen. Data of Hanson,¹³ Antisell¹⁴ and Addicks³ are plotted for comparison. Antisell's figures seem to be the only ones capable of being reduced to a smooth curve. The curve indicated parallels closely the curve presented here, averaging perhaps 1.1% lower in conductivity. The lower conductivity is probably due to impurities other than oxygen in Antisell's metal.

Fig. 6.—Effect of oxygen on conductivity of copper.

The data for the ternary melts are presented in Table III. The product mole fraction of iron \times mole fraction of cuprous oxide of these melts evaluates the position of the equilibrium in the fused alloy, assuming that while cooling no further separation of ferrous oxide from the metal phase takes place. The line abc is sufficiently defined by the order of magnitude of this product. In the melts Nos. 14, 16 and 17, the close agreement is perhaps, fortuitous, as no such analytical accuracy is claimed.

TABLE III
DATA FOR TERNARY MELTS

No.	Iron charged, %	Oxygen charged, %	Iron found, %	Oxygen found, %	Sulfur, %	Copper, %
14	0.13	0.02	0.0133	0.0035	0.0003	99.982

TABLE III (Concluded)

No.	Mole fraction Fe \times mole fraction Cu_2O	Cond. obs., %	Cond. calcd. from oxygen content (negl. Fe), %	Cond. lowering due to iron, %	Equiv. iron in solid sol., %	Micro- structure as cast
14	2.10×10^{-3}	101.80	102.05	0.25	0.0004	No eutectic
16	2.08×10^{-3}	101.85	102.05	.20	.0003	No eutectic
17	2.29×10^{-3}	102.0	102.0	.0	None	Copper plus eutectic
13	7.16×10^{-3}	101.85	101.7	— .15	None	Copper plus eutectic

The micro-structure of the alloys and the conductivity indicate the progress of the iron-copper oxide reaction at the eutectic temperature. Melts Nos. 14 and 16 contain copper, iron oxide and iron in solid solution of less than 0.0005%. No copper oxide eutectic remains. Melts Nos. 17 and 13 show residual copper oxide as eutectic. They contain iron in solid solution of the order of 0.0001%. These alloys indicate that the line TU is located on the diagram at such a low iron concentration as to practically coincide with the binary line of copper-oxygen. All alloys in the ternary system should react, therefore, at the eutectic temperature to form ferrous oxide. If the time be sufficient, the reaction will run either to complete oxidation of the iron or to the extinction of the cuprous oxide phase. Commercial copper containing the oxide eutectic should carry no iron in solid solution. The conductivity should be unaffected by the iron present.

The writer desires to express his appreciation of Dr. H. S. Lukens' kind interest in this work. To the U. S. Metals Refining Company and Mr. Sidney Rolle he is indebted for the conductivity measurements.

Summary

1. Thermodynamic calculations are advanced in this paper to question the validity of the existing data on the electrical conductivity of dilute solid solutions of iron in copper.

2. Revision of these data is made and iron is shown to reduce the conductivity of copper at the rate of 630% of the standard value for 1% iron.

3. The formation of ferrous oxide in alloys of copper, iron and oxygen is studied quantitatively. It is shown that iron can be completely oxidized in alloys containing cuprous oxide eutectic.

THE THERMAL DECOMPOSITION OF OZONE. THE COMPUTATION OF VELOCITY CONSTANTS DETERMINED BY THE MANOMETRIC METHOD

By R. O. GRIFFITH AND A. MCKEOWN

RECEIVED JULY 2, 1927

PUBLISHED NOVEMBER 5, 1927

In a recent paper¹ on the thermal decomposition of ozone, Wulf and Tolman criticize our work² on the same subject. As part of their criticism appears to rest on a misunderstanding of the nature of the corrections which should be applied in such work, and as also the necessity for and magnitude of such corrections are not generally appreciated, we may be allowed to reply to their criticism and give a somewhat fuller account of our methods, together with their application to the experimental data of other investigators of this reaction.

In the first place, Wulf and Tolman take exception to the fact that the apparatus used by us to follow the decomposition at 100° contained "dead space"—the connecting lines from the reaction tube and the compensator tube to the manometer—which necessitated corrections to our pressure readings. This criticism might be pertinent if the "dead space" in question were large or the corrections improperly applied. Actually, however, the "dead space" in our apparatus was made reasonably small, the two tubes being joined directly through capillary taps to the sulfuric acid manometer, which was constructed of capillary tubing of 2 mm. internal bore. With the acid menisci level in the manometer, the volume unjacketed on either side was between 1.0 and 1.5 cc. in all our experiments. Finer capillary tubing for the manometer was avoided to obviate the risk of lag in the response of the manometer liquid to changes of pressure. As regards the condition that the reaction should take place at constant volume, this was sufficiently ensured, since a registered change of pressure of 200 mm. of sulfuric acid produced a change of volume of less than 0.4 cc. in a total of 150 cc. Indeed, the error involved in our measurements in this particular is considerably less than for the corresponding static experiments of Warburg³ and of Jahn,⁴ which, however, Wulf and Tolman view in a much less critical light. Thus with Jahn's apparatus, a change of pressure of 200 mm. of sulfuric acid would produce a change of volume of 0.078 cc. in a total of 6.3 cc.

Of much more importance, numerically, are the corrections to the registered pressure differences which the use of a moving manometric liquid

and the consequent variations in volumes of the "dead spaces" entail, and we have been at considerable pains to gage and apply these properly. Wulf and Tolman appear to associate the necessity for such corrections with poor technique; actually, however, similar but much greater corrections are necessary and were applied (though inadequately) in the work of Warburg and of Jahn. We proceed to indicate the nature and magnitude of these corrections.

The experimental arrangement commonly used consists essentially of a reaction and a compensator tube, capable of being jacketed at the same temperature, and connected to each other through a sulfuric acid manometer of capillary bore. We denote by V' and V'' the jacketed volumes of the reaction and compensator tubes, respectively, and by v the volume of unjacketed "dead space" on either side when the manometric levels are the same. If now with the whole apparatus at room temperature (Θ_1° , absolute) the manometer levels are identical, they will only be the same when the jackets are raised to the higher temperature Θ_2° , provided that $V' = V''$. Let us suppose that the tubes are filled at room temperature and to the same pressure (P_1 mm. of sulfuric acid), the one tube with the reaction mixture, the compensator with air or with oxygen. If a pressure difference of p_1 mm. of sulfuric acid, measured with the apparatus at room temperature, is subsequently developed due to reaction, the "true" increase of pressure which would have been developed, if measured, say, with a Bourdon Gauge, is not p_1 but $p_1\alpha_1$, where $\alpha_1 = 1 + \frac{P_1\gamma}{2} \left(\frac{1}{V'} + \frac{1}{V''} \right)$. Here γ is the volume in cc. per mm. of manometer tubing. However, an observed pressure difference of p_2 measured with the tubes at Θ_2° does not similarly correspond to a "true" increase of pressure of $p_2\alpha_2$, where $\alpha_2 = 1 + \frac{P_2\gamma}{2} \left(\frac{1}{V'} + \frac{1}{V''} \right)$, and P_2 is the total pressure (in mm. of sulfuric acid) in either tube at Θ_2° . That this is not so is due to the presence of "dead space" which is always at the lower temperature, Θ_1° . Neither is it true for the same reason that $(p_2\alpha_2/p_1\alpha_1)$ is equal to the ratio of absolute temperatures Θ_2/Θ_1 . The only correct way of interpreting an observed pressure difference p_2 (measured with the tubes at Θ_2°) is to find the value of p_1 or of $p_1\alpha_1$, to which it corresponds at room temperature. This may be effected either by calculation from the equation

$$p_2 = \frac{\Theta_2 (P_1 + \alpha_1 p_1) (V' + v)}{V' \Theta_1 + \left(v + \frac{p_2 \gamma}{2} \right) \Theta_2} - \frac{\Theta_2 P_1 (V'' + v)}{V'' \Theta_1 + \left(v - \frac{p_2 \gamma}{2} \right) \Theta_2} \quad (1)$$

or the ratio p_2/p_1 may be determined experimentally. In our work, we employed the latter method, and values of the ratio p_2/p_1 under different experimental conditions are denoted by R in our tables.⁵

⁵ Ref. 2, pp. 2089-2091.

For our apparatus we found experimentally and have confirmed by independent calculation from (1) that the ratio p_2/p_1 under a given set of conditions is practically independent of the value of the registered pressure difference p_2 . This implies that all corrections to our observed pressure readings affect only the absolute value of the derived velocity constants. The necessity for and use of corrections cannot be held responsible in our experiments for any observed "trend" in the value of a velocity constant throughout a single run. We may also remark that the conditions with regard to "dead space" in our apparatus were comparatively good (that is, $V' \approx V''$, and v and γ reasonably small compared with V'). In accordance with this we find that, had we employed the faulty method of correction used by Warburg and by Jahn (see next paragraph), the absolute values of our velocity constants would not have been affected by more than 4%.

Turning now to the work of Warburg and of Jahn, we must first note that their method of correcting their velocity constants to absolute units is equivalent to assuming that each observed pressure difference at Θ_2° corresponds to a true pressure difference of $p_2\alpha_2$ at the same temperature. This assumption is untrue; the more so as the "dead space" conditions in their experiments are considerably less favorable than in ours. We have attempted to estimate the errors thereby involved in their velocity constants in what follows.

The method of experimentation adopted by the two workers was the same, but slightly different from our own procedure. Their reaction and compensator tubes were first filled with oxygen to a known common pressure at room temperature Θ_1° . The oxygen in the reaction tube was then partially ozonized, the jacketing tubes raised to Θ_2° and the course of the reaction followed manometrically. Transforming again observed pressure differences p_2 at Θ_2° to the corresponding pressure differences p_1 which would be registered with the whole apparatus at Θ_1° , and hence to "true" pressure differences $p_1\alpha_1$ at Θ_1° , the relation now applying is

$$\alpha = \frac{\Theta_2 P_1 (V' + v)}{V' \Theta_1 + \left(v + \frac{p_2 \gamma}{2}\right) \Theta_2} = \frac{\Theta_2 (P_1 - p_1 \alpha_1) (V' + v)}{V' \Theta_1 + \left(v - \frac{p_2 \gamma}{2}\right) \Theta_2} \quad (2)$$

In applying this equation to the data of Jahn and of Warburg, it is necessary to make some assumption regarding their values of v (the "dead space" on either side of the manometer). For both sets of measurements we have made the reasonable estimate that this volume corresponds to the volume of 25 cm. of the capillary tubing employed. This makes $v = 0.195$ cc. in Jahn's apparatus; $v = 0.135$ cc. in Apparatus VII of Warburg; and $v = 0.202$ cc. in Warburg's Apparatus III.

The correct velocity constant k_a expressed in the units (liters/moles-minutes) is then obtained by transforming all the observed pressure differ-

ences p_2 in a given experiment into the corresponding values of $p_1\alpha_1$, using $p_1\alpha_1 = 0$ as the infinity reading,⁶ and substituting in the kinetic equation

$$k_a = 380 \times \frac{13.59}{1.84} \times 0.08207 \times \Theta_1 \times \frac{1}{(p_1\alpha_1)^2} \cdot \frac{d(p_1\alpha_1)}{dt} \quad (3)$$

Considering first the data of Warburg for ozone decomposition, the "dead space" conditions are here not specially unfavorable, and recalculation of his results obtained with Tubes III and VII at 100°C. shows that his constants⁷ are in each case about 10% too high. At the higher temperature, 127°, the correction is greater; his constants should be about 15% greater than those given. It is when applied to Jahn's data, however, that the corrections assume very large proportions. In order to demonstrate this, we have recalculated the constants in three of Jahn's experiments (A_I, B_I, C_I, pp. 289 and 290 of his paper). The results are shown in Table I.

In the preceding table, the first column gives the time in minutes, the second the observed pressure differences in mm. sulfuric acid, and the third the corrected pressure differences, $p_1\alpha_1$, which are calculated from the figures in Col. 2 by use of Equation 2. The fourth column gives the values of the corrected velocity constants in absolute units calculated from Equation 3, and the last column the velocity constants which would be obtained by calculation according to the methods employed by Jahn. In both cases the constants are computed over successive time intervals. The bracketed figures at the foot of each final column are the values of k_a obtained by Jahn by the method of least squares. Before comparing the corrected velocity constants with those of Jahn, it is first to be observed that Jahn's calculations are faulty, owing to the use of incorrect estimates of the final pressures. His reaction and compensator tubes were at the same pressure at room temperature before ozonizing the contents of the former, and since the volume of the reaction tube is considerably greater than that of the compensator, the presence of "dead

⁷ The values of all the velocity constants in absolute units given in Warburg's paper are ten times too small. The 10% correction mentioned above refers to (Warburg's constants $\times 10$).

space" clearly necessitates that the final pressure difference at 127° will *not* be zero, as assumed by Jahn, but will be of opposite sign to the pressure effect caused by ozonization. This is shown in the tables by the asterisked values of the infinity readings for p_2 , which we have calculated by use of Equation 2. Errors in the value of p_∞ naturally affect the constancy of the calculated values of the velocity constants, and though this is partially disguised in Experiments A_I and C_I, it is fully revealed in Experiment B_I. Here the figures given in the final column, calculated with Jahn's assumption that p_2 at $t = \infty$ is zero, would appear to demonstrate an excellent bimolecular constant, but the figures in Col. 4 show that this agreement is fallacious and that proper correction gives a rapidly falling constant. In the other two experiments, the reaction was not followed for so long a time as in experiment B_I, and also there is a tendency for Jahn's constants to rise with time, both of which obscure the effect of correcting the infinity reading.

Comparing now Jahn's constants with the corrected ones, it is seen that his values in all three cases are of the order of 70–80% too high. It is not, however, our wish to lay any particular emphasis on the quantitative aspect of these figures, though we believe that they approximate to the true corrections necessary in his experiments; we desire simply to show that the published data of Jahn must be subject to quite large errors which are sufficient at least to render doubtful any conclusions drawn from his experiments by the manometric method. We draw attention to this, because Wulf and Tolman consider Jahn's experiments to demonstrate that "for ozonized oxygen which decomposes in accordance with the second order, the specific rate is closely inversely proportional to the total pressure." In our view, the uncertainties attached to Jahn's experimental data make any such conclusion of problematic worth.

We may summarize and compare the corrections necessary for "dead space" and moving manometric liquid in the experiments of Jahn, of Warburg and of ourselves in the following way. In our experiments the corrections necessary amount to and affect the observed velocity constants by between 7 and 22% depending on the total pressure; these corrections were properly applied. In Warburg's work the true corrections (for his experiments at 100°) amount to about 100%; the correction applied by him was somewhat less than this and leads to constants about 10% higher than those which should have been obtained. Finally, in Jahn's experiments the true correction lies between 200 and 95%, depending on the total pressure; the corrections actually applied by him were much too small, so that his constants are about 75% too high.

With regard to Wulf and Tolman's own experiments using the manometric method, they have applied no corrections to their pressure readings and in their paper they give no details of the dimensions of their mano-

meter capillary. However, from a later (private) communication of Dr. Wulf, it appears that in the majority of their static experiments manometer tubing of diameter 0.87 mm. was employed. The volume of their compensator being 322 cc., the error due to non-application of the appropriate pressure corrections only amounts to about 2%.

These authors have also objected to our method of determining the final pressure increase corresponding to complete de-ozonization in each run. Admittedly small errors might enter here, but in all experiments pressure readings were taken up to between three-quarters and seven-eighths of total decomposition of the ozone initially present. Granting as a liberal estimate a 5% error in our determination of the pressure increase, which would be caused by decomposition of the residual ozone, the maximum error in our value of p_{∞} is still less than 1%. Wulf and Tolman's own method of finding p_{∞} is open to more serious criticism. After following the reaction for some time at 100°, they raise the temperature of the reaction vessel to 150° for fifteen minutes and assume that de-ozonization is then complete. Actually, for the Runs 10 and 15 which they give in detail in Table I (pp. 1189-90 of their paper), this is far from being the case. Taking their own value of the bimolecular velocity coefficient for ozone decomposition at 147.7°, namely, $k_2 = 1.3 \times 10^4$ cc./moles-sec., and noting that in Run 10 the extent of decomposition at this temperature corresponds to a pressure increase of 2.77 cm. of sulfuric acid, it is easy to calculate that there still remains, at the end of the fifteen minutes at 150°, a concentration of ozone equivalent to 0.60 cm. in the same units. This means that each value of the pressure difference P given in their Table I (Run 10) is 0.60 cm. too low. The large errors thereby involved may be appreciated from the following table, in which a number of the values of k_2 for Run 10 as calculated by Wulf and Tolman (Col. 4) are compared with the values (Col. 5) recalculated by us from the corrected pressure differences.

It will be observed that the corrected velocity coefficients are 12 to 22% less than those given by Wulf and Tolman, and also that the fall in the value of k_2 (corr.) with time is more pronounced. The true extent of this trend in the velocity coefficient is more correctly obtained by calculating the velocity coefficients for successive time intervals by the relation

$$k'_2 = \frac{\text{const.}}{k_2 - k_1} \left(\frac{1}{P_2} - \frac{1}{P_1} \right)$$

instead of referring each coefficient back to the conditions at $t = 0$ as is done in using the formula

$$k_2 = \frac{\text{const.}}{t} \left(\frac{1}{P} - \frac{1}{P_0} \right)$$

The value of k'_2 falls by about 33% while the concentration of ozone drops to one-third of its initial value.

TABLE II

t	P	P (corr.)	$k_2 \times 10^{-3}$ (W. and T.)	$k_2 \times 10^{-3}$ (corr.)	$k'_2 \times 10^{-3}$
0	9.61	10.21	1.82
12	8.24	8.84	2.07	1.82	1.68
15	7.98	8.58	2.03	1.79	1.65
19	7.65	8.25	2.01	1.76	1.61
25	7.22	7.82	1.98	1.73	1.62
31	6.82	7.42	1.97	1.71	1.49
37	6.49	7.09	1.94	1.68	1.57
46	6.03	6.63	1.93	1.65	1.51
58	5.52	6.12	1.91	1.62	1.43
72	5.04	5.64	1.88	1.59	1.44
87	4.60	5.20	1.87	1.56	1.46
102	4.22	4.82	1.87	1.54	1.41
117	3.90	4.50	1.87	1.53	1.36
132	3.63	4.23	1.87	1.51	1.27
160	3.23	3.83	1.85	1.47	1.22
202	2.77	3.37	1.83	1.42	

In a private communication Dr. Wulf points out that we have probably overestimated the extent of the errors in his infinity pressure readings since (1) we have taken no account of the times necessary for heating the reaction system up to 150° and for cooling after the superheating, and (2) the value we take for k_2 at the temperature of superheating may be too low. Instead of 1.3×10^4 , Dr. Wulf considers 1.9×10^4 to be a fairer estimate for k_2 at 150° , and he computes that 0.25 cm. is nearer the probable error in the final pressure of Run 10. Granted these possibilities, k'_2 in Experiment 10 would then fall from 1.96×10^3 to 1.5×10^3 throughout the run.

Summary

The application by various workers of the manometric method to the investigation of the thermal decomposition of ozone is discussed. It is shown that the derived velocity constants may be in error through (a)

incorrect interpretation of the observed pressure differences and (b) faulty estimation of the pressure readings corresponding to total decomposition. Warburg's data are slightly in error under (a), Wulf and Tolman's data rather more seriously in respect of (b), while Jahn's results are subject to very considerable errors under both heads.

THE DENSITIES OF COEXISTING LIQUID AND GASEOUS CARBON DIOXIDE AND THE SOLUBILITY OF WATER IN LIQUID CARBON DIOXIDE

H. H. LOWRY AND W. R. ERICKSON

RECEIVED JULY 13, 1927

PUBLISHED NOVEMBER 5, 1927

At the usually prevailing temperatures liquid carbon dioxide is less dense than water and not miscible with it. Therefore, theoretically, the degree of dryness of liquid carbon dioxide which has been separated mechanically from liquid water depends only on the solubility of the water in the liquid carbon dioxide. Experiments have been performed in an attempt to determine this solubility.

The method chosen was to determine the density of gaseous carbon dioxide in the coexisting state, both in the presence and absence of water. If water is appreciably soluble in liquid carbon dioxide, it should lower the vapor pressure and hence the density of the coexisting gaseous carbon dioxide. It may be calculated by means of Raoult's law that a solubility of 0.1%¹ by weight of water in liquid carbon dioxide will cause a decrease in vapor pressure of about 0.25%. The averages of three sets of determinations of the density of saturated gaseous carbon dioxide at temperatures ranging from -5.8 to 22.9° in the absence of water were 0.08% lower than the averages of two sets of determinations made in the presence of liquid water. This difference is opposite in sign to what would be expected if there were any solubility and is attributed entirely to experimental error.² The results obtained may be interpreted to indicate that the solubility of water in liquid carbon dioxide is less than 0.05% by weight over the temperature range investigated.

Experimental Method and Data

For the present investigation there was chosen the sealed tube method

¹ This is an upper limit of the solubility as suggested by experiments performed by Thomas Simon, *Z. ges. Kohlensäure Ind.*, 6, 239 (1900), and similar preliminary experiments performed by the authors.

² The average deviation of the experimentally determined gas density from the value calculated from the equation best fitting the entire data is 0.7%. Thus, while the probable error of any single datum is about 0.6%, consideration of the entire data indicates that the calculated values are probably correct within $\pm 0.1\%$.

of Young³ which has not previously been used for carbon dioxide. In this method different weights of carbon dioxide are sealed into glass tubes of sufficient strength to withstand the pressures developed, and the volumes occupied by the gas and liquid determined. This determination requires only the measurement of the length occupied by either gas or liquid in a tube which has been previously calibrated for volume.

Now,

$$W = v_l d_l + v_g d_g \quad (1)$$

where W is the total weight of carbon dioxide, v_l , v_g , d_l and d_g are the volumes and densities of liquid and gaseous carbon dioxide, respectively. W may be obtained at the end of an experiment by determining the difference in weight of the tube full and empty. Since in Equation 1 there are two unknowns, d_l and d_g , it is necessary to make determinations on two tubes either of different total volumes or containing different total weights of carbon dioxide.

The experimental error of the method is largely one of reading length. As used by Young on many organic liquids, where lengths were read only to 0.1 mm., the errors under different conditions ranged from 0.5 to 6%.⁴ Nevertheless his data⁵ are apparently consistent to about 0.1%. In the present investigation lengths were read with a traveling microscope to 0.002 mm. Temperature was determined with a thermometer calibrated at the ice-point, 0°, and at the transition temperature of sodium sulfate decahydrate, 32.8°. On account of the great difference in density of the gas and liquid phases, correction was also made for the volume of the liquid meniscus,⁶ which otherwise would be included with the gas volume. Corrections based on direct measurements were also applied to the volume of the tube for distortion introduced on sealing the ends of the tube. The reading of the length of tube filled by gas and liquid was in each case determined after the temperature was raised and again after it was lowered to the temperature of the experiment. The lengths so obtained agreed on the average to 0.020 mm. The arithmetical average of the two readings was used in the calculations. In order to facilitate reaching thermal equilibrium a small rod of permalloy was sealed in the tube for stirring the liquid. This stirring was accomplished by raising and lowering a small electromagnet around the tube. Calculations showed that the volume increase in the tube due to expansion caused by the maximum pressure developed within it would amount to only 0.02% of the total volume and hence no correction was made. Calculation also showed that changes in volume of the tube due to temperature changes are of the same order of magnitude and could also be neglected. Even with these corrections and precautions, analysis of the data obtained in three separate runs indicates that the average deviation of a single observation for the liquid density is $\pm 0.1\%$, and since an error in determination of the liquid density introduces a larger error, opposite in sign, in the determination of the gas density, the average deviation of a single observation of gas density is greater, that is, 0.7%. Hence, to obtain a much higher

⁵ As summarized in *Proc. Roy. Soc. Dublin*, **12**, 374 (1910). It is not clear whether these data are original observations or interpolated values.

⁶ "International Critical Tables," Vol. 1, pp. 72 and 73, 1926. For this purpose values of the surface tension of liquid carbon dioxide were obtained from the data given in the Landolt-Börnstein Tabellen, 5th edition, 1923.

degree of accuracy, a larger number of observations would be necessary at each temperature. It may be estimated, however, that mathematical analysis of the data of this investigation permits values of coëxisting liquid and gaseous carbon dioxide to be calculated with an accuracy of $\pm 0.1\%$ over the temperature range -5.8 to 22.9° .

The data obtained are given in Table I. For purposes of comparison there are included in this table values of d_l , d_g and $(d_l + d_g)/2$ calculated from the equations

$$d_l = 0.4683 + 0.001442(t_k - t) + 0.1318 \sqrt[3]{(t_k - t)} \quad (2)^7$$

$$d_g = 0.4683 + 0.001442(t_k - t) - 0.1318 \sqrt[3]{(t_k - t)} \quad (3)$$

and

$$(d_l + d_g)/2 = 0.4683 + 0.001442(t_k - t) \quad (4)$$

TABLE I
THE DENSITIES OF COEXISTING LIQUID AND GASEOUS CARBON DIOXIDE

$t, ^\circ\text{C.}$	d_l			d_g			$(d_l + d_g)/2$		
	Obs.	Calcd.	Calcd.-obs.	Obs.	Calcd.	Calcd.-obs.	Obs.	Calcd.	Calcd.-obs.
22.9	0.7422	0.7448	+0.0026	0.2163	0.2152	-0.0011	0.4793	0.4800	+0.0007
17.2	.8045	.8044	- .0001	.1721	.1720	- .0001	.4883	.4882	- .0001
15.2	.8216	.8216	.0000	.1607	.1606	- .0001	.4912	.4911	- .0001
11.2	.8547	.8535	- .0012	.1390	.1401	+ .0011	.4969	.4968	- .0001
6.2	.8878	.8886	+ .0008	.1217	.1196	- .0021	.5048	.5041	- .0007
1.2	.9198	.9201	+ .0003	.1029	.1025	- .0004	.5114	.5113	- .0001
-1.8	.9378	.9376	- .0002	.0940	.0936	- .0004	.5159	.5156	- .0003
-5.8	.9604	.9598	- .0006	.0803	.0828	+ .0025	.5204	.5213	+ .0009

For these calculations, t_k was assumed to be 31.0° ⁸ and the critical density, 0.4683, was obtained by plotting $(d_l + d_g)/2$ against t and extrapolating the straight line thus obtained to 31.0° . This method of obtaining the critical density, first suggested by Cailletet and Mathias,⁹ is very convenient, since by averaging the densities the errors are minimized, due to the fact that in the method used too high a value of the density of either phase is necessarily accompanied by too low a value of the other phase. Since the liquid density is just as much greater as the gas density is lower than their average, the equation giving either as a function of temperature should be obtained by addition to or subtraction from the equation representing their average of an additional term. The agreement of the data with Equations 2, 3 and 4 showed that the data may be satisfactorily represented in this way.

Since the values obtained in the presence of excess water agree with the

⁷ Attention might be called to the fact that for all materials for which the data are available the densities of the coëxisting gaseous and liquid phase are less or greater, respectively, than their average densities at any temperature, within about 100° of their critical temperature, by a quantity $a \sqrt[n]{t_k - t}$, where $n = 3.000$.

A theoretical discussion of this relationship is given by S. Sugden, *J. Chem. Soc.*, 1927, p. 1780 ($n = 10/3$).

⁸ Landolt-Börnstein Tabellen, 5th edition, 1923.

⁹ Cailletet and Mathias, *Compt. rend.*, 102, 1202 (1886).

values given in Table I within the experimental error, they will not be separately tabulated. It should be stated that at about 4° the water in the tube appeared to freeze and offered considerable resistance to passage of the stirrer. According to W. Hempel and J. Seidel¹⁰ carbon dioxide

forms a hydrate, $\text{CO}_2 \cdot 9\text{H}_2\text{O}$, which melts at 8° and 43 atmospheres. It seems probable that, due to supercooling, the hydrate did not form at the melting point in our experiments.

The data obtained in this investigation are plotted in Fig. 1. For

¹⁰ Hempel and Seidel, *Ber.*, 31, 2997 (1898). (See also P. Villard, *Compt. rend.*, 119, 368 (1894) who describes the hydrate as $\text{CO}_2 \cdot 6\text{H}_2\text{O}$.)

purposes of comparison with other recorded data there are also plotted the results of previous investigators. The curves are drawn to fit Equations 2, 3 and 4. In Table II there is presented a summary of the interpolated values at 5° intervals from -5° to the critical temperature for all observers except Andréeff,¹¹ whose points are undoubtedly in considerable error. The values of density given by F. G. Keyes and A. W. Kenny,¹² although not original data, are also included in the figure and in Table II.

TABLE II

INTERPOLATED VALUES OF THE DENSITIES OF COEXISTING LIQUID AND GASEOUS CARBON DIOXIDE AT TEMPERATURES FROM -5 TO 31°

<i>t</i> , °C.	Liquid						Gaseous

^a C&M, Cailletet and Mathias;⁹ A, Amagat;¹⁰ B, Behn;¹⁴ J, Jenkin;¹⁵ K&K, Keyes and Kenny;¹² L&E, Lowry and Erickson.

^b Extrapolated according to formula given by Cailletet and Mathias.

^c According to Amagat's data, $t_k = 31.35$ and $d_k = d_g = 0.464$.

Consideration of the data given in Table II shows in general that there is quite satisfactory agreement among the observers. It is evident, however, that the equations used by Keyes and Kenny give values of density considerably too low for the liquid phase at the higher temperatures and for the gas phase at the lower temperatures.

Summary

The densities of coëxistent liquid and gaseous carbon dioxide have been measured and it has been shown that they can be satisfactorily represented by equations involving the first and one-third powers of the temperature on the critical scale over a temperature range from -5.8 to 22.9°. A comparison of the data of other observers with these data has shown them to be in substantial agreement. The data indicate that the critical density of carbon dioxide is 0.4683, which may be compared with the value 0.464 of Amagat and 0.4597, as judged by Keyes and Kenny, from analysis of earlier data.

¹¹ Andréeff, *Ann.*, 110, 1 (1859).

¹² Keyes and Kenny, *J. Am. Soc. Refrig. Eng.*, 3, 48 (1916).

¹³ Amagat, *Compt. rend.*, 114, 1093 (1892).

¹⁴ Behn, *Ann. Physik*, [4] 3, 733 (1900).

¹⁵ Jenkin, *Proc. Roy. Soc. (London)*, 98, 170 (1920).

It has been shown that the density of saturated carbon dioxide vapor is the same in the presence or absence of water within the experimental error. Assuming applicability of Raoult's law and direct proportionality between vapor pressure and vapor density, it may be calculated that the solubility of water in liquid carbon dioxide is less than about 0.05% by weight over the temperature range of this investigation. Attention has been called to qualitative evidence of the formation of a solid hydrate of carbon dioxide at about -1° .

THE SYSTEM POTASSIUM CARBONATE, SODIUM CARBONATE AND WATER AT 40° AND THE TRIHYDRATE OF SODIUM CARBONATE

By J. W. BAIN

RECEIVED JULY 29, 1927

PUBLISHED NOVEMBER 5, 1927

An investigation of this system has been proceeding in this Laboratory for a number of years and brief statements of progress have appeared elsewhere.¹ The excellent investigations of Hill and Miller² have thrown a flood of light upon the various phases which exist between 20 and 40° and have explained some of the difficulties encountered in the work here; conflicting results which were met with early in our study have focused attention on the isotherm of 40° . This communication gives additional data which had escaped the notice of previous investigators.

At the outset of our work a number of determinations confirmed the accuracy of the results of Osaka³ and of Kremann and Zitek⁴ regarding the composition of the saturated solution; the residues were not analyzed and the existence of the double salt $K_2CO_3 \cdot Na_2CO_3 \cdot 12H_2O$ was assumed, instead of the solid solution $(K_2Na_2)CO_3 \cdot 6H_2O$ found by Hill and Miller. In order to be well beyond the transition point of the supposed double salt, the temperature of 40° was selected for the next isotherm. An inspection of the solubility curves for potassium and sodium carbonates showed that there was only a slight variation in solubility in both cases with a change of temperature of several degrees, and for this reason an ordinary thermometer divided to single degrees was considered sufficiently accurate to show the temperature of the bath; this choice gave much trouble subsequently.

Experimental Methods

The carbonates used were of c. p. quality and each lot was analyzed before use; the samples conformed to the usual standards. Weighed quantities of the components were placed in L-shaped glass tubes which were rocked to and fro in the bath, the movement of a large bubble of air producing a stirring action. From time to time the tubes were removed and shaken vigorously to break up crusts, and in some instances the solid phase was filtered off, ground in a mortar and returned to the tube. The samples were withdrawn by a weighing pipet and, after dilution, the sodium and potassium were determined as chlorides in one portion, an operation in which wide glass tubes with bent-up, drawn-out ends⁶ were almost indispensable; in another portion potassium was determined as perchlorate. All determinations were made in duplicate and the agreement was excellent.

Fig. 1.

The solid phases were filtered off, sucked dry, dissolved and analyzed as above. Hill and Miller's method of centrifuging, which was only published toward the conclusion of our work, has been tried and is undoubtedly a great improvement. During the course of the investigation sixty-seven separate experiments have been carried out, the large number being due to the difficulty in securing solutions in equilibrium with a stable phase; from these the following results have been selected; temperature, 40°.

The curves lying to the left of Point 14 were thoroughly established by April, 1924, but no concordant results could be obtained in the remainder of the field. Variable results from solutions of the same composition led to the conclusion that equilibrium was only very slowly attained and,

^a For convenience, the symbols of Hill and Miller have been used. K₂/s = K₂CO₃·3/2H₂O; KN = K₂CO₃·Na₂CO₃; N₁ = Na₂CO₃·H₂O; N₂ = Na₂CO₃·3H₂O. The solid phases in Nos. 3 to 7 were not determined and are assigned on the basis of Hill and Miller's isotherm at 36°.

consequently, the period of shaking was increased first to a fortnight and then to greater lengths as indicated in the table. The conclusion was finally reached that the temperature of the bath oscillated about the temperature of a transition point, and that a new hydrate of sodium carbonate was present. It is very easy to obtain solutions supersaturated with respect to the monohydrate and of the numerous results which were obtained in consequence, numbers 14A and 14B are placed on the diagram upon a dotted line indicating the metastable prolongation of the curve stretching from 7 to 14.

As is shown in the diagram, the projection of the tie lines between the points 14, 18 and 22, indicating the composition of the solution and of the moist residue, intersect the side of the triangle at very obtuse angles and consequently little reliance can be placed upon them. It was, therefore, necessary to investigate the composition of the solid phase in equi-

librium with solutions lying to the right of point 14 by some other method.

A sample of sodium carbonate which had been shaken with an amount of water sufficient only to partially dissolve it, was filtered in a tube with a Jena glass disk surrounded by water at 42°; after a few moments' suction the moist salt was washed with a very small quantity of ether, poured on dropwise, and was then rapidly removed to a stoppered weighing bottle.

Anal. 1.0702 g. titrated with 0.9562 *N* HCl, using methyl orange, required 14.0 cc., = 0.7102 g. Na_2CO_3 , whence $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O} = 1:2.98$ 0.6768 g. heated at 270–300° gave 0.4507 g. Na_2CO_3 , whence $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O} = 1:2.95$.

To confirm this result, 50.0 g. of Na_2CO_3 , 4.0 g. of NaCl and 60.18 g. of H_2O were shaken for a number of days at 41°; in the filtered solution there were found: 0.6771 g. of NaCl = 0.5015 g. of Na_2CO_3 + 0.1202 g. of NaCl in 1.9355 g. of solution, on the assumption that all the NaCl present was in solution; the NaCl alone = 0.1202 g.; H_2O as solution = 43.64 g.; Na_2CO_3 in solid phase, 33.20 g.; hence $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O} = 1:2.93$.

Samples of the solid phase were also centrifuged as suggested by Hill and Miller and it was found after a number of trials that great care had to be taken to prevent the sample from falling below 40°, since otherwise the results were unsatisfactory.

Anal. 0.5479 g. of the centrifuged salt lost on heating 0.1850 g. of H_2O , whence $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O} = 1:3.02$.

The results of these independent methods, taken together with the intersections of the tie lines on the $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$ side of the triangle, are evidence of the existence of a trihydrate of sodium carbonate, the solubility of which is represented by the curve from Points 14 to 24. Solutions prepared by agitating sodium carbonate for a few hours at 40° or over are saturated with respect to the metastable monohydrate but are supersaturated with respect to the stable trihydrate; since the change from one form to the other is slow, the investigators of the solubility of this salt, even such careful and experienced workers as Wells and McAdam,⁶ have overlooked the existence of the trihydrate. The present data on solubility above 40° are undoubtedly in error and will be further investigated in this Laboratory.

It is not yet possible to state definitely how long a sample must be shaken at 41° or slightly higher in order that the complete conversion to the trihydrate may be assured, but at present it is believed that not less than six days should be allowed.

An attempt was made to determine with some precision the transition point by the thermal method, using the procedure of Richards.⁷ A series of runs was made with slowly rising and falling temperatures which yielded

⁶ Wells and McAdam, *THIS JOURNAL*, 29, 721 (1907).

⁷ Richards, *Am. J. Sci.*, [4] 6, 201 (1898).

definite indications of a transition point although the constancy of temperature lasted only for a few minutes. The change of one hydrate into the other proceeds slowly, and the existence of the monohydrate above the transition point for days as a metastable form is indicative of this sluggishness; the trihydrate appears to pass over into the monohydrate more rapidly but the rate is still low. The transition of the trihydrate into the monohydrate is accompanied by the evolution of heat. When these difficulties had developed during the first few runs, attempts were made to obtain more favorable conditions, that is, the monohydrate prepared at 37° was added to the trihydrate at 41° and the mixture slowly cooled and then heated again. The converse procedure was also tried but no method of accelerating the change from one hydrate to the other could be found. In all, seventeen runs were made; the arrests with rising temperature occurred from 39.60 to 39.98° and on cooling at 39.97 to 39.85° . The transition temperature is, therefore, assumed for the present to be $39.8^{\circ} \pm 0.1^{\circ}$.

The compound $\text{Na}_2\text{CO}_3 \cdot 3\text{H}_2\text{O}$ has not been previously described except as associated with the efflorescent soda in the dried river beds of the Cordilleras,⁸ and as a deposit from hot springs near Saxby River, Queensland.⁹

The greater portion of the experimental work in this investigation has been carried out by a number of students, whose assistance is gratefully acknowledged.

Summary

1. The system $\text{K}_2\text{CO}_3 + \text{Na}_2\text{CO}_3 + \text{H}_2\text{O}$ has been studied at 40° .
2. The existence of the trihydrate of sodium carbonate has been proved.
3. The transition point in the system $\text{Na}_2\text{CO}_3 \cdot 3\text{H}_2\text{O} - \text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$ is $39.8 \pm 0.1^{\circ}$.
4. The solubility data for sodium carbonate at 40° and for some unknown higher range in temperature, as at present recorded, refer to the composition of solutions in equilibrium with the metastable monohydrate and require revision.

THE POTENTIOMETRIC DETERMINATION OF INDIUM

By ULRIC B. BRAY¹ AND H. DARWIN KIRSCHMAN

RECEIVED AUGUST 6, 1927

PUBLISHED NOVEMBER 5, 1927

Introduction

An accurate and fairly rapid method of analysis of indium solutions has become desirable in order to facilitate further investigations on indium in this Laboratory. The two methods described in the literature are the electrodeposition^{2,3,4} of the metal and the weighing of the indium oxide obtained by igniting the precipitated hydroxide.^{5,6}

The electrodeposition of indium from a chloride solution, either in the presence of formic acid and ammonia or in the presence of Rochelle salt, as suggested by earlier authors, was found unsuitable for an accurate quantitative determination with chloride solutions. However, by using a sulfate solution, with a current density of 0.4 ampere per square decimeter and a potential of about 4 volts, very adherent deposits of indium with no platinum black were obtained with a rotating cathode. But the difficulty of precipitating the last few milligrams of indium from the solution, as observed by the present authors in over a dozen electroplating experiments, makes this an uncertain method of analysis. As mentioned by Dennis and Geer, the electrodeposition of indium was found to be an excellent method of purifying it from iron, since one deposition from a sulfuric acid solution of the crude oxide gave a metal which showed no test for iron with potassium thiocyanate.

Determinations as the oxide, In_2O_3 , were made by essentially the method of Thiel and Koelsch as follows. The hydroxide was precipitated from the solution of the chloride by the addition of a slight excess of freshly filtered ammonium hydroxide. The white, flocculent precipitate was washed by decantation until free from chlorides with a 1% solution of ammonium nitrate and filtered into a Gooch crucible. In the first set of determinations the crucibles were heated over a blast-lamp for thirty minutes, cooled and weighed. This was repeated but a constant weight was not obtained. In the second set of determinations the crucibles were placed in an electric furnace and brought to about 850° for thirty minutes. This was repeated until the weight was constant to 0.2 mg. The crucibles

were then heated in the furnace at about 900° for about forty minutes, when a loss of weight of several milligrams occurred.

Both of these methods were thus found by the authors to be not well suited to the purpose at hand. A new method of analysis was therefore worked out. This consists in titrating the indium with potassium ferrocyanide and determining the end-point potentiometrically. Since indium forms with potassium ferrocyanide a precipitate which is insoluble in nitric and sulfuric acids and in hydrochloric acid up to 4 *N*, and since it does not give an insoluble compound with potassium ferricyanide, the system lends itself to this method of electrotitration. The composition of the insoluble compound formed during the titration has been investigated in order to obtain a convenient method of standardizing the ferrocyanide solution.

Apparatus

The apparatus used consists of (1) a motor-driven stirrer; (2) a 1 *N* KCl-calomel reference half-cell; (3) an oxidation-reduction electrode made by fusing 1 cm. of small (0.05 cm. diameter) platinum wire through the end of a small glass tube; (4) a certified buret; and (5) a Leeds and Northrup "Type K" potentiometer with a high sensitivity galvanometer. A beaker containing the unknown solution diluted to about 300 cc. is a convenient size. For the inert metal electrode a short platinum wire rather than a foil electrode is used. For the reference electrode a 1 *N* calomel half-cell is satisfactory and consequently no attempt has been made to use a system of bimetallic electrodes.^{7,8}

The Method of Titration

Preliminary experiments showed that solutions of indium chloride titrated potentiometrically give curves almost identical in form with those obtained by titrating zinc^{9,10,11,12} in acid solution at 70° with potassium ferrocyanide. During the potentiometric titration, equilibrium is reached at the oxidation-reduction electrode in less than thirty seconds, except in the immediate vicinity of the end-point where the voltage is changing rapidly. The ratio of indium solution to ferrocyanide solution obtained by taking the mid-point of the vertical section of the curve as the end-point was found to be quite constant. Stock solutions of carefully purified indium chloride were prepared by dissolving well-washed precipitates of the hydroxide in a slight excess of a constant-boiling solution of hydrochloric acid and diluting to about 0.03 or 0.07 molal.

The effects of acid, neutral salts, concentration of indium salt and temperature on the ratio of the two solutions were studied. In all experiments the ferrocyanide was added to the indium solution from the buret,

no attempt being made to study the effect of adding the indium to the ferrocyanide, since satisfactory results were obtained by the easier method. Voltages were read to one millivolt as soon as equilibrium was substantially established after each addition. At the beginning of the titration and up to within two or three cubic centimeters of the end-point the ferrocyanide was allowed to run from the buret fairly rapidly, because the final curve was found to be independent of the rate of addition. The first part of the curve is of little or no importance and depends to a considerable extent on the previous treatment of the platinum wire electrode. The voltage gradually rises with the addition of the ferrocyanide solution to about 0.62 volt and then remains practically constant until within a few cubic centimeters of the end-point, after which a gradual decrease of potential occurs. Thereafter additions of 0.5 cc. are made, and finally of 0.1 cc. as the end-point is more closely approached. Curve A of Fig. 1 is typical of the behavior at room temperature.

The effect of acid more concentrated than 0.05 *N* in the final solution is both to decrease the drop in potential at the end-point and to make the decrease take place gradually instead of suddenly. The effect of neutral salt is

essentially the same as that of acid; thus, several titrations made with solutions to which both hydrochloric acid and potassium acetate had been added gave curves similar to those obtained by using dilute acid with a corresponding amount of potassium chloride. When the decrease in voltage takes place gradually, as in solutions of high ionic strength, it is very difficult to obtain an accurate end-point. The curves obtained in these cases were similar to Curve B in Fig. 1.

Titration were made at room temperature (about $25 \pm 2^\circ$), at 45° and at 85° . The best curves were obtained at room temperature. At 45° the curve is still fairly good but at 85° the drop in voltage is too gradual. The end-points were in general determined independently by the two

Fig. 1.

authors from the titration data and seldom differed by more than 0.02 cc. The standard ferrocyanide solutions were kept in black lacquered bottles under an atmosphere of nitrogen.

In Table I are given the results of a number of titrations of two stock solutions, A and B, of indium chloride with the ferrocyanide solution. They show the accuracy with which the end-point can be determined under different conditions. The indium chloride solution was always about 0.02 *N* in hydrochloric acid.

Composition of the Compound between Indium and Potassium Ferrocyanide

While the reproducibility of the ratios of indium solution to ferrocyanide solution shows the end-point to be sharp, it is desirable to know the ratio of indium to ferrocyanide in the precipitated compound, in order not to have to rely upon a pure indium preparation as the means of standardizing the ferrocyanide solution. To establish the composition of this compound, it was first necessary to determine the actual molality of the ferrocyanide in the solution used. This was done as follows. A solution of potassium ferrocyanide was made 0.05 normal as closely as possible by weighing out selected crystals of the trihydrate, adding 0.5 g. of potassium ferricyanide, dissolving in water and diluting to exactly one liter. This 0.05 formal solution was then titrated electrometrically against two very carefully standardized zinc solutions which one of the authors had prepared for electromotive force measurements on zinc sulfate.¹³ Assuming the molality of the potassium ferrocyanide to be 0.05 in correspondence with the weight of crystals taken, the ratio of zinc to ferrocyanide in the titration was found to be 1.505 and 1.508 for the two separate zinc solutions. This is in agreement with Treadwell and Chevert,¹⁴ who have

¹³ U. B. Bray, *THIS JOURNAL*, **49**, 2372 (1927). The method of standardizing these zinc solutions was the potentiometric method, using another ferrocyanide solution. The basis of the standardization was Kahlbaum's "zur Analyse" zinc sticks and anhydrous zinc sulfate. All titrations were made under similar conditions of concentration, temperature and acidity.

¹⁴ Ref. 11. Although Verzijl and Kolthoff (ref. 12) report an error of a few tenths of a per cent. from the theoretical potentiometric end-point in ferrocyanide precipita-

shown that the insoluble compound formed between potassium ferrocyanide and zinc is $\text{Zn}_3\text{K}_2(\text{Fe}(\text{CN})_6)_2$. The exact molality of ferrocyanide solutions may therefore be determined by titrating against metallic zinc or standard zinc solutions and then making use of the ratio $3\text{Zn}:2\text{Fe}(\text{CN})_6$.

The next step in the determination of the composition of the indium ferrocyanide precipitate was to prepare pure indium by electrolysis on a rotating platinum cathode from a carefully purified solution of indium sulfate. The cathode coated with indium metal was washed, dried in an atmosphere of hydrogen at 110° and weighed. The sample taken for a titration was obtained by treating the electrode with 1-2 cc. of 12 *N* hydrochloric acid, washing it, drying and weighing again. This indium chloride solution was diluted to approximately 300 cc. and titrated as usual. The results of these titrations of solutions of weighed quantities of indium metal are given in Table II.

TABLE II
TITRATION OF METALLIC INDIUM AGAINST POTASSIUM FERROCYANIDE OF KNOWN MOLALITY

Milli atoms of indium	Milli moles of $\text{K}_4\text{Fe}(\text{CN})_6$	Ratio In $\text{Fe}(\text{CN})_6$
1.234	0.9874	1.250
1.203	.9634	1.245
3.067	2.437	1.258
0.8328	0.6653	1.252
1.486	1.187	1.251
1.670	1.335	1.254
	Average	1.252

The ratio of indium to ferrocyanide is clearly 1.25 or $5\text{In}:4\text{Fe}(\text{CN})_6$. Since the only other positive ions in the solution are potassium and hydrogen, the formula for the precipitated compound is presumably $\text{In}_5\text{K}(\text{Fe}(\text{CN})_6)_4$. The determination of this definite ratio of indium to ferrocyanide in combination with the 3 to 2 ratio of zinc to ferrocyanide found by Treadwell and Chevert makes it possible to standardize with metallic zinc the ferrocyanide solutions that are to be used for indium titrations. The availability of pure zinc metal as compared with indium metal makes this method of standardization convenient.

Summary

A method of analyzing indium solutions by titrating with potassium ferrocyanide and determining the end-point potentiometrically has been described. The accuracy of the end-point is estimated at one or two-tenths of a per cent.

The precipitate formed between potassium ferrocyanide and indium solutions has been shown to be definite under the conditions described. In titrations depending upon the electrolyte present, any such small errors would tend to cancel out with the subsequent indium titration.

and to contain indium and ferrocyanide in the ratio $5\text{In} : 4\text{Fe}(\text{CN})_6$ (within 0.2%). The formula of the precipitate is therefore presumably $\text{In}_5\text{K}(\text{Fe}(\text{CN})_6)_4$. The determination of the ratio of indium to ferrocyanide in this compound permits using metallic zinc for standardizing the ferrocyanide solution, since the composition of the zinc ferrocyanide precipitate has been determined.

THE HIGH-TEMPERATURE EQUILIBRIUM BETWEEN THORIUM OXIDE AND CARBON

BY C. H. PRESCOTT, JR. AND W. B. HINCKE

RECEIVED AUGUST 12, 1927

PUBLISHED NOVEMBER 5, 1927

Plan of the Investigation

The present work is a continuation of a program of research in the field of high-temperature equilibria, using the same general methods and apparatus that have been more completely described in an article on zirconium oxide and carbon.¹ Many facilities have been added to increase the precision and improve the physical conditions of the work. The equilibrium measurements have been carried on up to a temperature of 2500°K . As a result of the higher temperatures now employed many new sources of difficulty and error have been encountered, necessitating a complete study of the temperature corrections for the deviations in behavior of the carbon furnace from that of an ideal black body. It has not been possible to make the carbon elements strictly reproducible but, in spite of the elevated temperature, results have been obtained comparable in precision to the previous work under more moderate conditions.

Previous work on the reduction of thorium oxide by carbon is that of Troost² and of Moissan and Étard.³ Impure thorium metal can be obtained, but with excess of carbon the carbide, ThC_2 , is formed. This is a yellow, crystalline compound that yields a wide variety of hydrocarbons on hydrolysis with water. These have been studied in detail by Lebeau and Damiens.⁴

Acknowledgment is due to Dr. W. E. Forsythe of the Nela Research Laboratory for assistance with the pyrometry.

This investigation was aided financially from a grant made to Professor A. A. Noyes by the Carnegie Institution of Washington.

The Temperature Measurements

The temperature was measured with an optical pyrometer of the disappearing filament type made in the laboratory shop after a design by Forsythe.⁶ Two thicknesses of Corning red glass were used for a monochromatic screen and absorption screens were used of noviweld glass, shade six and shade eight. These were calibrated through the courtesy of the Nela Research Laboratory. The effective wave length of the red screen was approximately 0.660μ . The pyrometer was calibrated against a standard ribbon filament tungsten lamp, also obtained from the Nela Research Laboratory.

Corrections for the emissive power of carbon were obtained on six different furnaces mounted in furnace bulb No. 1.¹ Each had three holes 0.38 mm. in diameter in its wall, 120° apart around its circumference, and 1.6 mm. apart along its axis at the center where the temperature was most uniform. The hole served as an experimental black body and a comparison of the temperature (T) measured there with the apparent temperature (S) of the adjacent wall afforded a determination of the effective emissive power (ϵ) of the carbon. This is calculated from the Wien radiation law by the formula

$$\frac{1}{T} - \frac{1}{S} = \frac{\lambda \ln \epsilon}{c_2}$$

Here λ is the effective wave length of the red screen and c_2 is $14,330\mu$ degrees. This effective emissive power is the quantity giving the actual correction between true and observed temperature as required for the equilibrium determinations. The data obtained on the emissive power from 1250 to 2700°K . are best summarized by the relation $\epsilon = 0.930 - 4.17 \cdot 10^{-5}T$.

It was found that the inside and outside surfaces of several of the furnaces were not quite concentric; there was considerable temperature gradient along the furnace except at the exact center; there were progressive changes in the surface due to volatilization, especially at the higher temperatures. As a result there were errors in the calculated emissive power, increasing with the temperature, corresponding to a variation in the temperature as great as 25° from the mean at 2700°K . To balance the errors as much as possible, equal numbers of determinations were made on each of the three holes on each furnace, and a mean square solution made of all the data.

Apparatus and Procedure

The main features of the apparatus and general procedure are the same as already described in connection with the work on zirconium. The furnace is a small tube of Acheson graphite 0.318 cm. in diameter at the central section, with a 0.05cm. wall.

⁶ Forsythe, *Astrophys. J.*, **43**, 295 (1916).

The detail of the furnace and its mounting in furnace bulb No. 2 are shown in Fig. 1. For the equilibrium measurements the furnace was loaded with a small pellet of compressed thorium dioxide and graphite and connected to the apparatus in a thermostat at 35° as shown in Fig. 2. The pressure of carbon monoxide was measured on a mercury manometer and the temperature measured by sighting the pyrometer at the center of the furnace through a window in the thermostat. The transmission of this system of two windows with water between was measured and found to be 78.7%.

Fig. 1.—Furnace bulb No. 2.

Fig. 2.—Diagram of apparatus for high temperature equilibria.

The power was drawn from a battery of sixty 150-ampere-hour storage cells. At 2500°K . six cells were connected in series and ten in parallel, the current being about 110 amperes. The current was measured and controlled by a Leeds and Northrup Type K potentiometer, using the potential drop across a 0.0034-ohm resistance. At constant current the temperature was very steady throughout a run, so only a few measurements were necessary. The pyrometer current was measured on the same potentiometer from the potential drop across a 1-ohm standard resistance.

Two observers were required, one to make pyrometer settings, read the manometer and perform manipulations, the other to read the potentiometer, regulate the furnace current and record data.

Most of the runs were from fifteen to forty minutes in length; each constituted a determination of the rate of change of pressure at a definite temperature and pressure. As it was more convenient to vary the temperature, a series of runs was made at approximately the same pressure, from which the equilibrium temperature could be estimated by interpolation.

It was found advisable to subject each furnace to a preliminary baking out at 2400°K. under a pressure of two atmospheres (above the equilibrium pressure of the reaction) to drive off adsorbed oxygen.

The product of the reaction was a yellow, microcrystalline aggregate smelling strongly of acetylene immediately upon removal from the furnace. Within a few hours it hydrolyzed to a buff-colored powder, with considerable increase in volume, even when kept over phosphorus pentoxide.

Fig. 3.--Original data at 6.54 cm.

Results of the Equilibrium Measurements

In working up the data the pressures during a run were plotted against the time. The slope of the best straight line gave the rate for the run. Rates at the same pressure were then plotted against the observed temperature (uncorrected). Each of the family of curves so obtained shows the combined influence of two factors, the deviation from equilibrium conditions and an exponential rise in the rate of reaction with temperature. The rate of pressure increase rises enormously with temperature above the equilibrium conditions, decreases to zero at equilibrium and becomes negative as the temperature is reduced, returning to zero as the temperature falls below 1800°K. The intercept of this curve was taken as the ob-

served equilibrium temperature (Figs. 3, 4 and 5 are given as typical examples). To this were added corrections for the transmission of the

Fig. 4.

window and for the emissivity of graphite to give the true temperature. The logarithms of the pressures in atmospheres were then plotted against

Fig. 5.

the reciprocals of the true equilibrium temperatures (Fig. 6). Since the change in the heat of reaction is small, these should fall on a straight

line and a least square solution was made for the most probable values of its constants. The largest deviation corresponds to an error of 40% in the pressure, which is easily accounted for by the imperfections of the furnace described in connection with the emissivity measurements. The final relation between equilibrium pressure in atmospheres and the true temperature in degrees Kelvin is given by the equation,

$$\text{Log } p = 8.069 - 19,325/T$$

The true temperatures and pressures are plotted in Fig. 7 in the original coördinates where the curve corresponds to the line in Fig. 6. These

Fig. 6.

values are tabulated in Table I where θ is the observed temperature, S is the brightness temperature of carbon (corrected for the transmission of the window), T is the true temperature (corrected for the emissivity of carbon) and p is the pressure.

TABLE I
EQUILIBRIUM PRESSURES AND TEMPERATURES

θ , °K.	S , °K.	T , °K.	p , atm.
2377	2441	2494	2.17
2341	2403	2454	1.39
2293	2352	2402	0.752
2170	2223	2265	.480
2158	2210	2252	.380
2092	2141	2179	.192
2035	2082	2117	.0861
1980	2024	2057	.0345

The reaction was so rapid, especially at the higher temperatures, that the interface was not closely comparable from one run to the next, producing considerable variation in the rates. Also, when near equilibrium, the rate would fall off after a couple of runs, probably due to a sintering effect increasing the particle size. It was particularly noticeable that on the reversal of the reaction after a large rate the initial rate was larger than anticipated until the newly formed material was exhausted. There were two very striking observations leading to the above explanations. While determining the equilibrium at 2500°K. the current was momentarily raised enough to fuse the pellet. No further reaction was detect-

Fig. 7.

able. One series of runs at low temperature was made on a pellet of exact proportions to produce ThC_2 . The forward rates were normal, but no reverse rates were obtained until the pressure was increased many fold, when an extremely slow reverse rate was observed under conditions where previously the reverse reaction went to completion before any readings could be taken. The published data were obtained on pellets containing an excess of oxide to separate the particles of carbide formed, the proportions corresponding to the hypothetical formation of ThC .

Besides the preliminary data which were not so correlated that an equilibrium temperature could be interpolated, one complete series of runs was discarded in which the rates were very small and erratic. It was found that the reverse reaction had gone to completion before the

readings were taken. On running the reaction ahead for a pressure increase of two centimeters a normal series of runs was obtained with no other change.

The Melting Point of Thorium Carbide

The behavior of a melted pellet has been partly described in the preceding paragraph. Besides the cessation of reaction, it was remarked that the furnace current had increased at the same setting of the control resistances. After regulating the current it was found that the temperature had dropped greatly. On removal it was seen that the pellet had wet the furnace wall and presumably short circuited the central segment. This suggested a method of determining the melting point of the carbide.

A pellet of proportions to yield ThC_2 was mounted in furnace bulb No. 1. It was run, *in vacuo*, at 2100°K . for an hour and a half so as to form the carbide. Carbon monoxide was then admitted to one atmosphere pressure and the temperature raised to 2500°K . The temperature was raised by approximately ten degree steps. At each setting the current was held constant and voltage read across the furnace bulb terminals before and after a series of pyrometer readings. The voltage increased slightly due to the volatilization of the furnace.

At a current of 120.5 amperes the true temperature was 2773°K . The voltage dropped from 7.783 volts to 7.772. Another series of readings showed that the temperature was dropping, and in a few minutes the temperature had dropped 50° , the potential 0.1 volt, and both were changing rapidly.

Upon removal, one-half of the pellet was found melted and the other was a microcrystalline aggregate as in previous preparations at lower temperatures. The preparation was probably reasonably pure at the moment of fusion, so the above value of 2773°K . is not far off.

Thermodynamic Calculations

The chemical reaction is undoubtedly

We may now proceed to calculate the free-energy increase (ΔF) and the heat-content increase (ΔH) attending this reaction when the carbon monoxide pressure is one atmosphere.

The value of ΔF may be derived from the equilibrium pressure p by the familiar thermodynamic equation $\Delta F^\circ = -RT \ln K$, where $K = p^2$. From the determinations of the equilibrium pressure p tabulated in Table I we thus obtain the values given in Table II.

TABLE II

FREE-ENERGY INCREASE ATTENDING THE REACTION

Temp., T , $^\circ\text{K}$.	2494	2454	2402	2265	2252	2179	2117	2057
ΔF° , cal.	-7685	-3224	2723	6612	8666	14301	20660	27543

From the expression for $\log_{10} p$ derived in the same section we similarly obtain the relations, $\Delta F^\circ = 176,970 - 73.89 T$, and $\Delta H = 176,970$ calories. At 2395°K . the free-energy change is zero and the actual equilibrium pressure is one atmosphere.

The molal heat capacities, C_p , of graphite and carbon monoxide were taken from Lewis and Randall,⁶ and those of thorium oxide and carbide estimated from Kopp's law according to the scheme given in Noyes and Sherrill.⁷

For C	$C_p = 1.1 + 0.0048T - 0.0000012T^2$
For CO	$C_p = 6.50 + 0.0010T$
For ThO_2	$C_p = 14.2$
For ThC_2	$C_p = 9.8$

From the above-mentioned heat of reaction and the zero value of the free-energy change at 2395°K . the following equations are obtained and from them by extrapolation the following values at room temperature.

$$\begin{aligned}\Delta H &= 194,261 + 4.2T - 0.0086T^2 + 0.0000016T^3 \\ \Delta F^\circ &= 194,261 - 4.2T \ln T + 0.0086T^2 - 0.0000008T^3 - 64.438T \\ \Delta H_{298} &= 194,790 \text{ cal.}; \Delta F^\circ_{298} = 188,660 \text{ cal.}\end{aligned}$$

Combining this heat of reaction with the heat of formation of carbon monoxide,⁸ and the heat of formation of thorium oxide,⁸ permits a calculation of the heat of formation of thorium carbide.

Summary

The chemical equilibrium between thorium oxide, graphite, thorium carbide and carbon monoxide has been determined at temperatures from 2000 to 2500°K ., and at pressures from two centimeters to two atmospheres.

Temperatures were measured with an optical pyrometer. The furnace was a graphite tube 0.318 cm. in diameter with a 0.05cm. wall supported on tungsten rods and enclosed in Pyrex glass. The pressures were read on a mercury manometer. The enclosed gas space was about 100 cc. and was all below the water level of a thermostat at 35° .

Experiments were made on compressed pellets of thorium oxide and graphite. The procedure was to determine at a series of temperatures and pressures the rate of change of pressure with the time. From a series of such experiments at a single pressure and different temperatures the equilibrium temperature was estimated.

⁶ Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., New York, 1923, pp. 89, 569, 576.

⁷ Noyes and Sherrill, "Chemical Principles," Macmillan Co., New York, 1922, p. 93.

⁸ Von Wartenberg, *Z. Elektrochem.*, 15, 869 (1909).

The increases in free-energy and heat-content that would attend this reaction between 2000 and 2500°K. at one atmosphere were found to be those given by the equations $\Delta F^\circ = 176,970 - 73.89T$, and $\Delta H = 176,970$ calories.

At 2395°K. the free-energy change becomes zero and the actual equilibrium pressure is one atmosphere.

THE HIGH-TEMPERATURE EQUILIBRIUM BETWEEN ALUMINUM OXIDE AND CARBON

BY C. H. PRESCOTT, JR.¹ AND W. B. HINCKE

RECEIVED AUGUST 12, 1927

PUBLISHED NOVEMBER 5, 1927

Plan of the Investigation

The present work is a continuation of a program of research in the field of high-temperature equilibria, using the same apparatus and procedure that have already been applied to reactions between zirconium oxide and carbon,² and thorium oxide and carbon.³ The extraordinary stability of the oxides and carbides of zirconium and thorium at incandescent temperatures has rendered them very fortunate objects of study. Though the results are no less definite, the volatility of aluminum carbide and its consequent tendency to depart from the reaction area have limited the precision attainable in the study of the equilibrium between aluminum oxide and carbon.

The first reliable study of aluminum carbide is that of Moissan⁴ who prepared it from its elements in the electric furnace. He found it to be a yellow, crystalline compound of composition corresponding to the formula Al_4C_3 , yielding methane on hydrolysis. Askenasy⁵ and his associates have shown that mixtures of carbide and metallic aluminum may be obtained by reduction of the oxide with carbon. Fraenkel⁶ has shown that the carbide is formed at more moderate temperatures. Ruff⁷ has made approximate measurements on the vapor pressure of aluminum carbide, finding that at 2200° the carbide melts and is in equilibrium with liquid aluminum and carbon and with a vapor at 400 mm.

pressure containing about equal parts of aluminum and aluminum carbide. Ruff⁸ has also determined the melting point of aluminum oxide as between 1965 and 2065°, stating that the oxide is volatile at about 1900°.

The present investigation has been aided financially from a grant made to Professor A. A. Noyes by the Carnegie Institution of Washington.

Apparatus and Procedure

The apparatus and general procedure have already been completely described in references (2) and (3).

Most of the runs were from ten to thirty-five minutes in length; each constituted a determination of the rate of change of pressure in the furnace bulb at a definite temperature and pressure. As it was more convenient to vary the temperature, a series of runs was made at approximately the same pressure, from which the equilibrium temperature could be estimated by interpolation. This procedure was followed on furnaces A to E. In the hope that a different procedure would give better curves for the interpolation, series were made at constant temperature and different pressures on furnaces F to H.

In preliminary experiments it was found that extremely intimate contact was necessary in order to prepare the carbide, so all subsequent work was done on pellets made by thoroughly grinding graphite and an excess of aluminum oxide in ether and just enough Nujol (a pure paraffin oil) to bind the sample when compressed in a pellet press. The excess oxide was to help make up for losses of aluminum by vaporization.

Forward rates with evolution of carbon monoxide were invariably accompanied by a cream-colored deposit on the walls of the glass tube enclosing the furnace, and a black or dark brown deposit at pressures below 5 cm. Reverse rates were frequently terminated by exhaustion of carbide, and more had to be generated by running at higher temperature or lower pressure before another reverse rate could be obtained. Furnaces A, B and C were run till no further reaction could be obtained. The residue of the charge was found to be a small quantity of graphite which ignited completely on a platinum foil. The remaining furnaces were run for but one equilibrium determination apiece; their charges always showed some residue of white oxide on ignition, and in most cases some yellow carbide was to be seen in the charge.

To remove absorbed oxygen from the graphite furnace, each was subjected to a preliminary baking for an hour at about 2050°K. under a pressure of 2.5 atmospheres of carbon monoxide (above the equilibrium pressure of the reaction). During this treatment a slight white deposit appeared which was probably aluminum oxide.

In a preliminary preparation given fifteen minutes at 2000°K., *in vacuo*,

⁸ Ruff, *Ber.*, **43**, 1571 (1910).

a preparation of yellow carbide mixed with graphite was obtained which gave a considerable evolution of hydrocarbon fumes on treatment with sodium hydroxide.

Fig. 1.—Furnace E. $\theta = 2134$. $T = 2224^{\circ}\text{K}$. $p = 4408$ atm.

Both the black and the white material deposited during the carbide formation dissolved completely in both hydrochloric acid and sodium

Fig. 2.—Furnace F. $T = 2071^{\circ}\text{K}$. $p = 141$ atm

hydroxide and gave characteristic tests for aluminum. On ignition the cream-colored material flashed and turned black. Both deposits

gave white oxide on continued ignition. Since it is reported⁹ that metallic aluminum reacts with carbon monoxide to give a mixture of carbide and oxide, and the black deposit appeared at low pressures where the rate of reaction was greatest, the black deposit was probably aluminum and the cream-colored aluminum carbide.

Results of the Equilibrium Measurements

The observed rates of change of pressure in the furnace bulb certainly give limits in almost all cases to the possible values of the equilibrium conditions, but due to the radical changes in the pellet and solid interface from one run to the next, the graphical interpolation is attended with considerable uncertainty. Figs. 1 and 2 are given as typical examples of the plots of rate of change of pressure.

Fig. 3.

In Fig. 3, the logarithms of the equilibrium pressures in atmospheres are plotted against the reciprocals of the true temperatures. Since the change in the heat of reaction is small, these points should fall on a straight line and a least square solution was made for its constants. As the earlier values were less certain, and, in particular, since determining more than one equilibrium on each furnace was inadvisable, equal weight was given to the values obtained on each furnace, that is, A_1 , A_2 and A_3 were weighted $1/3$ each, and B_1 , B_2 , C_1 and C_2 , $1/2$ each. The final relation between the equilibrium pressure in atmospheres and the true temperature in degrees Kelvin is given in the equation

$$\text{Log } p = 8.21 - 18,480/T$$

⁹ Pring, *J. Chem. Soc.*, 87, 1530 (1905).

The true temperatures and pressures are plotted in Fig. 4 in the original coördinates where the curve corresponds to the line in Fig. 3. These values are tabulated in Table I where θ is the observed temperature, S is the

Fig. 4.—Equilibrium pressures and temperatures

brightness temperature of carbon (corrected for the transmission of the window), T is the true temperature (corrected for the emissivity of carbon) and p is the pressure.

Thermodynamic Calculations

The equation expressing the chemical reaction is undoubtedly

The value of ΔF° , the free-energy increases attending this reaction, may be derived from the familiar thermodynamic equation, $\Delta F^\circ = -RT \ln K$, where $K = p^6$. From the determinations of the equilibrium pressure p tabulated in Table I we thus obtain the values given in Table II.

TABLE II
 FREE ENERGY INCREASE

Detn.	Temp. T, °K.	ΔF°	Detn.	Temp. T, °K.	ΔF°
A ₁	1967	-76,990	C ₂	2183	-7634
A ₂	2030	-36,750	D	2138	-21,020
A ₃	2293	3150	E	2224	-21,740
B ₁	2137	5112	F	2071	-47,880
B ₂	2237	22,090	G	2248	-10,808
C ₁	2030	-49,270	H	1987	-62,020

From the expression for $\log_{10} p$ derived in the same section we similarly obtain the relations $\Delta F^\circ = 507,760 - 225.6T$, and $\Delta H = 507,760$ calories. At 2251°K. the free-energy change is zero and the actual equilibrium pressure is one atmosphere.

The molal heat capacities, C_p , of graphite and carbon monoxide were taken from Lewis and Randall,¹⁰ and those of aluminum oxide and carbide from Kopp's law according to the scheme given in Noyes and Sherrill,¹¹ as giving a reasonable approximation at high temperatures.

$$\begin{array}{ll}
 \text{For C} & C_p = 1.1 + 0.00487T - 0.00000127T^2 \\
 \text{For CO} & C_p = 6.50 + 0.00107T \\
 \text{For Al}_2\text{O}_3 & C_p = 24.4 \\
 \text{For Al}_4\text{C}_3 & C_p = 30.2
 \end{array}$$

From the above-mentioned heat of reaction and the zero value of the free-energy change at 2251°K., the following equations are obtained and from them by extrapolation the following values at room temperature,

$$\begin{aligned}
 \Delta H &= 537,310 + 10.50T - 0.0186T^2 + 0.00000367T^3 \\
 \Delta F^\circ &= 537,310 - 10.50T \ln T + 0.0186T^2 - 0.00000187T^3 - 190.39T \\
 \Delta H_{298} &= 538,900 \text{ cal.} \\
 \Delta F^\circ_{298} &= 464,300
 \end{aligned}$$

Using these values and the values for the formation of aluminum oxide given by Parks and Kelley,¹² and values for the formation of carbon monoxide from Lewis and Randall,¹⁰ values may be calculated for the formation of aluminum carbide from its elements.

From heats of combustion determined by Berthelot,¹³ the heat of reaction for the reduction of aluminum oxide to carbide may be calculated, as well as the heat of formation of aluminum carbide.

¹⁰ Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., New York, 1923, pp. 80, 560, 576.

¹¹ Noyes and Sherrill, "Chemical Principles," Macmillan Co., New York, 1922, p. 93.

¹² Parks and Kelley, *J. Phys. Chem.*, **30**, 47 (1926).

¹³ Berthelot, *Ann. Chim. Phys.*, [7] **22**, 470 (1901); [7] **22**, 479 (1901); Berthelot and Petit, *ibid.*, [6] **18**, 98 (1889); Berthelot and Matignon, *ibid.*, [6] **30**, 555 (1893).

The first value is in disagreement with the results of the present work by 160,000 calories. However, the determination of the heat of reaction is not so accurate as those for the free energy, and the slope of the line in Fig. 3 could be reduced by one-third without very serious prejudice to the data; but Berthelot himself remarked that the heat of formation of the carbide seemed abnormally large. The presence of oxide in his carbide might account for the discrepancy.

Summary

Determinations have been made of the chemical equilibrium for the reaction

The increases in free energy and heat content that would attend this reaction between 2000 and 2300°K. and one atmosphere pressure were found to be those given by the equations, $\Delta F^\circ = 507,760 - 225.6T$ and $\Delta H = 507,760$ calories. At 2251°K. the free-energy change is zero and the actual equilibrium pressure is one atmosphere.

AZIDO-CARBONDISULFIDE. III. BEHAVIOR OF AZIDO-CARBONDISULFIDE TOWARD CHLORINE, BROMINE AND IODINE¹

By WM. HOWLETT GARDNER AND A. W. BROWNE

RECEIVED AUGUST 12, 1927

PUBLISHED NOVEMBER 5, 1927

Azido-carbondisulfide may not inappropriately be designated as a *universal reagent* in the sense in which water has been termed a "universal solvent." Its reactivity toward acids and alkalies, toward oxidizing and reducing agents, toward certain metals and non-metals, toward water and ammonia, and apparently even toward certain organic solvents, together with its tendency to undergo an extremely regular autocatalytic decomposition at room temperature, seems to entitle this substance to characterization as an almost unique reagent.

In connection with the distinctly halogenoid character of azido-carbon-

¹ For the earlier articles of this series see (a) Browne, Hoel, Smith and Swezey, *THIS JOURNAL*, **45**, 2541 (1923); (b) Wilcoxon, McKinney and Browne, *ibid.*, **47**, 1916 (1925). The current article is based upon a part of the thesis presented to the Faculty of the Graduate School of Cornell University by William Howlett Gardner in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

disulfide the question has arisen as to whether this reagent may be caused to react with any of the other halogenoids, or with any of the halogens, forming inter-halogenoid or halogen-halogenoid compounds analogous to the inter-halogen compounds. The latter part of this question has been answered in the present investigation.

From the list of inter-halogen compounds theoretically capable of existence as definite chemical individuals, bromine trifluoride,² iodine pentafluoride,^{3,3c} iodine monochloride and trichloride⁴ and iodine monobromide⁵ have been prepared. Among the halogen-halogenoid compounds are chlorazide,⁶ bromazide⁷ and iodazide,⁸ cyanogen chloride,⁹ bromide,¹⁰ and iodide;¹¹ and thiocyanogen monochloride and trichloride.¹² The inter-halogenoids include cyanazide,¹³ cyanogen thiocyanate,¹⁴ and cyanogen selenocyanate.¹⁵

Behavior of Azido-carbondisulfide toward Chlorine

When dry azido-carbondisulfide is brought into contact at room temperature with chlorine, either in the gaseous form or in concentrated aqueous solution, a violent explosion occurs at once. It is very probable that the initial reaction consists in an exothermic union of chlorine with the halogenoid, resulting in the transitory, superficial formation of a chlorine azido-dithiocarbonate in accordance with the equation

Since a rise of temperature of but a few degrees suffices to initiate the explosion of azido-carbondisulfide, however, the reaction does not proceed

far before the reacting mass explodes, yielding the usual products of decomposition of the halogenoid.^{1a}

By passing chlorine gas through an anhydrous solution of azido-carbon-disulfide in chloroform at -15° no evidence of decomposition is obtained, unless the chlorine is introduced in large excess. After the unused chlorine has been removed by means of a current of dry air, the solution is found to have acquired a characteristic pungent odor and a white solid appears after vaporization of the greater part of the solvent. Even at temperatures below -20° this undergoes gradual transformation into a viscous, yellow oil, insoluble in water and in chloroform. The vapor of this oil affects the eyes and, if inhaled, appears to act as a heart depressant. It attacks rubber, causing it to swell. Contact of the oil with the skin causes blistering. At room temperature the oil undergoes rapid decomposition with evolution of gas.

Qualitative tests indicate that the unstable yellow oil may be a chlorine compound of azido-carbondisulfide of the formula ClSCSN_3 . It has not yet been found possible to carry quantitative determinations of the compound to satisfactory completion.

Behavior of Azido-carbondisulfide toward Bromine

Attempts to prepare a bromine azido-dithiocarbonate by interaction of liquid bromine and solid azido-carbondisulfide at ordinary temperatures resulted in violent explosions. Even at temperatures slightly above the melting point of bromine, rapid decomposition was found to take place.

In organic solvents such as ethyl alcohol, acetone, ether, chloroform or carbon tetrachloride, however, the bromine color is immediately discharged by azido-carbondisulfide and no evolution of gas occurs if the solution is kept at a temperature below -5° , unless an excess of bromine is present. Evaporation of the resulting solutions at -10° by means of dry air yields a white, odorless, amorphous product which immediately turns yellow above -5° . The water extract of the white or of the yellow substance was found to contain bromides in considerable amount. The yellow solid, while not explosive, turns brownish in color slowly on standing, and rapidly when heated to 200° .

Because of the fact that solutions of azido-carbondisulfide in organic solvents after treatment with bromine solutions do not liberate iodine from potassium iodide until free bromine is present, it was found possible to titrate such solutions at -10° , using moist starch-potassium iodide paper as an outside indicator. The degree of accuracy obtainable by this method is somewhat lowered by the difficulty of judging the end-point and by the rather rapid deterioration of the bromine solutions.

With carbon tetrachloride and with ether as solvents, such titrations indicate that bromine reacts with the azido-carbondisulfide in equivalent

(1:1) ratio under the prevailing conditions. With other organic solvents varying results were obtained. In chloroform, for example, the results indicate that union takes place in a ratio smaller than 1:1. In ethyl bromide, on the other hand, no reaction at all was observed to occur.

When solutions of bromine in carbon tetrachloride, chloroform or ether were added to a suspension of silver azido-dithiocarbonate in the same liquid at -10° , the color of the bromine was at once discharged and silver bromide was formed. The colorless filtrate, like the solutions obtained by interaction of bromine and azido-carbondisulfide, showed no action upon aqueous solutions of potassium iodide, on treatment with iron filings gave no evidence of the presence of free thiocyanogen and underwent no decomposition with liberation of nitrogen below -5° . Evaporation at -10° yielded as before a white, amorphous solid apparently identical in properties and behavior with that just described.

Hydrolysis of non-aqueous solutions of bromine azido-dithiocarbonate by the action of aqueous alkalis yields solutions of the greenish-yellow color characteristic of similarly hydrolyzed azido-carbondisulfide.^{1a} The presence of both bromine ion and azido-dithiocarbonate ion was readily established. Sulfites and thiosulfates were also demonstrated to be present. The following equations express the reactions believed to occur during hydrolysis of the compound in concentrated solutions of potassium hydroxide.

Determinations of the bromine-sulfur ratio were made upon samples of bromine azido-dithiocarbonate prepared by the interaction of bromine and the silver salt in ether, carbon tetrachloride and chloroform. The results indicate that in ether the formation of a tribromo-azido-dithiocarbonate takes place, while in the other solvents a mixture of a mono-bromo and a tribromo compound is obtained.

From these results it may be inferred that the reaction between bromine and silver azido-dithiocarbonate probably occurs in accordance with either or both of the equations

Owing to the extreme instability of these compounds and their solutions, it has not yet been found possible to accomplish their complete isolation or more exact determinations of their composition.

Behavior of Azido-carbondisulfide toward Iodine

Treatment of solutions of azido-carbondisulfide in carbon tetrachloride, acetone or ethyl alcohol at temperatures between 0° and -10° with dilute

solutions of iodine in these solvents does not result in a discharge of the iodine color. Unlike chlorine and bromine, therefore, iodine does not combine directly with the halogenoid under the specified conditions.

Addition of solid iodine to a concentrated aqueous solution of sodium azido-dithiocarbonate results in the immediate separation of a heavy, black oil.

Iodine reacts at once with silver azido-dithiocarbonate suspended in chloroform with formation of silver iodide. The filtrate is found to contain no iodine, however, unless this reagent has been used in excess. Therefore, no union of iodine with azido-carbondisulfide may be assumed to take place. The reaction of the substances in chloroform appears to follow a course similar to that of the reaction between iodine and sodium azido-dithiocarbonate in aqueous solution, and may be expressed by the equation

Summary

Solid azido-carbondisulfide reacts explosively with chlorine and bromine. In certain non-aqueous solvents more controllable reactions take place, with probable formation of the compounds $ClSCSN_3$ and $BrSCSN_3$. Bromine reacts with silver azido-dithiocarbonate in ether to form a tri-bromo-azido-dithiocarbonate, Br_3SCSN_3 , and in chloroform and carbon tetrachloride to form a mixture of the monobromo and tribromo compounds.

The extreme instability of these compounds precludes their exact analysis and description.

Iodine forms no compound with azido-carbondisulfide under the conditions investigated.

HYDROGEN PEROXIDE FORMATION PHOTSENSITIZED BY MERCURY VAPOR

BY ABRAHAM LINCOLN MARSHALL

RECEIVED AUGUST 17, 1927

PUBLISHED NOVEMBER 5, 1927

This paper represents an effort to clear up some of the uncertain points in the photochemical combination of hydrogen and oxygen when sensitized to λ 2536.7 Å. from a cold mercury arc by means of mercury vapor. In a previous paper¹ this reaction was studied in a static system and the rates of reaction observed at that time were not at all reproducible. It was found, however, that for individual experiments the rate of reaction was best represented by the equation

$$\frac{d}{dt} (H_2O) = K \left(\frac{p_{H_2}}{p_{H_2} + p_{O_2}} \right)$$

¹ Marshall, *J. Phys. Chem.*, **30**, 34 (1926).

It was found that in practically all the experiments the reaction came to an end at a point corresponding within the experimental error to that calculated on the basis of the reaction $\text{H}_2 + \frac{1}{2}\text{O}_2 = \text{H}_2\text{O}$. Also, with gas mixtures of composition $2\text{H}_2 + \text{O}_2$, the rate-time curves were linear over the whole range of the reaction, which stopped abruptly when all the gas had combined. On the basis of this and a previous investigation, it was suggested by Taylor² and Marshall¹ that the reaction involved hydrogen peroxide as an intermediate product, the postulated mechanism being

with subsequent decomposition of the hydrogen peroxide vapor by a variety of processes of which one was undoubtedly the oxidation of mercury vapor.³ That this supposition was correct was shown subsequently by Marshall,⁴ who was able to remove quite large quantities of hydrogen peroxide from the reaction system by the use of a streaming method.

In the light of this result, it seemed that a further study of this reaction might bring to light some fresh factors of interest. In the original investigation liquid mercury was always present in the system and was relied on to keep the concentration of mercury vapor constant. The deposition of mercury on the walls of the reaction chamber altered the amount of light entering the system and the presence of liquid mercury made it impossible to determine the real temperature coefficient of the reaction. In the present investigation the gas mixtures were circulated by means of a glass mercury reciprocating pump (H) at a rate of about 250 liters per hour. The gas was saturated with mercury vapor at a known pressure in the saturator (A) before entering the reaction vessel (C). The temperature of the reaction system was controlled by means of the water-bath (E). Hydrogen peroxide was removed from the gas stream by means of a very efficient gas scrubbing bottle (G). A large reservoir (F) which was kept at constant temperature was introduced into the system to control the rate of pressure change which was measured on the manometer (K) and also reduce fluctuations in the manometer due to the motion of the mercury column in the pump (H), which was continually changing the volume of the system within certain limits.

Design of Arc

The design of the quartz mercury arc used in such an investigation is very important as it is essential to obtain constant illumination. In previous work the author has used the regular vertical type of Cooper-Hewitt lab.-arc, cooling the cathode end to a point about 1 cm., above the

¹ Taylor, *Trans. Faraday Soc.*, 21, 560 (1926).

² Elder and Rideal, *ibid.*, 23, 550 (1927).

⁴ Marshall, *J. Phys. Chem.*, 30, 1078 (1926).

mercury level. This, however, is unsatisfactory as it is almost impossible to keep the mercury pressure in the arc constant. An improved type of arc (B) was used in the present investigation, similar to that described by Taylor.⁵ The electrodes were made *entirely* of tungsten and it was found possible to carry currents up to 25 amperes without any blackening of the quartz walls of the arc. The arc was connected directly to a mercury

Fig. 1.

diffusion pump which was always kept in operation while the arc was running. The cathode end of the arc was immersed in water (D) which was flowing rapidly over the arc structure; the temperature was controlled within 1° by means of an electric heater. In this manner it was possible to vary the temperature over the range $13\text{--}80^\circ$.

Kinetics of Reaction

Table I gives the data for a typical experiment. In subsequent tables the rate will be given for the steady state. It was observed throughout the investigation that during the first five to ten minutes of an experiment

⁵ Taylor, *THIS JOURNAL*, **48**, 2844 (1926).

the rate was gradually accelerating to a constant value characteristic for the conditions under investigation. It was thought that this might be due to temperature changes in the system caused by heating from the arc and to the fact that the arc has to operate for some time before reaching a steady state.

TABLE I
DATA FOR TYPICAL EXPERIMENT

Temperature of Hg in arc, 30°; temperature of reaction chamber, 67°; gas saturated with Hg vapor at 50°; p_{H_2} , 520 mm.; p_{O_2} , 212 mm.; arc current, 15 amps.

Time	Press., mm.	Δp , mm./min.
0	165	
2	186	10.5
4	215	14.5
5	249	17.0
8	282	16.5
10	318	18.0
13	376	19.4
15	415	19.5
17	454	19.5
19	496	21.0
21	541	22.5
23	593	26.0
Finish	608	

The last column gives the rate of pressure change in mm. per minute.

In this experiment 410 cc. of H_2O_2 gas was formed. Since the total pressure change was 443 mm., the amount of hydrogen peroxide formed would correspond to a volume for the apparatus of 1570 cc. The estimated volume was 1500 cc.; no measurement of this was made, however, as the reservoir was destroyed by an explosion before the experiments were completed. It is certain, however, that the main product of the reaction is hydrogen peroxide.

In Table II are given the data for a series of experiments varying the relative concentrations of the two gases. In the last experiment listed the oxygen concentration was very high and the result is somewhat uncertain since the rate gradually decreased with time; quite large quantities of yellow mercuric oxide were formed in the cell and in the tube leading to the scrubbing bottle, which seriously interfered with rate measurements in the later stages of the experiment. In most of the experiments to be described practically no mercuric oxide deposited in the reaction chamber and only small quantities in the tube leading to the absorber. After each experiment, however, the system was washed out with nitric acid and water to remove any oxide formed.

In all the ensuing experiments the reaction was carried on for a sufficient period to ensure a reliable value for the rate. The fourth column gives a measure of the total amount of reaction, from which the duration of the

experiment can be calculated. The fifth column gives the total amount of peroxide formed measured as cc. of gas at 0° and 760 mm. pressure. When the ratio (cc. H₂O₂)/(total pressure change in mm.) falls below 1.10, it indicates that in the later stages of the reaction some of the peroxide initially formed was being decomposed; this always showed in the experiments as a decrease in rate. A value of the ratio of 1.10 corresponds to pure peroxide as the reaction product. The value of the data in these two columns is to indicate the extent to which it is possible to avoid decomposition of the peroxide.

TABLE II

DATA WITH VARYING CONCENTRATIONS OF THE TWO GASES

Gas saturated with mercury vapor at 50°; temperature of reaction chamber, 60°; temperature of mercury in arc, 30°; arc current, 15 amps.

p_{H_2} , mm.	p_{O_2} , mm.	Rate in mm./min	Total press. change	Cc. of H ₂ O ₂ formed	N_{H_2}	Rate/ N_{H_2}
581	237	17 22	443	408	0.79	24.7
740	130	20	236	212	.92	21.7
425	368	12 3	597	326	.58	21.2
146	699	3	106	43	.155	19.9

In Table III the results are given for another series of experiments with an arc current of 1 ampere.

TABLE III

RESULTS WITH ARC CURRENT OF 1 AMPERE

Gas saturated with mercury vapor at 40°; temperature of reaction chamber, 60°; temperature of mercury in arc, 40°; arc current, 1 amp.

p_{H_2} , mm.	p_{O_2} , mm.	Rate in mm./min	Total press. change	Cc. of H ₂ O ₂ formed	N_{H_2}	Rate/ N_{H_2}
581	239	1 52	148	146	0.71	2.14
775	58	2 00			0.93	2.15
781	10	2 1			0.99	2.12
364	475	0 92			0.43	2.14

The constancy of the reaction velocity constants given in the last column of Tables II and III shows that in these experiments the rate of hydrogen peroxide formation is proportional to the mole fraction of hydrogen present.

$$\frac{d}{dt} (H_2O_2) = K \frac{p_{H_2}}{p_{H_2} + p_{O_2}}$$

In the previous investigation¹ using the static system, this same equation was found to hold for the rate of water formation, which seems to indicate that in the previous experiments the rate of decomposition of hydrogen peroxide was of the same order of magnitude as its rate of formation. One of the interesting features of this work is the removal of practically all of the hydrogen peroxide undecomposed.

Variation of Rate with Mercury Concentration

An attempt was next made to study the effect of the various other controllable variables on the rate of the reaction. It was possible to vary the

mercury vapor concentration over a twenty-five fold range and the results obtained are listed in Tables IV and V.

TABLE IV

RESULTS WITH VARIABLE MERCURY VAPOR CONCENTRATION

Temperature of reaction chamber, 65°; temperature of mercury in arc, 30°; arc current, 15–15.5 amps.; p_{H_2} , 580 mm.; p_{O_2} , 250 mm.

Temp. of Hg, saturator, °C.	Rate in mm./min.	Total press. change	Cc. of H_2O_2 formed	p_{H_2} in mm.
19	6.3	436	467	0.0013
31	11.8	414	463	
41	16.0	434	449	.006
50	17–22	443	407	
61	18.6	476	417	.03

A later series of experiments with different operating conditions is given in Table V.

TABLE V

LATER RESULTS WITH VARIABLE MERCURY VAPOR CONCENTRATION

Temperature of reaction chamber, 95°; temperature of mercury in arc, 41°; arc current, 3 amps.

Temp. of Hg saturator, °C.	Rate in mm./min.	Total press. change	Cc. of H_2O_2 formed
19	2.93	293	329
31	5.20	391	421
64	5.47	330	250

It was observed that quite large quantities of mercuric oxide were formed in the experiments with high mercury concentrations and the yield of hydrogen peroxide for a given pressure change was much lower, pointing to a considerable amount of decomposition.

Variation of Rate with Mercury Pressure in Arc

A number of experiments were performed varying the temperature of the mercury in the arc and the results are given in Tables VI and VII.

TABLE VI

RESULTS WITH VARIABLE MERCURY ARC TEMPERATURE

Temperature of reaction chamber, 69°; temperature of mercury saturator, 50°; arc current, 3.1 amps.; p_{H_2} , 580 mm.; p_{O_2} , 250 mm.

Temp. of Hg in arc, °C.	17	40	51	87
Rate in mm./min.	2.5	7.5	7.0	2.0

This was all one experiment; the total pressure change was 443 mm. and 417 cc. of H_2O_2 was formed. The next experiment was made without removing any mercuric oxide formed in the previous one.

Temp. of Hg in arc, °C.	40	11	32	40	52
Rate in mm./min.	6.0	2.2	5.6	6.1	5.7

Total pressure change, 502 mm.; cc. of H_2O_2 formed, 293.

It will be observed that in the experiment with the dirty cell the amount of peroxide decomposed was quite large. It may well be that mercuric oxide plays an important role in this decomposition. In Table VII is listed later series of experiments which were performed under better controlled conditions.

TABLE VII

LATER EXPERIMENTS WITH VARIABLE MERCURY ARC TEMPERATURE

Temperature of mercury saturator, 31°; temperature of reaction chamber, 95°; arc current, 3 amps.

Temp. of Hg in arc, °C.	Rate of mm./min.	Total press. change	Cc. of H ₂ O ₂ formed
13	1.40	199	218
29	3.22	221	246
41	5.20	391	420
49	4.66	396	444
61	3.17	403	469
81	1.76	275	326

This indicates that under these conditions the optimum concentration of mercury vapor for securing the largest amount of resonance light is about 0.01 mm.

Variation of Rate with Arc Current

In the next series of experiments the arc current was varied over as wide limits as possible.

TABLE VIII

RESULTS WITH WIDELY VARIED ARC CURRENT

Temperature of mercury in arc, 52°; temperature of mercury saturator, 50°; temperature of reaction chamber, 70°; p_{H_2} , 580 mm.; p_{O_2} , 250 mm.

Arc current	25	15	10
Rate	18.2	13.3	12.3

Total pressure change, 464 mm.; cc. of H₂O₂ formed, 327.

The data given in this table were collected in a single experiment and are not so reliable as those in the following table but are included to give a complete record of all the experiments carried out.

TABLE IX

RESULTS WITH WIDELY VARIED ARC CURRENT

Temperature of Hg in arc, 42°; temperature of mercury saturator, 31°; temperature of reaction chamber, 95°.

Arc current	Rate	Total press. change	Cc. of H ₂ O ₂ formed
15.5	14.9	337	331
21	20.9	360	371
9.7	11.0	366	395
5	7.75		
3	5.20	391	422

All the data obtained on the variation of rate with arc current are plotted in Fig. 2. It will be observed that in this graph the rate is proportional to

the current up to 6 amps. and then commences to diverge from strict proportionality so that at 21 amps. the rate has fallen to two-thirds of that calculated from the 6 amp. rate. It is quite probable that the amount of resonance radiation given by the arc varies in a similar manner with the current, in which case the reaction rate would be proportional to the first power of the light intensity. Measurements are now in progress to check up quantitatively on this part of the problem.

Fig. 2.

True Temperature Coefficient of Reaction

In the first half of this investigation very little difficulty was experienced in obtaining reproducible results, but towards the end it became more

difficult and the source of the difficulty was never definitely located. For this reason, the experiments on the temperature coefficient are not as reliable as those given above. They are, however, the average results of a large number of experiments and give the temperature coefficient within a factor of a few per cent. In Table X we have the result of a single experiment while Table XI is the average of a large series.

TABLE X
RESULTS OF ONE EXPERIMENT

Temperature of mercury saturator, 30°; temperature of mercury in arc, 40°; arc current, 3 amps.; p_{H_2} , 598 mm.; p_{O_2} , 241 mm.

Temperature of reaction chamber, °C.	Rate in mm./min.	N_{H_2} (average)
96	4.56	0.735
40	3.08	0.783

When these results are calculated for the same mole fraction of hydrogen the temperature coefficient for a 10° rise in temperature comes out as 1.13.

TABLE XI
AVERAGES OF RESULTS

Temperature of mercury saturator, 32°; temperature of mercury in arc, 50°; p_{H_2} , 600 mm.; p_{O_2} , 260 mm.

Temperature of reaction chamber, °C.	Rate in mm./min.	Temperature of reaction chamber, °C.	Rate in mm./min.	
<i>Arc current 15 amps.</i>		<i>Arc current, 5 amps.</i>		
100	12.3	100	4.32	T. C. = 1.044
100	10.6	40	3.3	
100	11.8	100	3.80	
50	9.9	40	3.09	T. C. = 1.038
50	8.8			
100	10.5			
50	9.6			
<i>Averages</i>				
100	11.3			
50	9.4			

From this last series of measurements, it appears that the temperature coefficient is about 1.04. This is the order of magnitude usually found for a true photochemical reaction and if correct seems to indicate that the amount of energy absorbed by the system from the arc is independent of temperature.

Summary

1. The kinetics of the photochemical reaction between hydrogen and oxygen when sensitized by mercury vapor is given by the equation

$$\frac{d}{dt} (H_2O_2) = K \frac{p_{H_2}}{p_{H_2} + p_{O_2}}$$

2. The optimum concentration of mercury vapor for the reaction is about 0.005 mm.; while higher concentrations give a greater rate of re-

action, this is offset by decomposition of the hydrogen peroxide initially formed.

3. The mercury vapor lamp gives the most resonance radiation (λ 2536.7 Å.) with a mercury pressure of about 0.01 mm.

4. The rate of reaction is roughly proportional to the arc current, suggesting that the rate varies as the first power of the light intensity.

5. The temperature coefficient of the reaction is 1.04.

6. The product of reaction is predominantly hydrogen peroxide, the maximum rate of formation observed being two grams per hour.

THE SYSTEM $\text{MgSO}_4\text{-H}_2\text{O}$ FROM 68 TO 240°¹

BY HOMER LOUIS ROBSON

RECEIVED AUGUST 18, 1927

PUBLISHED NOVEMBER 5, 1927

Five hydrates of magnesium sulfate may exist in contact with aqueous solutions of the salt near their boiling points. These are the monoclinic or ordinary hexahydrate, the penta-, tetra-, five-fourths and monohydrates.² Of these, the hexahydrate is the stable phase from 48.4° to 68° and may be followed up to 100°. The transition point of the hexahydrate to the monohydrate was found by Van't Hoff, Meyerhoffer and Smith⁴ to be 68°, and the monohydrate is the stable phase from this temperature up to 240°. They also found the transition of the hexahydrate into the five-fourths hydrate to lie between 68 and 72°⁶ and that of the pentahydrate into the tetrahydrate to lie close to 77.5°. The transition

¹ Part of a thesis submitted to the Faculty of the Graduate Division of the University of California in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

² Other hydrates of magnesium sulfate are the dodecahydrate prepared by Fritsche (a) (Fritsche, *Pogg. Ann.*, **42**, 577 (1842), see also observations by F. G. Cottrell, mentioned by Van't Hoff, Meyerhoffer and Smith, *Sitzb. preuss. Akad. Wiss.*, **1901**, 1035), the rhombic heptahydrate or epsom salt (b) (for properties see E. S. Larsen, "The Microscopic Identification of the Non-Opaque Minerals," Bulletin 679, U. S. Geol. Survey, 1921, and Groth, "Chemische Krystallographie," Part 2, **1908**, p. 429), the tetragonal hexahydrate prepared by L. de Boisbaudran (c) (de Boisbaudran, *Ann. chim. phys.*, (4) **18**, 260 (1869)), the monoclinic heptahydrate prepared by Loewel (d) (Loewel, *Ann. chim. phys.*, (3) **43**, 405 (1855); Groth, ref. 2 b, p. 431), and the dihydrate.

³ Carpenter and Jette, *THIS JOURNAL*, **45**, 578 (1923). The rhombic heptahydrate is the stable phase below this temperature.

⁴ Van't Hoff, Meyerhoffer and Smith, *Sitzb. preuss. Akad. Wiss.*, **1901**, 1034.

⁵ The nearness of this point to that found for the hexahydrate—monohydrate transition caused them to doubt the identity of the five-fourths hydrate (ref. 4, footnote to page 1037).

point of the hexahydrate into the pentahydrate was found by T. Estreicher-Rozbiersky to be 77.5° .^{4,6}

The transition of the tetrahydrate into the hexahydrate occurs fairly rapidly. A mixture of the tetrahydrate and a solution saturated with respect to it was cooled one degree per hour while being stirred; at 77° lumps which were found to contain the hexahydrate formed in the mixture. The hexahydrate may form alone if the solution is slowly evaporated at its boiling point. If the evaporation is rapid, or if the solution is agitated, the penta- and tetrahydrates form along with the hexahydrate. The tetrahydrate is the more stable of the three and solutions in equilibrium with it may be stirred for several days at 100° without the formation of lower hydrates. The five-fourths, and possibly the monohydrate also, may be induced to form by violent boiling or by inoculation from crusts formed on the sides of the vessel during evaporation. The solution comes to equilibrium with these slowly.

Preparation of Hydrates

Crystals of the penta- and tetrahydrates were first obtained by Wyruboff⁷ by evaporation of a solution of magnesium sulfate acidified with sulfuric acid at 50° . They have also been obtained by Van't Hoff and Estreicher-Rozbiersky⁸ by the evaporation of solutions of magnesium sulfate containing magnesium chloride at 25° . Playfair⁹ and Thorpe and Watts¹⁰ claimed to have prepared the pentahydrate by drying the heptahydrate to constant weight over sulfuric acid and, according to Millon,¹¹ the pentahydrate may be prepared by heating the heptahydrate to 40° in moist air.

Van't Hoff and Dawson¹² found that above 40° the tetrahydrate was replaced by the dihydrate when in contact with solutions of magnesium sulfate also saturated with respect to $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$. This hydrate was unstable and at 65° was replaced by the five-fourths hydrate, which apparently was the stable phase in these solutions down to 20° . Both the

⁴ Wiedemann, *Pogg. Ann.*, 17, 571 (1882), from dilatometric observations, concluded that there were two forms of the hexahydrate with a transition point under 92° . To test this, solutions in equilibrium with the monoclinic hexahydrate at 95° and containing a very little of the solid in suspension were inoculated with crystals of tetragonal nickel sulfate hexahydrate, which L. de Boisbaudran²⁰ had found to be isomorphous with tetragonal magnesium sulfate hexahydrate. This did not cause the formation of a tetragonal (optically uniaxial) hydrate of magnesium sulfate, so that it does not seem probable that the tetragonal hexahydrate is formed at this temperature. No other hexahydrate of magnesium sulfate is known. Van't Hoff, Meyerhoffer and Smith⁴ suggest that he observed the change of the pentahydrate to the tetrahydrate.

¹² Van't Hoff and Dawson, *Sitzb. preuss. Akad. Wiss.*, 1899, 340.

dihydrate and the five-fourths hydrate are unstable with respect to the monohydrate above about 25° ¹³ in contact with solid $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, but the monohydrate ordinarily does not form spontaneously under 75 – 85° .

Playfair,⁹ Hannay¹⁴ and Millon¹⁵ observed that the dihydrate was formed on drying the heptahydrate in air at 100° . Hannay stated that his data favored the existence of a trihydrate but an examination of his curves does not warrant this. Millon obtained evidence in favor of a hydrate intermediate between the di- and monohydrates at 115° and this was confirmed by Van't Hoff and Dawson,¹² who found that the rate of water loss drops to one-tenth after the composition $\text{MgSO}_4 \cdot 5/4\text{H}_2\text{O}$ has been reached. The dihydrate is best prepared in this way by allowing crystals of the heptahydrate to effloresce in air at 50 – 60° and then heating the powder at 100° for two hours. The product was found to contain crystals of the tetrahydrate and some monohydrate as a very fine powder. After drying in an oven at 95° for one day, the moisture content of a 3 mm. layer of the salt was found to be 17.5%, after two days, 15.6% and after three days 14.4%, showing a slowing up at the composition of the five-fourths hydrate, which has 15.7% of water. The dehydration can be continued to the monohydrate at this temperature. If the crystals of the heptahydrate are allowed to melt and then dried at 100° , a cake is formed containing the monohydrate.

Playfair⁹ prepared the dihydrate by the action of boiling absolute alcohol on the heptahydrate. This is not a satisfactory method for the preparation of this salt. The heptahydrate is rapidly converted into the tetrahydrate by this treatment. If the tetrahydrate is boiled with three to four times its weight of absolute alcohol for twelve hours, most of it is converted into the dihydrate, but considerable five-fourths hydrate and finely divided monohydrate are formed with it. On further boiling the dihydrate and five-fourths hydrate may be converted into the monohydrate.

The monohydrate occurs in nature and is called kieserite. It may be prepared by heating the higher hydrates to 140 – 180° for several days.^{9,10} Kieserite loses its water slowly at 250° and rapidly at 350° . Water may be determined readily by heating to 500° in an open crucible. The decomposition of anhydrous magnesium sulfate was found to be inappreciable at 750° but rapid above 850° .¹⁶

¹³ Van't Hoff and Meyerhoffer, *Sitzb. preuss. Akad. Wiss.*, 1904, 1418, inferred that the monohydrate was formed in contact with $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ above 18° but did not actually determine the transition point. Their conclusion was not confirmed by W. C. Blasdale, *J. Ind. Eng. Chem.*, 12, 164 (1920), who found that the monohydrate was apparently unstable at 25° .

¹⁴ Hannay, *J. Chem. Soc.*, (2) 32, 381 (1877).

¹⁵ Millon, ref. 11. He also states that the dihydrate may be prepared by keeping the heptahydrate in contact with very dry air at 35° for one month. The product probably contains considerable monohydrate.

¹⁶ Cf. Marchali, *J. chim. phys.*, 22, 325 (1925).

Solubility Relations

A search was made for the solubility curve of the dihydrate between 70° and the boiling point, but it was not found. Solutions in equilibrium with the hexahydrate or tetrahydrate slowly came to equilibrium with the monohydrate when inoculated with preparations of the dihydrate, most of which had close to the theoretical water content, but contained some monohydrate.

The curve of the five-fourths hydrate was not determined, but from similar experiments it would appear to lie very slightly above the curve for the monohydrate at 95°.

Wyruboff¹⁷ observed that the solubility curves of the penta- and tetrahydrates were close together in sulfuric acid solutions at 50°. They are

Fig. 1.—The system $\text{MgSO}_4\text{-H}_2\text{O}$ from 68 to 240°.

apparently close together in aqueous solutions at 100°. Both hydrates are formed in the boiling solution but on stirring at 95° the pentahydrate slowly disappears and the solubility drops slightly, from which it is assumed that the pentahydrate curve lies slightly above that of the tetrahydrate, as indicated in Fig. 1.

Geiger¹⁸ gave for the solubility at 83°, 67.2 g. of MgSO_4 per 100 g. of water, but the solid phase present with his solutions was probably the hexahydrate. Smith¹⁸ gave the concentration of a solution in equilibrium with kieserite at 80° as 62.8 g. of MgSO_4 per 100 g. of water and Meyerhoffer¹⁸ obtained 68.5 at 99.4°. These points fall on the tetrahydrate curve as determined in this investigation, so that the solid phase was probably the tetrahydrate and not kieserite. Mayeda¹⁹ gave 51.2 g. per 100 g. of water at 105°, a value slightly above the curve for the mono-

¹⁷ Ref. 7, p. 369.

¹⁸ From Landolt-Bornstein Tabellen, 1923 ed.

¹⁹ Mayeda, *J. Chem. Ind. (Japan)*, 23, 573 (1920).

hydrate given in this paper. Étard²⁰ gave for the solubility of magnesium sulfate the following values.

Temperature, °C.	130	145	164	188
Per cent. MgSO ₄ , liquid phase	45.3	38.0	29.3	20.4
G. of MgSO ₄ per 100 g. of water (calcd.)	82.8	61.3	41.4	25.6

Étard enclosed his solutions in sealed tubes divided into two equal chambers by a constriction in the middle. The salt and solution were placed in one chamber and the tube was sealed off; the tube was then placed in a thermostat and after shaking a few times the liquid phase was poured into the empty chamber through the constriction, which acted as a filter. The tube was then cooled and the contents analyzed. He does not state the time given for the solutions to come to equilibrium. Suspensions of kieserite in solutions in equilibrium with it require several hours or even days to settle and Étard's liquid phase probably contained some finely divided kieserite. The salt may be more granular when formed from a supersaturated solution with comparatively little agitation.

Étard's results may give the composition of solutions on the supersolubility curve of kieserite. On this assumption, solutions lying below the curve could be agitated without depositing the salt, while those above it would deposit kieserite by spontaneous crystallization upon agitation.²¹

The data given in the following table are in agreement with this interpretation of Étard's data.

TABLE I

Temp., °C.	Hours stirred	Liquid phase ^a Before stirring	After stirring	Salt formed	Remarks
154	4	37	same	none	below Étard's curve
154	1½	47	same	none	below Étard's curve
192	1	12	same	none	below Étard's curve
155	1½	57	37	kieserite	above Étard's curve
155	1½	58	32	kieserite	above Étard's curve
195	3	24	4.6	kieserite	above Étard's curve

^a Liquid phase given in g. of MgSO₄ per 100 g. of water.

The trials in this table were not inoculated with kieserite. They are represented by circles in Fig. 1, while Étard's measurements are represented by crosses. Étard observed that a solution containing 33.3 g. of magnesium sulfate per 100 g. of water crystallized spontaneously at 180°.

When a solution exceeds the supersolubility curve, crystallization occurs spontaneously upon agitation, with the formation of many very small crystals. As the crystal surface exposed by these very fine crystals is large, the formation of a small quantity of them would be expected to be

²⁰ Étard, *Ann. chim. phys.*, (7) 2, 503 (1894).

²¹ Blasdale, "Equilibria in Saturated Salt Solutions," A. C. S. Monograph Series, No. 31, 1927, p. 66.

more effective in reducing the supersaturation of the solution than the presence of several times as much of the salt in a coarser crystalline form. Trials which became inoculated through exceeding the supersolubility curve came to equilibrium more rapidly than those which were inoculated with 5 or 10% of kieserite by weight.

The solubility curve of kieserite is given by Landolt-Börnstein, 1923 ed., as passing through the values given by Smith and Meyerhoffer and the last two values given by Étard.

Identification of Hydrates

The hydrates of magnesium sulfate occurring near the boiling point may be identified with the aid of the petrographic microscope. After a portion of the liquid phase had been taken for analysis, the suspended hydrates were allowed to settle for a few minutes and a small quantity was removed with a glass or perforated platinum spoon. When the hexahydrate, pentahydrate or tetrahydrate was present, this was rubbed dry on warmed filter paper or pressed on a porous plate warmed to 80°. These hydrates are partially decomposed by pressing dry on a porous plate warmed to 100°, which treatment was required to dry the monohydrate. Some hexahydrate formed by cooling of the adhering liquor while pressing the solids dry between filter paper. The absorbent cotton rolls used by dentists were found of value in drying the samples. Some of the samples were washed with alcohol, but this is objectionable as the addition of absolute alcohol to a saturated solution of magnesium sulfate at 80–90° usually precipitates some tetrahydrate.

The optical properties of the hydrates are given in the following table.²²

TABLE II

THE OPTICAL PROPERTIES OF THE HYDRATES

Hydrate	α	β	γ	2V sign disp.	Orientation	System
Hexa-	1.438	1.463	1.465	29° - $\rho > v$	$Y = b, X \wedge c - 25^\circ$	Monoclinic
Penta-	1.482	1.492	1.493	45° - $\rho < v$	X near b	Triclinic
Tetra-	1.490	1.491	1.497	50° + $\rho > v$	$Z = b, X \wedge c 81^\circ$	Monoclinic
Di-		1.493	radiate clusters of very fine needles			
Five-fourths	1.512	1.530	indices of diamond-shaped crystals			
Mono-	1.523	1.535	1.586	57° + $\rho > v$	$Y = b, Z \wedge c 76\frac{1}{2}^\circ$	Monoclinic

The monoclinic hexahydrate may be recognized by its indices of refraction and small optic angle. The penta- and tetrahydrates may be distinguished by their difference in sign. When prepared from solutions containing magnesium chloride, the tetrahydrate appears in six-sided

²² The nomenclature is that employed by Larsen, ref. 2 b. The optical orientation of the hexa-, penta- and tetrahydrates, with their optic angles and dispersion, is given by Wyrouboff, ref. 7. The indices of refraction given in this table are probably accurate to ± 0.003 . The optical properties of the monohydrate are given by Larsen, ref. 2 b, p. 211.

plates, showing the forms $m(110)$ and $b(010)$.²³ The angle $m \wedge m$ is $48^\circ 40'$ and frequently this angle may be measured to within 1° under the microscope. No dome or pyramid faces were observed. Cleavage was observed parallel to $a(100)$ and $b(010)$. The pentahydrate and hexahydrate are elongated in the direction of the c axis, and do not show cleavage. Crushed fragments of the three hydrates look very similar when placed between crossed nicols with parallel light.

The needles of the dihydrate show varying extinction angles and elongation and were too fine for the observation of their optical properties. Single crystals of the five-fourths hydrate were not observed. The

Fig. 2.—The system $\text{MgSO}_4 \cdot \text{H}_2\text{O}$ from 160 to 240° .

diamond-shaped crystals show crossed twinning, with the opposite quadrants extinguishing at 5° to the symmetry plane of the diamond. The twinning is often imperfect.

In all the trials except those above 200° kieserite occurred in aggregates of very small grains, which were too small for the observation of crystal structure or optical character. It may be recognized by its high index of refraction and fine-grained structure. Solutions inoculated with preparations of kieserite and al-

lowed to come to equilibrium with it had minimum contents of magnesium sulfate. After trials at 226° , 240° and 246° had been sampled, the valve of the solubility bomb (see below) was left open until all of the liquid phase had passed out. The bomb was then quickly opened and the solid phase found to be granular and quite dry. On analysis it gave 1.00, 0.99 and 0.98 molecules of water per molecule of magnesium sulfate, respectively. Some of the grains were large enough so that interference figures could be obtained. As there is no break in the solubility curve, this was taken as evidence that the solid phase present in the trials between 100° and 240° and which fell on the "monohydrate" curve was in reality the monohydrate.

Description of Apparatus

In the experiments under 100° , the solutions in contact with the solid phase were stirred in 4×30 cm. tubes immersed in an oil-bath kept constant to within half a degree. The tube was closed off with a rubber stopper where it projected above the level of the

²³ Indices assigned by Groth, ref. 2 b, p. 413.

oil, the stirring screw coming through a glass tubing which passed through this stopper. After sufficient stirring, about 30 g. of the solution was filtered through a dried alundum thimble²⁴ into a weight pipet and analyzed.

The trials above 100° were made with a gold-plated bomb of Monel metal, shown in Fig. 3. This consisted of a cylindrical vessel A, 9 cm. long by 3.25 cm. inside diameter, and a head-piece B which carried the filtering apparatus and the needle valve. The upper part of the cylinder was 4 cm. in diameter and was threaded to receive the head, which screwed into it against a flat gold washer C resting on a 3mm. shoulder. The gold washer was $\frac{1}{60}$ inch thick and the volume of the cylinder up to the shoulder was 70 cc. This arrangement gave a joint that was satisfactory for the pressures encountered up to 240° but which did not hold well at higher temperatures.

The head was hollowed out to a depth of 1 cm. to give a flat surface 3.5 cm. in diameter, and the filtering apparatus was mounted in this recession. This consisted of an alundum disk D, $1 \times \frac{1}{8}$ inche, with a beveled edge, the composition being given by the Norton Co. as RA98. This was held against the flat surface of the head by four prongs attached to an expansion ring E. Under the alundum disk was an asbestos pad, then a flat gold washer F which was 3 cm. in diameter and $\frac{1}{100}$ inch thick, with a 6mm. hole in the center. Under this washer was another asbestos pad. The asbestos pads were prepared by suspending carefully selected, long fiber asbestos in water and then slowly evaporating off the water. They could be compressed to a thickness of $\frac{1}{600}$ of an inch.

The hole in the washer gave an empty space of negligible volume directly over the needle valve G. After the salt and water mixture had been stirred the required length of time, the bomb was removed from the bath and clamped head downwards. When the needle valve was opened, the liquid phase was forced through the alundum disk into the valve chamber under its own vapor pressure and through

an opening in the side of this chamber into the delivery tube J. The delivery tube was a short piece of $\frac{1}{8}$ -inch copper tubing attached to a brass piece which screwed into the opening in the head. While the bomb was in the oil-bath, the opening was closed with a plug H. The delivery tube was connected to the condenser, which was a U-shaped copper tube $\frac{3}{4}$ inch in diameter and two feet long, weighing 125 g. During sampling this was partially immersed in ice water. The end not connected to the delivery tube was open to the atmosphere. No water vapor was observed to come out of this end.

After about 30 g. of liquid had been drawn off, the valve was closed and the contents of the condenser analyzed. With trials run above 160° this quantity of liquid was obtained in about thirty seconds, depending upon the amount of solid salt inside the

Fig. 3.—Solubility bomb.

²⁴ The thimbles were supplied by the Norton Company. Those most satisfactory were of mix RA98. The solutions filtered through thimbles of this composition rapidly, carrying a negligible quantity of kieserite into the sample where it was present in the tubes. Thimbles of composition RA225 gave clear solutions, but the liquid phase passed through them very slowly.

bomb. At lower temperatures a longer time was required, the trial at 126° taking two and one-half minutes. The time taken for the liquid phase to pass the filter did not seem to affect the results.

The bomb had an outer brass shell to prevent rapid loss of heat after it had been taken from the bath. After charging, the bomb was fastened to a stirring device and rotated at 60 r.p.m. in a bath of meprolene kept at constant temperature within half a degree. The bath was thoroughly stirred and the temperature taken with two calibrated thermometers. When stirred a sufficient length of time, the bomb was taken from the bath, clamped to a stand, the delivery tube and condenser were attached and the valve was opened, this taking about one minute. From preliminary experiments with ice it was estimated that the contents of the bomb were within one degree of the temperature of the bath after twenty-five minutes of stirring.

This apparatus was designed to measure equilibrium in ternary salt-water systems, but with most of the salt solutions experimented with crystals formed in the valve chamber during sampling. With magnesium sulfate, the negative slope of the solubility curve with temperature, and its tendency to supersaturate, prevented error from this source.

An attempt was made to employ a filter outside the bomb. This consisted of a male brass piece which screwed into the opening in the head of the bomb, and also into a 1" brass sleeve, which was closed at one end except for an eighth-inch delivery tube going to the condenser as in other experiments. An alundum disk was placed between two lead washers in the sleeve and the male piece screwed tightly against the outer washer. On opening the valve, the liquid was forced out through the valve chamber and the alundum disc into the discharge tube and so to the condenser.

This arrangement was unsatisfactory, chiefly because the liquid phase cooled after passing through the needle valve, due to the release of pressure and consequent evaporation, and so was filtered from any solid salt it carried along with it at a lower temperature than it had before leaving the bomb. With kieserite the solubility increased with falling temperature and this apparatus gave high results. As there is a drop in pressure across the filter, any filter which the liquid phase might pass after leaving the needle valve would become cooled by the evaporation of some of the water and so introduce an error. To avoid this the filter must be placed inside the bomb.

Results

Solutions came to equilibrium with the hexahydrate in a few minutes, and to equilibrium with the penta- and tetrahydrates fairly rapidly. Three to seven days were required for solutions to come to equilibrium with kieserite under 100° , unless an abundance of solid phase was present. Equilibrium was not obtained in less than twenty-four hours' stirring under 160° nor with less than four hours' stirring under 190° , but was obtained after stirring for one-half hour at 238° . Many trials, well inoculated, which were stirred for shorter periods gave high results.

There appears to be a relation between the degree of crystallographic perfection exhibited by a salt and the rapidity with which it comes to equilibrium with its aqueous solution. Thus kieserite is poorly crystallized under 200° and comes to equilibrium slowly. Above this temperature it is granular and comes to equilibrium rapidly. The dihydrate would be expected to come to equilibrium slowly. Salts such as sodium chloride, potassium chloride and potassium sulfate, which are well crystallized, formed crystals in the valve chamber in experiments at 150° even when no delivery tube was employed, while sodium sulfate and sodium carbonate, which are less well crystallized, could be filtered with the external filter, but the solutions altered in composition in passing through the apparatus.

The trials made with the bomb fall on a definite line, as may be seen from Fig. 2, in which the values from 160 to 240° are plotted on a larger scale. All the trials which fulfilled the requirements of adequate inoculation, duration of stirring and proper filtering fell within one degree of this curve. The samples were analyzed by precipitating an aliquot part with barium chloride, the method being accurate to 0.1% by trials against pure sodium sulfate.

Table III gives the results of experiments which are considered satisfactory. Three values of Mulder¹⁸ and those of Smith and Meyerhoffer previously mentioned are included. The values are plotted in Fig. 1.

In conclusion, the author wishes to express his thanks to Professor W. C. Blasdale for his valuable assistance during this research.

Summary

1. An apparatus has been described with which solubility determinations have been made up to 240° , with magnesium sulfate monohydrate as the solid phase.

2. The solubility curve of magnesium sulfate monohydrate was found to fall off rapidly with increase of temperature from 68 to 200° , and then to decrease slowly at least to 238° . Equilibrium was obtained very slowly under 200° and more rapidly above that temperature.

3. It has been suggested that the solubility measurements of Étard on this salt give the position of the supersolubility curve, and observations in agreement with this have been tabulated.

4. The solubility curves of magnesium sulfate hexa-, penta- and tetra-hydrate have been studied at 85, 95 and 100°.

5. The preparation of the hexa-, penta-, tetra-, di-, five-fourths and monohydrates of magnesium sulfate has been discussed, together with their identification with the aid of the petrographic microscope, and new optical data for the hexa-, penta, tetra-, di- and five-fourths hydrates have been given.

6. It has been suggested that there is a relation between the degree of crystallographic perfection exhibited by a salt and the rate at which it comes to equilibrium with its aqueous solution.

THE CATALYTIC ACTIVITY AND ADSORPTIVE POWER OF SUPPORTED IRON, COBALT, NICKEL, COPPER AND SILVER

BY ROBERT N. PEASE AND LELAND STEWART

RECEIVED AUGUST 20, 1927

PUBLISHED NOVEMBER 5, 1927

This paper records the results of experiments on the activities of similarly prepared, supported iron, cobalt, nickel, copper and silver catalysts in the hydrogenation of ethylene. The experiments were undertaken with the view to determine the true relative activities of these metals as hydrogenation catalysts and to obtaining preliminary results on reaction kinetics.

The specific activity of a contact catalyst depends ultimately on its chemical nature. In addition, however, the catalytic effect as experimentally determined is conditioned by the area of surface exposed per unit volume of reactants and by its submicroscopic form, and these vary from one sample to the next. If a comparison of two substances as catalysts is desired, therefore, some standardization relative to surface characteristics is required. Bulk catalysts are out of the question, because the utmost care in preparation cannot ensure similarity of surface. Supported catalysts are of greater promise. The surface of a porous refractory will not change with any ordinary treatment and a film of the substance to be examined spread over the surface should assume the form of the latter. Consequently, if the catalysts to be compared are supported on average samples of the same refractory material, it may fairly be assumed that differences in activity are chiefly due to the specific properties of the substances under investigation.

We have prepared a uniform supply of crushed diatomite brick and have impregnated samples with such quantities of solutions of the nitrates of the metals as would correspond to 1 gram atom of metal per 1000 g. of dry brick. These samples were then dried slowly, calcined and reduced. The amount of the metal is admittedly arbitrary. It is approximately

that (10%) commonly used in preparing supported catalysts. We cannot say how thick a film it corresponds to, but we do know that the brick was not encrusted and appeared different only in color after treatment.

Preparation of Catalysts

The catalysts were all prepared in the same manner except for the final temperature of reduction. Non-Pareil porous, diatomite brick (kindly furnished by the Armstrong Cork Co.) was broken up and screened to 5-10 mesh. The granules were boiled in 15% nitric acid, washed repeatedly with distilled water and finally dried at a low red heat. Twenty g. (about 70 cc. apparent volume) was used for each catalyst. This was weighed out and placed in a small flask. It was found that such a sample would absorb nearly its own weight of water without becoming definitely wet. Solutions of the nitrates of the metals were accordingly made up to contain the requisite quantity of metal (corresponding to 1 gram atom per 1000 g. of brick) in 15 cc. of solution. This amount of solution was then placed in a dropping funnel and allowed to flow drop by drop onto the brick granules while the latter were agitated. The granules were then transferred to a section of large (2 inch) glass tubing and warm, dry air was slowly drawn over them. The tube was occasionally turned. The catalyst was then transferred to the catalyst bulb, which was sealed to the apparatus. The catalyst was then further heated gradually to 350-400° in a stream of air to calcine it and was finally reduced in hydrogen. Temperatures of reduction were: iron, 450°; cobalt, 370°; nickel, 300° (to 420° at end); copper, 200°; silver, 150° (to 250° at end). In no case was there evidence of a loss of metal from the support at any point in the procedure.

The nitrates were all c. p., those of cobalt and nickel being sold as nickel-free and cobalt-free, respectively.

The apparatus, method and preparation of gases were the same as those used in earlier work on this reaction.¹ The apparatus consisted of a catalyst bulb, manometer, gas buret, Töpler pump and gas reservoirs, all sealed together through suitable stop-cocks. Reaction rates were measured by the pressure decrease at constant volume. Adsorptions were obtained by comparing isotherms with that of helium.

Results

Our measurements are summarized in the following tables. Initial rates of reaction, obtained by extrapolation, are compared with initial partial pressures. Determinations were made at such temperatures as would give appreciable rates. In the case of nickel and cobalt, the rates were immeasurably high even at 20°, so that no quantitative data were obtained. Reaction was practically complete in the time (a few seconds) taken to admit the gases. We can only say that these substances are of another order of activity than any of the others.

The data on copper are taken from the work of Dr. C. A. Harris.²

The results indicate that supported iron and silver are considerably better catalysts and supported copper is a somewhat poorer catalyst than the average corresponding unsupported materials. Schmidt,³ for example, finds unsupported iron, prepared from the hydroxide, only moderately

Silver	C ₂ H ₄	100	0.10	1.15

active at 100°. Copper prepared from the carbonate is considerably more active than the iron, and silver has a very low and variable activity. Likewise Sabatier⁴ finds unsupported iron active only above 180°. The same is reported of copper but the authors have regularly employed copper in several forms at 0°. Silver is not even mentioned. Our supported iron catalyst is active at 0°, the copper at 50° and the silver at 100°.

We interpret these results to mean that the advantage of using a support is to lend stability where this is needed. The high temperatures (400–500°) required to reduce iron oxide promote deactivation by sintering, while the extreme softness of silver renders it especially susceptible in this regard. Copper, on the other hand, can be reduced at low temperatures and is only

⁴ Sabatier, Reid, "Catalysis in Organic Chemistry," D. Van Nostrand Company, New York, 1923, p. 180.

moderately soft, so that a support is of no particular advantage. The fact that supported copper is actually less active than unsupported material is doubtless due to a smaller surface exposure. This is borne out by the uniformly low hydrogen adsorptions on all samples, even nickel adsorbing only 2.85 cc. at 1 atmosphere.

The adsorption of hydrogen by nickel and cobalt being considerably greater than by the other metals correlates with the high catalytic activity of the former. Adsorption of hydrogen by iron, copper and silver is small and probably the same within experimental error. Iron stands out with respect to ethylene adsorption and it is this apparently which places it above copper in catalytic activity.

As to reaction kinetics, the rate in the presence of silver at 100° is closely proportional to the hydrogen concentration and independent of the ethylene as was found for copper¹ at this temperature. Owing to the deactivation of the iron catalyst with use, the kinetics at 0° are not entirely clear. Excess of hydrogen undoubtedly increases the rate. The influence of ethylene is not great, but it is uncertain whether it is positive or negative. The kinetics in presence of copper are thoroughly treated in another paper.¹

The temperature coefficients give for the heats of activation, 6200 cal. in the case of iron between 0 and 20°, 13,200 cal. in the case of copper between 0 and 100°¹ and 9800 cal. in the case of silver between 50 and 100°.

These comparative results serve anew to emphasize the marked superiority of nickel and cobalt as hydrogenation catalysts over their neighbors, iron and copper, in the periodic table. Reference to Sabatier,⁴ reveals that the corresponding members of the two succeeding long periods stand in like relation. Thus, palladium and rhodium are considerably more active than ruthenium and silver and the same holds for platinum and presumably iridium, as compared with osmium and gold.

It is probably not without significance in catalytic theory that these highly active metals are those whose ions in solution enter into so great a variety of stable complexes. The tendency to form the latter seems to be traceable to electron sharing. Schmidt⁵ would have it that the function of the metal in catalytic hydrogenation is to provide a medium wherein hydrogen may become ionized. Without accepting in full the somewhat elaborate analysis of this investigator, one can readily agree that the electron systems of hydrogen and the substance hydrogenated are profoundly disturbed when they come in contact with the metal. It would be difficult to show that complete ionization actually takes place. The important point is, perhaps, that the associative property of the metal brings the reactants together, and the metal, by its tendency to share electrons, renders both labile, whereupon they may settle down into a system characterized by lower free energy.

¹ Ref. 3, p. 193.

Summary

1. Supported catalysts of iron, cobalt, nickel, copper and silver have been prepared by as nearly similar methods as possible and their activity in the hydrogenation of ethylene has been determined. Cobalt and nickel caused instantaneous action at -20° , iron was moderately active at 0° , copper at 50° and silver at 100° . The effect of the support appears to be to increase the effectiveness of all but copper. This is discussed.

2. Adsorption measurements show much more hydrogen adsorbed by nickel and cobalt than by the other metals, and more ethylene is adsorbed by iron.

3. Reaction kinetics in the presence of silver at 100° show that the rate is proportional to the hydrogen and independent of the ethylene concentration, as was found for copper. In the presence of iron at 0° , excess of hydrogen increases the rate while excess of ethylene exerts little influence.

4. Attention is called to the periodicity among the metals in catalytic properties and the correlation with complex ion formation. An association rather than a dissociation theory of catalytic hydrogenation is indicated.

A SIMPLE TYPE OF FLOWING JUNCTION

BY E. J. ROBERTS AND F. FENWICK

RECEIVED AUGUST 24, 1927

PUBLISHED NOVEMBER 5, 1927

In connection with a study of the relation of the potential of an antimony electrode in contact with a solution saturated with antimony trioxide to the acidity of that solution, the problem of obtaining a reproducible liquid junction potential between the antimony electrode and the reference electrode (Ag, AgCl, 3.5 *M* KCl) became of prime importance. The electrode vessels used were modifications of the type described by Brönsted,¹ in which the solution flows slowly down through a deep layer of the saturating substance, past the electrode proper, to the junction; therefore, a flowing junction device requiring only small volumes of electrolyte and possessing an easy flexibility of adjustment to solutions of widely varying density was highly desirable. None of the arrangements previously described² meet these requirements. It was found, however, that by interposition of a thin mica plate vertically between the ends of the pair of horizontal exit tubes from the electrodes so that the streaming electrolytes flow slowly down opposite faces of the plate past a small hole, through which alone the solutions make contact, the resulting junction is satisfactory in all respects.

¹ Brönsted, *Kgl. Danske Videnskab. Selskab, Math.-fys. Medd.*, 3, No. 9 (1920).

² Lamb and Larson, *THIS JOURNAL*, 42, 229 (1920); (b) MacInnes and Yeh, *ibid.*, 43, 2563 (1921); (c) Scatchard, *ibid.*, 47, 696 (1925).

A diagram of the arrangement of the electrodes and of the mica plate is presented in the figure, which also illustrates the shape of plate finally adopted. *M* is the type of electrode vessel developed for the calomel electrode as a simply made, convenient form for use with a flowing junction. *S* is the type of vessel employed either for the silver-silver chloride electrode used in testing the reliability and value of this type of junction, or for the antimony-antimony trioxide electrode to be discussed in a later paper;

Fig. 1.—Arrangement of apparatus and detail of mica plate for liquid junction.

its length above the upper stopcocks is about 20 cm., the capacity of the bulb being 25–50 cc. The lower end of each vessel is bent horizontally, tapered, if necessary, to an internal diameter of 2–3 mm. and paraffined near the tip to obviate creeping of the liquid. These tips slip into side tubes in a glass tube *H* and are adjusted so that the issuing drops of liquid touch the mica plate *P*, conveniently held in a gash in a rubber stopper in *H*. The detail drawing of the plate shows its construction. A hole about 1 mm. in diameter is drilled in a thin strip of mica (about 1.5 by 7 cm.) by means of a glass-rod drill, working from both sides of the plate so that the edges are as smooth as possible; it is placed about 5 mm. below the exit tubes of the electrodes. The lower edge of the plate is notched and the faces are painted with hot paraffin, except for a narrow channel (indicated by dotted lines) past the

hole to one of the points, opposite points on the two sides; this insures that the only liquid junction is at the aperture in the plate.

The electrodes were kept in an air thermostat maintained at $25 \pm 0.02^\circ$, the exit tubes passing through the floor of the air chamber, *T*. The temperature of the surroundings was usually about 3° below that of the thermostat but the junction potentials encountered in the solutions investigated were sufficiently low so that changes due to fluctuations in the room temperature could be neglected. The cocks 3 and 3', attached to the electrodes by means of rubber tubing for convenience in filling the vessels, have their keys scratched near the bore at both ends, the scratches

being diametrically opposite, to facilitate the adjustment of the rate of flow. Cocks 2 and 2' serve for the thorough washing of the metal electrode with the electrolyte when the electrode is set up and at frequent intervals when it is in use but they are kept closed during the actual measurements, the by-pass cocks 1 and 1' being open. Before the mica plate is set in place the flow of the electrolytes is made as nearly equal as possible, 4-6 drops per minute being a suitable rate; then the plate is inserted and the exit tubes are brought against the opposite faces. The potential very quickly adjusts itself to a constant value, the time required being usually a matter of seconds and never more than a few minutes. Under favorable conditions (that is, small junction potentials) the variation in the potential proved to be less than 0.05 mv. over a period of several days.

The Liquid Junction Potential Between 0.1 *M* HCl and 0.1 *M* KCl at 25°

In order to test the accuracy and reproducibility of the junction potentials obtained with the device described, the potential between 0.1 *M* HCl and 0.1 *M* KCl, which has been investigated by MacInnes and Yeh,^{2b} was measured.

Preparation of Material

Silver.—Crystals of metallic silver were prepared by the rapid electrolysis of a solution of silver nitrate between small platinum wire electrodes, the anode being placed in a porous cup to prevent contamination of the metal with silver peroxide. The silver crystals were packed in a close mass around the platinum lead wire in the electrode vessel, held in place by a cotton plug at the bottom and covered with a layer of *crystalline* silver chloride about 10 cm. deep.

Silver Chloride.^a—Silver chloride was precipitated from a solution of silver nitrate by the addition of a solution of constant-boiling hydrochloric acid and the carefully washed precipitate dissolved in redistilled ammonium hydroxide. The resulting solution was filtered and the ammonia removed by absorption in sulfuric acid under a bell jar. The crystals of silver chloride were filtered and dried in a vacuum. The salt was protected from the action of light by a red lacquer coating on the electrode vessel and on the heating lamps of the thermostat. No appreciable darkening had occurred after five months' use of an electrode.

Mercury.—Mercury was purified by running it in a fine stream several times through a solution of mercurous nitrate and nitric acid, followed by distillation in a vacuum.

Calomel.—Pure mercury was dissolved in nitric acid, the mercury being present in considerable excess, and mercurous chloride precipitated by the addition of a solution of constant-boiling hydrochloric acid. After washing many times by decantation, the mixture of mercury and mercurous chloride was sucked dry on a Büchner funnel and shaken several days with water, changing the water every few hours. The material was kept under water in a brown bottle until required, when it was washed repeatedly with the particular solution to be used in the electrode under construction.

Potassium Chloride.—Ordinary "C. P." potassium chloride was recrystallized three times.

^a Crystalline silver chloride prepared by this method has been used by Professor J. N. Brønsted.

Hydrochloric Acid.—A strictly 0.1 *M* solution of hydrochloric acid was prepared by diluting a slightly stronger, carefully analyzed solution of the constant-boiling acid.

The following single electrodes were made up: (1) Ag, AgCl, 0.1 *M* HCl; (2) Ag, AgCl, 0.1 *M* KCl; (3) Hg, Hg₂Cl₂, 0.1 *M* KCl. The solutions used in all the electrodes were saturated with the corresponding metal chloride by shaking with an excess of the salt for from three to twelve hours in the thermostat before they were put into the electrode vessels. It is evident that the difference in potential between the first and second electrodes is a direct measure of the junction potential if the usual assumption is made that the activity of chloride ion in two fairly dilute solutions of equal ionic strength is the same. It is also apparent that there is no junction potential between the second and third electrodes and that the junction between the first and third is sensibly the same as between the first and second. Therefore, the difference in potential between the two possible cells comprising the calomel electrode as one pole is a measure of the junction potential. The experimentally determined potentials and their deviations over the period of observation are listed in Table I.

TABLE I

THE MEASURED POTENTIAL AT THE JUNCTION OF 0.1 *M* HCl AND 0.1 *M* KCl AT 25°

Cell	Potential, mv.	Mean deviation, mv.
Ag, AgCl, 0.1 <i>M</i> HCl 0.1 <i>M</i> KCl, AgCl, Ag	28.00	0.03
Ag, AgCl, 0.1 <i>M</i> HCl 0.1 <i>M</i> KCl, Hg ₂ Cl ₂ , Hg	73.3	.15
Ag, AgCl, 0.1 <i>M</i> KCl, Hg ₂ Cl ₂ , Hg	45.30	.05
(By difference)		
Ag, AgCl, 0.1 <i>M</i> HCl 0.1 <i>M</i> KCl, AgCl, Ag	28.00	

The difference in potential between a silver chloride electrode and a calomel electrode in the same chloride solution, the third cell in Table I, has been measured by Gerke⁴ for 1.0 *M* KCl and 1.0 *M* HCl. He obtained 45.5 mv. at 25°, which is in close agreement with our value of 45.3 mv. Both sets of measurements were made with finely divided crystalline silver electrodes but Gerke used the granular silver chloride obtained by direct precipitation. The value computed by Scatchard^{2c} from his revised activity data is 46.6 mv. The discrepancy between this last value and those obtained by direct measurement is probably due to the method of extrapolation used in deriving the activities, which is not entirely arbitrary, since Scatchard found excellent uniformity between silver electrodes prepared by three different methods—finely divided crystalline metal made electrolytically by Linhart,⁵ that obtained from the thermal decomposition of silver oxide by Noyes and Ellis,⁶ and his own electroplated platinum.⁷

⁴ Gerke, *THIS JOURNAL*, **44**, 1684 (1922).

⁶ Noyes and Ellis, *ibid.*, **39**, 2532 (1917).

⁷ Scatchard, *ibid.*, **47**, 641 (1925).

A summary of a number of values for the liquid junction potential is given in Table II.

TABLE II
COMPARISON OF VALUES FOR THE POTENTIAL AT THE JUNCTION OF 0.1 *M* HCl AND 0.1 *M* KCl AT 25°

	Potential, mv.
Measured directly	28.00
By difference	28.00
Measured directly, MacInnes and Yeh	26.78
Computed, Lewis and Sargent formula	28.4

It will be observed that our value is greater than that found by MacInnes and Yeh, lying between the value of the latter authors and that computed by the Lewis and Sargent formula,⁸ $E_j = RT/F \ln \Lambda/\Lambda'$. The ratio of the equivalent conductances of 0.1 *M* HCl and 0.1 *M* KCl, Λ/Λ' , calculated from our measured value of the junction potential, E_j , is 2.974. From the conductance data given by MacInnes and Yeh this ratio is 3.026. The difference, 1.7%, is far too great to be accounted for by any probable error in the conductivity measurements. It seems most plausible to ascribe the discrepancy to the abnormality of the potassium ion pointed out by MacInnes and Yeh, who found good correspondence between the calculated and measured junction potentials at the boundaries of a number of univalent chloride solutions except in the presence of potassium ion.

The reproducibility of the potentials at the liquid junctions formed in the manner described is certainly within 0.2 mv.; with regard to the absolute accuracy no definite statement can be made. The extreme simplicity of the arrangement, the ease and rapidity with which it can be set up and the fact that a small volume of liquid suffices for quite an extended series of measurements may be emphasized. Moreover, it eliminates the necessity of maintaining the column heights in the two arms of the cell in inverse ratio to the densities of the electrode solutions to insure equal rates of flow, a marked advantage over other forms of flowing junction.

In conclusion the authors wish to acknowledge their indebtedness to Dr. John Johnston for many valuable suggestions in connection with this work.

Summary

A simple arrangement for obtaining reproducible liquid junction potentials between two flowing electrolytes is described and its applicability tested by determining the potential at the boundary of 0.1 *M* HCl and 0.1 *M* KCl. The result obtained is in satisfactory agreement with that computed from the theoretical equation of Lewis and Sargent and in fair accord with the measured value of MacInnes and Yeh.

THE HEAT OF FORMATION OF ZINC OXIDE

BY GEORGE S. PARKS, CHARLES E. HABLUTZEL AND LAWRENCE E. WEBSTER

RECEIVED AUGUST 24, 1927

PUBLISHED NOVEMBER 5, 1927

The data in the literature for the heat of formation of zinc oxide are extremely discordant. Thus Mellor¹ gives ten values ranging from 86,900 cal. (Andrews, 1852) to 82,970 cal. (the lowest result of de Forcrand, 1902). Of these the results of de Forcrand are the latest and probably the most reliable. More recently Parr and Moose² have reported the value 84,900 cal., obtained by direct combination of the elements, and Maier and Ralston³ have calculated the values, 82,830 and 83,097 cal., from equilibria measurements and from thermal data, respectively. In view of this situation the present investigation was undertaken.

Richards and Burgess⁴ have determined the heat of solution of zinc in hydrochloric acid. In the present case we have measured the heat of solution of zinc oxide under precisely comparable conditions. These two heats of solution, combined with the heat of formation of water, serve as a basis for the calculation of a very reliable value for the heat of formation of zinc oxide from its elements.

Experimental Part

Richards and Burgess in their experiments dissolved 7.5 g. of zinc in 941.4 g. of hydrochloric acid of the strength 1HCl-20H₂O (approximately 2.633 *N*). We accordingly prepared acid of this concentration and in six series of determinations measured the heat effect observed when 25.83 g. of zinc oxide was dissolved in 2605 g. of acid. Thus the resulting solutions in our experiments had the same concentration of hydrochloric acid and zinc chloride as those obtained by Richards and Burgess.

As a calorimeter for the measurement of the heat of solution we used a Pyrex Dewar jar of 3 liters' capacity, for which a thin cover of cork, coated with paraffin, was made. Three small holes were punched in this cover for the stirrer, for the Beckmann thermometer and for the introduction of the zinc oxide. The glass stirrer was of the propeller type, with eight blades, and gave adequate circulation when operated at about 200 r.p.m. The Beckmann thermometer had been calibrated by the United States Bureau of Standards immediately before the measurements. The heat capacity of the apparatus as a whole was measured first in a series of nine determinations by an electrical method and subsequently in a series

of five determinations by a rough method of mixtures, the respective mean results being 182 and 185 calories per degree. Accordingly we have used 183 calories in our calculations. For the specific heat of the acid the value of Richards and Rowe,⁵ 0.8486 cal./g., was assumed.

In some preliminary experiments with our apparatus it was found that a small part of the oxide had a tendency to cake at the bottom of the Dewar jar and thereby took considerable time to go into solution. This difficulty seemed to be due entirely to the shape of the bottom of the jar and was remedied by introducing about a kilogram of mercury into the container. The mercury took no part in the reaction⁶ and, as its specific heat was known, a correction of about 36 calories per degree was added to the heat capacity of the apparatus as previously found. Under these conditions the 25.83 g. of zinc oxide went into solution within a period of five minutes, with a temperature rise of about two degrees above the initial temperature, 18.0°. The Regnault-Pfaundler method was employed in determining the cooling corrections during the solution process and the usual calorimetric precautions were observed throughout the measurements. The reproducibility of the results thus obtained is illustrated by the fact that the nine consecutive runs on Sample I showed an average deviation of 15 calories (0.10%) from the mean value, the maximum deviation being 35 calories (0.23%).

The zinc oxide samples were prepared from Baker's c. p. materials, made by the "wet process" and "dry process," respectively. The manufacturer's analyses as well as subsequent analyses made in this Laboratory indicated that the total impurities were much less than 0.1% in all instances. Sample I was "wet-process" oxide which had been dried on a hot-plate at about 110° for 24 hours. Samples II and III were a similar material which had been heated for 24 hours in an electric furnace at 500° and 800–1000°, respectively. This process of heating at high temperatures caused considerable shrinkage in the apparent volume of the oxide. Sample IV was "dry-process" oxide which had been dried on a hot-plate at 110° for 24 hours and Sample V was similar material heated at 500° for 12 hours. These last two samples occupied a larger volume per gram and apparently were much more finely divided than the corresponding ones prepared from the wet-process product. Sample VI was "recrystallized" oxide, made by sealing dry-process material into an evacuated (0.01 mm.) silica flask and heating to approximately 1100° for about 60 hours.⁷

The following table summarizes our results for the heat of solution of these six samples of zinc oxide in acid of the strength 1HCl-20H₂O. The data are expressed in terms of the 18° calorie for a final temperature of 20.0°.

⁵ Richards and Rowe, *Proc. Am. Acad. Arts Sci.*, **43**, 475 (1908).

⁶ As a matter of fact, in a number of determinations, including about half of those in Series IV, the mercury was omitted. The results obtained in these cases showed no essential differences from the others, although a somewhat longer time interval was required for complete solution of the oxide.

⁷ Numbers VI and IV were identical with "samples 2 and 3," respectively, employed in some previous heat-capacity determinations (Maier, Parks and Anderson, *This Journal* **48**, 2572 (1926)).

Dixon,⁵ Flügel,⁶ Adams,⁷ Harkins⁸ with students, Randall and Vanselow⁹ and Hovorka and Rodebush,¹⁰ Bedford,¹¹ and Barnes, Archibald and McIntosh¹² used a differential platinum thermometer and Griffiths,¹³ as long ago as 1891, employed the platinum thermometer for boiling- and freezing-point determinations.

The second development is that of improving the determination of concentration. Roloff¹⁴ was the first to analyze his solution after a large amount of solid solvent had separated. Some method of analyzing the solution in equilibrium with the solid solvent has been used in all of the modern determinations. The same end was accomplished by Walker and Robertson¹⁵ and by Richards¹⁶ when they mixed the solution with pieces of ice. This method has distinct advantages, as enumerated in the latter paper.

The most careful determinations of the freezing point of dilute solutions of hydrochloric acid by Randall and Vanselow⁹ include these improvements and constitute, with those of Hovorka and Rodebush,¹⁰ the most refined experiments reported.

The purpose of the present experiments was to extend the results to more concentrated solutions. The activity coefficients as calculated by the methods of Lewis and Randall¹⁷ are also reported.

Experimental Procedure

Temperature intervals were measured with a platinum thermometer and Wheatstone bridge manufactured by the Leeds and Northrup Company. The thermometer and bridge were standardized by the Bureau of Standards, the thermometer having a resistance in melting ice, (R_0), of 25.246 international ohms, a fundamental interval (F. I.) of 9.8059 ohms, a value of δ (in the Callendar formula) of 1.509 and an accuracy of 0.01% in the measurement of temperature intervals. The bridge was certified to be reliable to 0.00005 ohms under specified conditions. The bridge was maintained at a constant temperature within 0.1° by a suitable thermostat. A current of approximately 3 milli-amperes was used through the thermometer. As a consequence of the precautions taken, none of the connections being changed during the experiments and the

battery and galvanometer circuits including mercury-cup switches, the recorded temperature intervals should be accurate to 0.0005° , making certain the third decimal figure.

The temperatures were calculated by the Callendar formula

$$pt = \frac{R_t - R_0}{FI} \times 100$$

$$t - pt = \delta \left(\frac{t}{100} - 1 \right) \left(\frac{t}{100} \right)$$

where t is the temperature in Centigrade degrees and pt the "platinum temperature."

The apparatus in which the freezing mixture was maintained consisted of an unsilvered Dewar cylinder of Pyrex glass approximately 24 cm. deep with an inside diameter of 5 cm. It was fitted with a rubber stopper holding the thermometer, a stirrer,

a tube for the withdrawal of a sample of solution and a tube by which the system could be evacuated or pressure applied. The tube for the removal of the sample extended to a depth about three-quarters down the coil of platinum wire in the thermometer and terminated in a small bulb filled with glass wool to prevent the passage of any small pieces of ice.¹⁸ The sample of solution was removed by applying a pressure of clean air, thus avoiding the possibility of losing material in the form of a vapor. This precaution is not so important in the case of solutions of hydrochloric acid as if the solute had an appreciable vapor pressure, when an indeterminate amount of material would be lost if suction was applied.

¹⁸ For a similar device, see Richards and Fraprie, *Proc. Amer. Acad. Arts Sci.*, **36**, 507 (1901).

The Dewar cylinder was immersed in an agitated bath of ice and salt solution whose concentration was regulated so that the temperature was maintained slightly below that inside the Dewar cylinder.

The water used had been thrice distilled (freed from organic matter, ammonia and carbon dioxide). A sample prepared on the day previous to the experiment was boiled for about two hours to free it from dissolved air, then stoppered in a Pyrex flask and chilled to 0°, cooling under its own vapor. Precautions to prevent the solution of air are necessary, for its solubility may be different in water than in the hydrochloric acid. Randall and Vanselow seem to be the first to report precautions of this nature.

The ice was prepared from a commercial product by shaving—thereby producing a finely divided solid that would make a mush with water—washed three times, finally with the best water. Clear pieces of ice were selected for the preparation of the sample. When this ice was mixed with the water, air was held mechanically in the interstices. This was immediately removed by suction. Precaution was taken to prevent the melting of the ice during the whole manipulation. The temperature of this freezing mixture corresponded well within 0.001° with a mixture of water and ice prepared by supercooling a sample of the best water and then shaking.¹⁹

The hydrochloric acid was prepared from C. P. acid by fractionally distilling three times, the middle portion being used each time. A final distillation, to remove any dissolved glass, was made just before the experiment. The all-Pyrex distilling apparatus had been used with hydrochloric acid many times. This acid was chilled before introduction into the freezing mixture.

The procedure during a determination was as follows. The washed ice was mixed with the water and evacuated several times to remove air held in the ice and then evacuated again for twenty minutes after the thermometer had been introduced and the apparatus assembled. The pressure was then released and the mixture stirred. The resistance of the thermometer in this ice-bath was determined each day and taken as R_0 . A sufficient amount of acid was then added, the system evacuated for about fifteen minutes after a brief preliminary stirring and the resistance of the thermometer measured again (at atmospheric pressure). With a suitable regulation of the temperature in the outside bath, this equilibrium temperature would remain constant within the accuracy of the thermometer for some time. After about five minutes of constant temperature, a final reading was made and the sample withdrawn by applying pressure.

This sample, of approximately 40 cc., was divided into two portions, weighed and analyzed gravimetrically by precipitating and weighing as silver chloride. All weights were reduced to vacuum. The concentrations, expressed in gram equivalents per 1000 g. of solution (6.9764 wt. AgCl/wt. solution) and thence the molality (m , the gram equivalents per 1000 g. of solvent), were calculated using the molecular weight of hydrochloric acid as 36.466.

A second point was obtained by adding more chilled water and acid and repeating the technique. Not more than three points were obtained on the same day. The concentrations were so chosen that the determinations

¹⁹ Ref. 10, p. 2426.

of one day would overlap those of another day, thus producing verifications of previous experiments.

The results are given in Table I. The first column gives the number of the experiment; the second the molality, (m); the third the temperature lowering, (Θ), or the freezing point in degrees below Centigrade zero; and the fourth the ratio of temperature to molality, (Θ/m).

TABLE I
THE FREEZING POINTS OF AQUEOUS SOLUTIONS OF HYDROCHLORIC ACID

No.	m	Θ	Θ/m
1	0.08321	0.2934	3.526
2	.1427	.5033	3.527
3	.2024	.7145	3.530
4	.2198	.7771	3.538
5	.2374	.8440	3.554
6	.3080	1.1000	3.571
7	.3137	1.1202	3.571
8	.4082	1.4738	3.610
9	.5275	1.9344	3.666
10	.6363	2.3664	3.719
11	.6785	2.5465	3.753

15	.8945	3.4545	3.862
16	.9765	3.8192	3.911
17	1.0324	4.0721	3.944

Of these determinations, three are inconsistent with the rest, namely, numbers 5, 11 and 13. They have not been considered in subsequent calculations.

The ratio Θ/m is plotted as ordinate against Θ as abscissa in Figure 1. Data as enumerated in Landolt-Börnstein's "Tabellen,"²⁰ as well as those of Richards and Jackson²¹ and a few of Randall and Vanselow's are plotted for comparison.

Theoretical Calculations

From these data can be calculated by the graphical methods of Lewis and Randall²² the mean activities of the ions and the activity coefficients. The latter can be compared with those calculated by Lewis and Randall²³ from the e.m.f. measurements of Linhart²⁴ and those of Scatchard.²⁵

The graphical method of calculating the "preliminary activity co-

²⁵ Scatchard, *ibid.*, **47**, 641 (1925).

efficient" (γ'), that applying to the temperature of the freezing mixture and uncorrected for the heat of solution, necessitates the evaluation of areas under curves from infinite dilution to the concentration in question. The value of $\gamma_{25^\circ} = 0.819$ for $m = 0.070$, as interpolated from Scatchard's data, was accepted in order to evaluate the area for more dilute solutions. If the value of $\gamma_{25^\circ} = 0.824$ (interpolated from Randall and Vanselow's data) is used, the results are correspondingly higher.

The calculation of the factor by which the "preliminary activity coefficient" must be multiplied to give the corrected activity coefficient at 25° requires a knowledge of heat data, all of which are not available in the literature. The values for the partial molal heat capacities (\overline{c}_p) were taken from the paper of Randall and Ramage,²⁶ while those for the partial molal heat content of the solvent (\overline{L}_1) were very generously supplied by Professor Merle Randall.²⁷ The results of these calculations are given in Table II.

TABLE II
COMPARISON OF THE ACTIVITY COEFFICIENTS*

m	γ'	γ/γ'	γ_{25° , F.P.	γ_{25° , S.	γ_{25° , L. and R.
0.1	0.803	0.996	0.800	0.801	0.804

ment is quite satisfactory. Similar data for solutions up to 0.1 *M* have been discussed by Scatchard.²⁸

The writer wishes to express his indebtedness and gratitude to the Elizabeth Thompson Science Fund for providing mechanical aid in the calculations.

Summary

A report is made of the determination of the freezing points of aqueous solutions of hydrochloric acid up to a concentration of 1.0 molal, making use of a platinum thermometer as a temperature measuring device.

The activity coefficients are calculated and compared with those derived from electromotive force measurements.

SOME PHYSICAL PROPERTIES OF VINYL CHLORIDE

BY L. I. DANA, J. N. BURDICK AND A. C. JENKINS

RECEIVED SEPTEMBER 16, 1927

PUBLISHED NOVEMBER 5, 1927

Although vinyl chloride (C_2H_3Cl) has been known as a chemical compound for a number of years, owing to the difficulties attending its preparation and purification, relatively little exact work has been done with it. Recent progress in chemical synthesis has made this material available in quantity commercially and therefore it has seemed worth while to review previous work on the subject in order to ascertain the present state of knowledge of the properties.

Beyond a few scattered values of the boiling point of vinyl chloride, very little has been published concerning its physical properties. Recently the desirability of utilizing vinyl chloride as a refrigerating fluid (boiling point -13.9°) has been suggested, and hence it has appeared desirable to conduct an experimental determination of its most important physical properties. In this investigation the measurements of the vapor-pressure curve, liquid densities and freezing point are reported; in addition a few of its other physical properties have been estimated from theory.

Description of Experiments

Vapor-Pressure Curve.—Commercial samples of vinyl chloride¹ were obtained in small steel cylinders. This liquid was purified by fractional distillation in a vacuum insulated, low-temperature Hempel column and was further subjected to a fractional distillation in a closed, low-

²⁸ Scatchard, *THIS JOURNAL*, **47**, 641 (1925). See also LaMer, *Trans. Amer. Electrochem. Soc.*, **51**, (1927), preprint No. 58; and Van Laar, *Z. anorg. allgem. Chem.*, **139**, 108 (1924).

¹ Material obtained from the Carbide and Carbon Chemicals Corporation, New York City.

temperature fractionation apparatus, operated with a Langmuir pump in series for the purpose of removing the traces of moisture and all non-condensable gases. Finally, the samples were tested for boiling range and pressure drop in the vapor-pressure apparatus mentioned below. On distilling off over 95% of the sample at constant temperature, the pressure drop was found to be less than 2 mm. in 760 mm. of Hg, and on distilling off at constant pressure the temperature drop was less than 0.05°. It is probable that the purity was higher than 99.9%.

The vapor pressures were measured over the temperature range from -28 to 60°, corresponding to a pressure range of 40 to 760 cm. of Hg absolute or from 0.5 to 10 atm. absolute. Below and around one atmosphere a mercury manometer, with a vacuum over one arm, was employed for the pressure measurement. From one to five atmospheres a tall mercury manometer was used, while above this pressure a dead-weight piston gage served to measure the pressure. Various forms of containers for the sample were used. In general the experimental technique was similar to that used in the measurement of the vapor pressures of some paraffin hydrocarbons,² to which work reference is made for experimental details.

The boiling point at one atmosphere was determined a number of times and was found to be -13.9, $\pm 0.1^\circ$. Biltz³ gives the boiling range as -18 to -15°, which would seem to be much too low temperatures and too wide a range to correspond with the pure material tested in this investigation. In the following table are given the values of the pressures and corresponding temperatures observed for the vapor pressures.

TABLE I
VAPOR PRESSURES OF VINYL CHLORIDE

Temp., °C.	Press., cm. Hg	Temp., °C.	Press., cm. Hg	Temp., °C.	Press., cm. Hg
-28.73	39.56	4.01	149.06	39.72	450.0
-23.02	51.30	5.53	158.2	46.80	543.4
-16.61	67.76	16.21	225.8	54.87	667.6
-13.61	76.75	25.72	302.7	60.34	758.6
- 8.32	94.90	33.53	378.9	60.34	760.3
- 1.57	122.48	39.72	449.2		

The experimental observations have been combined into the well-known Nernst⁴ equation of the form

$$\log p = a + b/T + 1.75 \log T + cT$$

in which the pressure p is expressed in atmospheres absolute and the temperature T in degrees centigrade absolute. The values for the constants are as follows

$$a = 0.8420; \quad b = -1150.9; \quad c = -0.002415$$

³ Biltz, *Ber.*, 35, 3525 (1902).

⁴ Nernst, "Theoretical Chemistry," Macmillan Co., New York, 1923, p. 815.

On the average the agreement of the observed results with those computed by the formula is within the experimental error, 0.3%.

Liquid Densities.—The method employed for the determination of the liquid densities has been described in an earlier paper by the authors,⁴ and is similar to that used by the Bureau of Standards on ammonia.⁵ Preliminary experiments were first made in a Pyrex pycnometer in which only the coefficient of expansion of the liquid was measured, since the weight of liquid vinyl chloride in the pycnometer was not ascertained. The final measurements were made with the pycnometer, shown in Fig. 1, constructed of Jena 16^{III} glass. After calibrating the pycnometer carefully with mercury, the sample was condensed in and the pycnometer sealed off. Readings of the liquid in the stem were observed at various temperatures from -13 to 60° in a thermo-regulated bath and the temperatures were read by a platinum resistance thermometer. By weighing the pycnometer full and empty, the corrected weight of vinyl chloride was found to be 5.9716 g. Enough data were then available for computing the absolute density. The results for the coefficient of expansion agreed to 0.1% with those obtained with the Pyrex pycnometer.

Correction has to be applied for the quantity of vapor in the vapor space above the liquid in the pycnometer. No experimental values for the vapor densities are available, however, so that these values were computed theoretically. Since, however, the maximum value for this correction is about 0.15% and an accuracy

⁴ Cragoe and Harper, Bureau of Standards, Scientific Paper, No. 420.

Fig. 1.—Piezometer for liquid densities.

of 0.1% is claimed for the results, it is evident that an accuracy of 50% for the vapor density correction is sufficient. It is believed that the vapor density can be computed with much higher accuracy and as a matter of interest this has been done and the results are given later on.

RESISTANCE THERMOMETER

Fig. 2.—Freezing-point apparatus.

The liquid densities of vinyl chloride are shown in Table II.

It is believed that the results are good to 0.1%.

An empirical formula representing the results from -13 to 60° is as follows

$$d = 0.9471 - 0.001746t - 0.00000324t^2$$

in which d is the liquid density in grams per cc. and t is the temperature in degrees centigrade. The data agree with the formula to better than 0.1%.

Freezing Point.—Since relatively large quantities of vinyl chloride, purified by fractional distillation for the vapor-pressure measurements, had been prepared, it was decided to determine the freezing point by direct immersion of the thermometer in a large sample. The apparatus is shown in Fig. 2. Throughout the measurements the sample was handled in a closed system to keep out moisture. Liquid air was employed as the cooling medium. With a single tube the rate of cooling was too rapid; hence a double-walled tube was used. This also had the effect of producing a uniform temperature gradient in the freezing-point sample. Preliminary determinations with a calibrated, propane filled, low temperature thermometer resulted in the value -159° . The final and most accurate determination was made with a platinum resistance thermometer which had previously

been calibrated at the freezing point of mercury, the sublimation point of carbon dioxide and the boiling point of oxygen.² The period of freezing lasted about seven minutes and the freezing temperature was

constant to within 0.1° at -159.7° . Considering the purity of the sample it is safe to claim an accuracy of 0.1° for this freezing point.

TABLE II
LIQUID DENSITIES OF VINYL CHLORIDE

Temp., $^\circ\text{C.}$	Liquid density, g./cc.	Temp., $^\circ\text{C.}$	Liquid density, g./cc.
-12.96	0.9692	39.57	0.8733
1.32	.9443	48.20	.8555
13.49	.9223	59.91	.8310
28.11	.8955		

Estimated Vapor Densities and Latent Heats

Since the vapor densities were required for correction terms to the liquid densities, it appeared worth while to estimate them as accurately as possible so that the values might be of use elsewhere. At the same time, since the vapor-pressure curve was measured, the latent heats could be estimated with the aid of Clapeyron's equation.

Unfortunately the critical constants of vinyl chloride are not known so that the law of corresponding states could not be employed directly; but van Laar⁶ has described methods based on empirical relationships by means of which the critical constants may be computed, which in turn serve in other relationships from which the specific volumes can be ascertained. By these methods the estimated critical pressure is 52.2 atm. while the estimated critical temperature is 142° .

In the following table the estimated specific volumes of the saturated vapor, estimated by the method of van Laar, are given.

TABLE III
ESTIMATED SPECIFIC VOLUMES OF SATURATED VAPOR OF VINYL CHLORIDE

Temp., $^\circ\text{C.}$	Spec. vol., cc./g.	Temp., $^\circ\text{C.}$	Spec. vol., cc./g.
-30	635	20	105.4
-20	418	30	79.7
-10	284	40	60.3
0	199	50	46.3
+10	143.3	60	36.2

To compute the latent heats the above values for the specific volumes were used and the slopes of the vapor-pressure curve were determined graphically.

The latent heats were also computed by means of the law of corresponding states, comparing with the values given by Holst⁷ for methyl chloride. At the boiling point the values by the two methods agree to 1%, while at 50° they agree to 5%.

30	100.2	76.2	78.5
40	124	73.2	76.6
50	151	70.1	74.4

Summary

The vapor pressure of vinyl chloride was measured from -28 to 60°. The normal boiling point was found to be -13.9, $\pm 0.1^\circ$.

The liquid densities were measured over the temperature range -13 to 60°.

The freezing point was found to be -159.7, $\pm 0.1^\circ$.

Estimated values of the vapor densities and latent heats were computed from theoretical relationships.

BUFFALO, NEW YORK

NOTE

Calculation of Heats of Combustion.—Kharasch and Sher¹ have applied the electronic conception of valence to the calculation of heats of combustion of organic compounds. They find that the energy change which accompanies the displacement of one valence electron from the position which it occupies in methane, a carbon chain or the benzene nucleus to the position after combustion in carbon dioxide is 26.05 kg. cal. per mole. Thus the heat of combustion of a hydrocarbon is given by the product $26.05 \times N$, where N is the number of electrons displaced.² Electrons associated with bonds other than C—C and C—H are accompanied by an additional energy change during combustion. To the term $26.05 N$, Kharasch and Sher add 26 kg. cal. for each aliphatic ether group, 13 kg. cal. for each ethylenic linkage, primary alcohol, ester or aromatic ether group and 6.5 kg. cal. for each secondary alcohol or ketone group. No correction is added for tertiary alcohol, phenol or acid groups. In most cases this method gives good results, but for aromatic compounds the calculated values are uniformly higher than the experimental values and the

¹ Kharasch and Sher, *J. Phys. Chem.*, 29, 625 (1925).

² Each bond corresponds to two electrons. In oxygen compounds the two oxygen bonds are disregarded. Thus N is 8 for methane, 30 for benzene, 58 for phenyl benzoate, etc.

deviations become greater as the number of benzene nuclei increases. This necessitates a correction for each benzene nucleus. The method proposed for this correction follows.

The electrons associated with three of the bonds of the benzene nucleus (μ electrons) will be assumed to differ in energy relations from those of the other twelve (λ electrons).³ There is an energy change of 24.85 and 26.05 kg. cal. per mole, respectively, for each μ and λ electron present in the compound being burned. The heat of combustion in kg. cal. per mole at constant pressure of compounds containing C and H, or C, H and O, is given by the equation⁴ $Q_p = 26.05\lambda + 24.85\mu + 22.7$ for each ether group + 19.5 for each aldehyde group + 13 for each ethylenic linkage, primary alcohol or ester group + 6.5 for each secondary alcohol group + 3.2 for each phenol or tertiary alcohol group + 0.0 for each acid or ketone group.

Of the 57 aromatic compounds containing C and H, or C, H and O, whose heats of combustion were calculated by Kharasch and Sher, the new method gives results closer to the experimental values in 37 cases and the same in 7 cases. The average per cent. difference between experimental and calculated values is lowered from 0.52 to 0.32%. Table I shows per cent. difference between calculated and experimental values for 171 aromatic compounds of different types.

TABLE I

DIFFERENCE BETWEEN CALCULATED AND EXPERIMENTAL HEATS OF COMBUSTION

Aromatic compounds containing C and H, or C, H and O	No. of calculations	Difference between calculated and experimental values

RATE OF REACTION BETWEEN BROMINE AND UNSATURATED FATTY ACIDS AS EVIDENCE OF STEREO-ISOMERISM¹

BY CALVIN A. KNAUSS AND JUDSON G. SMULL

RECEIVED MAY 12, 1927

PUBLISHED NOVEMBER 5, 1927

Various studies on the action of bromine toward unsaturated fatty glycerides indicated that the rate of reaction was dependent upon several factors. Thus, the nature and dilution of the solvent has a marked effect on the rate of bromination.

Working under the same conditions with respect to solvent, the rate of bromination was applied to glycerides of oleic, linolic and linolenic acids, respectively, and to the free fatty acids of the respective glycerides. The rate of bromination was found to vary with the different unsaturated fatty acids.

The effect of ultraviolet light during the bromination was also studied, with the result that certain stereo-isomers of unsaturated acids were determined which escaped detection by the present methods of analysis.

In an investigation the authors have undertaken dealing with the stereo-isomers of linolenic acid they observed that in the bromination of the fatty acids of linseed and other oils several factors seemed to influence the addition of the bromine to the unsaturated acids as, for example, the concentration of the solvent, the composition of the fatty acids and light. A supposedly pure sample of linolenic acid was found to have an iodine number of 223 by the Wijs method and a hexabromide number of 46, while the theoretical number is 274.3. Erdman and Bedford reported an iodine number of 227 for linolenic acid. It is very difficult to explain these discrepancies but when it is considered that the *cis* modifications of stereo-isomeric compounds generally react with bromine only with difficulty, a new view of this phenomenon may be taken. The authors are certain that linolenic acid is present in linseed oil in several stereo-isomeric forms (this work is to be reported in a later paper), so that an explanation of the erratic action of the fatty acids of drying oils may be found from a stereochemical consideration of this problem.

Historical

A survey of the literature has shown that although the iodine number of oils is an important characteristic, very little work has been reported on halogenation of fatty acids aside from the methods for the determination of iodine number.

McIlhiney² reported a method of bromination which he advocated as a

¹ Presented before the Paint and Varnish Division of the American Chemical Society at its 73rd meeting, Richmond, Virginia.

² McIlhiney, *THIS JOURNAL*, 21, 1084 (1899).

substitute for the iodine methods. He used a *N*/3 solution of bromine in carbon tetrachloride, allowed the solution to stand for only two minutes, then added potassium iodide and titrated with sodium thiosulfate. After this titration was finished, neutral potassium iodate solution was added and the liberated iodine, equivalent to free hydrogen bromide, was titrated and calculated as the substitution.

Cerdeiras³ has studied the rate of reaction of the Wijs reagent on fats and fatty acids but the reaction was too rapid to draw any positive conclusions with respect to the different components of the fatty acids.

Kaufmann⁴ describes the use of bromine instead of iodine for the analysis of oils and has shown the action of bromine in a number of solvents toward highly unsaturated compounds. Thus, bromine dissolved in carbon tetrachloride was found to be less reactive than bromine in chloroform and, further, bromine in methyl alcohol saturated with sodium bromide was in most cases less reactive than in carbon tetrachloride. The latter mixture he recommended as a reagent for the analysis of oils. Kaufmann also reported some data showing a comparison of the rate of bromination of linseed oil in carbon tetrachloride and in methyl alcohol saturated with sodium bromide. The experiments were carried out in sunlight and in the dark; the results are given as the equivalent of iodine absorbed. The results reported by Kaufmann are as follows.

TABLE I
BROMINATION OF LINSEED OIL (IODINE No. 182)

Time	Carbon tetrachloride		Methyl alcohol and sodium bromide	
	Dark	Sunlight	Dark	Sunlight
2 min.	152.0	178.1
10 min.	151.2	183.0	156.2	161.3
30 min.	152.8	190.5	157.4	163.8
60 min.	156.8	194.3	160.7	164.3
24 hours	183.0	239.5 ^a	183.3	182.0
48 hours	182.0	252.0	183.5	181.6

^a No mention is made by Kaufmann as to whether any substitution had taken place to give these high values.

Kaufmann⁵ also reported the rate of bromination of cinnamic acid both in the dark and in ultraviolet light but no mention is made of the use of ultraviolet light in the experiments with linseed oil. He reported the addition of six bromine atoms to elaeostearic acid and no substitution when exposed to ultraviolet light for forty minutes.

Coffey⁶ has shown that the different constituents of linseed oil oxidize differently, so that it would appear reasonable to assume that the different constituents should brominate differently.

Experimental Procedure

These investigators have shown that unsaturated compounds react slowly with bromine when the solution is dilute. Sunlight and ultraviolet light increase this rate of reaction, producing greater bromine absorption without necessarily causing substitution.

In order to study the action of bromine on "drying" oils, the fatty acids of poppy seed, soya bean, linseed and perilla oils were treated with a dilute solution of bromine in carbon tetrachloride for different periods of time. The amount of bromine that reacted with the fatty acids was calculated on the basis of iodine numbers. The calculation to an iodine number was made so as to have a ready reference to the ordinary iodine number of the fatty acids as determined by the Wijs method. These results were then compared with the results for oleic, linolic and linolenic acids by similar treatment. In order to determine if light produced any action between bromine and the fatty acids aside from substitution, the fatty acids were allowed to stand in contact with bromine for an hour in the dark. These solutions were then subjected to ultraviolet irradiation for definite periods of time and the amounts of additive and substitutive bromine determined.

Materials

Bromine-Carbon Tetrachloride Solution.—Two and six-tenths cc. of bromine was added to 800 cc. of Eastman Kodak Co. "sulfur free" carbon tetrachloride which was freshly distilled over phosphorus pentoxide before adding the bromine. It is necessary that extreme precaution be taken to have the liquids dry or else bromine acids will form and cause substitution with the fatty acids.

Fatty Acids.—Twenty-five g. of poppy seed, soya bean, linseed and perilla oils were each dissolved in 50 cc. of alcohol and saponified with potassium hydroxide in an atmosphere of carbon dioxide. The potassium soaps were converted into the free acids by treatment with dilute hydrochloric acid. The fatty acids were then dissolved in ethyl ether and dried over anhydrous sodium sulfate. The ether was evaporated just before using the acids.

The fatty acids from the different oils had the following iodine numbers by the Wijs method.

Poppy seed oil fatty acids.....	135.5
Soya bean oil fatty acids.....	137.0
Linseed oil fatty acids.....	186.4
Perilla oil fatty acids.....	197.1

Oleic Acid.—The oleic acid used was so-called c. p. quality. It had an iodine number of 86.0. The theoretical iodine number is 90.

Linolic Acid.—The linolic acid was so-called c. p. quality with an iodine number of 184.0; theoretical, 181.4.

Linolenic Acid.—The linolenic acid was prepared by treating 50 g. of white crystalline hexabromostearic acid with 15 g. of freshly reduced zinc dust in 100 cc. of absolute methyl alcohol saturated with dry hydrogen chloride gas. This mixture was refluxed on a water-bath and mechanically stirred for about three hours. Dry carbon dioxide and hydrogen chloride was passed into the flask during the reaction. The mixture was then treated with warm brine to remove the methyl ester from excess methyl

alcohol. The methyl ester of linolenic acid was then saponified with potassium hydroxide and the potassium salt hydrolyzed with dilute hydrochloric acid. The linolenic acid thus produced was washed several times with water until it gave no test for halogens. It was then dissolved in ethyl ether to remove any unchanged hexabromide, filtered and the ethereal solution dried with sodium sulfate. The ether was removed by distillation; yield, 90%. This linolenic acid had an iodine number of 222.8; theoretical, 274.3.

Method

In studying the reaction between bromine and the fatty acids in the dark the methods of McIlhiney and of Kaufmann were combined with some slight modifications. One g. of the fatty acid from the freshly saponified oil was dissolved in 200 cc. of the bromine-carbon tetrachloride solution and diluted to 250 cc. with carbon tetrachloride. The mixture was thoroughly shaken and placed in the dark at room temperature. At periods of 5, 10, 20 and 30 minutes, 1 hour, 24 hours and 48 hours, 25 cc. of the solution was removed, 15 cc. of a 15% solution of potassium iodide and 100 cc. of water were added and it was titrated with standard sodium thiosulfate solution in the usual manner. When the end-point was reached, 5 cc. of a 2% solution of sodium iodate was added. If the blue starch-iodide color reappeared, the titration was continued to the end-point. The amount of sodium thiosulfate used for this second titration was doubled and calculated as the substitution value.

In studying the reaction between bromine and the fatty acids due to ultraviolet irradiation, the method used was similar to the above except that the solution of fatty acids and bromine remained mixed in the dark for one hour, then 25cc. portions were placed in quartz tubes and exposed to a Cooper-Hewitt quartz Uviarc at a distance of 30 cm. (12 inches) for periods of 5, 15, 30 and 60 minutes. The titrations for additive and substitutive bromine were similar to the above. By keeping the reacting mixture in the dark for an hour the amount of bromine absorbed was in nearly all cases practically equivalent to the ordinary iodine number. As the study of the reaction under ultraviolet irradiation was not to increase the speed of the reaction but rather to determine if any increase in bromine addition took place, it was advisable practically to complete the additive reaction before exposure. Under this condition any increase in iodine number will correspond to bromine which does not react with the fatty acids in the dark.

Experimental Results

As mentioned before, instead of reporting the results as the amount of bromine absorbed, the calculations are converted to the equivalent iodine number.

The results have been presented in the following tables. Table II comprises the results of the reaction between the fatty acids of poppy seed, soya bean, linseed and perilla oils with bromine in the dark for definite periods of time. Table III shows the results of the same fatty acids and bromine after standing in the dark for one hour and then being exposed to ultraviolet light for definite periods. Table IV gives the results for oleic, linolic and linolenic acids corresponding to Table II, and Table V corresponds to Table III with the same acids. The columns headed "Addit." are equivalent iodine numbers corresponding to the amount of additive bromine, and those headed "Subst." correspond to substitutive bromine.

It is interesting to note that the amount of substitution seems to corre-

spond to the amount of hydroxy acids present in linseed oil. If this assumption is correct, then hydroxy acids may be present in poppy seed and perilla oils.

The effect of the ultraviolet light seems to increase the energy of the reacting mixture so that more bromine is absorbed by the fatty acids than under normal conditions.

Discussion of Results

An examination of the results which are summarized in the tables indicates that in the case of the so-called pure oleic and linolic acids, there are

other substances present which react with bromine under the influence of ultraviolet light to yield the high values reported. The oleic acid used was the U. S. P. grade and might possibly contain some linolic acid. Likewise, linolic acid, which is usually prepared from poppy seed or soya bean oil, is also difficult to obtain pure. In fact, Pfahler⁷ claims that up to the present time pure linolic acid has not been prepared from an oil in a way analogous to Erdmann's method for linolenic acid. The high results with linolic acid may, therefore, be due partly to the presence of a stereo-isomer of linolenic acid which is not detectable by the hexabromide method of Eibner.

In the case of linolenic acid, which was prepared from hexabromolinolenic acid by de-bromination, according to the method of Erdmann, an iodine number lower than the theoretical is shown. Pfahler⁷ also states that the iodine number of acids prepared in this manner is always lower than the theoretical and that the low value is not due to impure acid. It is known that de-bromination in many cases causes stereomutation to forms which do not readily absorb halogen.

If this view is correct, then the acids should absorb more bromine under the influence of ultraviolet light. This has actually been accomplished, as will be seen from the results as given in tabular form. The abnormally high results for oleic and linolic acids beyond that assumed for the presence of other acids are as yet unexplainable, and work has been outlined, and is in progress, in an endeavor to explain these values. Linolenic acid, however, does not reach the theoretical value of absorption, even under the influence of ultraviolet light. It does show greater absorption than by the ordinary method, which indicates the presence of stereo-isomers.

The rate of bromine addition, in the dark, shows that oleic and linolic acids react more rapidly than linolenic acid. Oleic and linolic acids, therefore, should react more slowly toward oxygen than does linolenic acid, since compounds of this order which react slowly toward bromine do react more readily toward oxygen or hydroxyl. This is actually the case.

The results obtained on the mixed fatty acids of the different oils follow in a general way the results on the individual acids, with the further interesting observation that they all absorb more bromine under the influence of ultraviolet light than in the dark. This then indicated the presence of stereo-isomers which are not determined by present methods of analysis.

This same condition holds true for the other oils which are known to yield solid hexabromides under the ordinary treatment. The additional bromine absorbed means that, just as in poppy seed oil, there is another isomer present which does not react with bromine in the ordinary way.

⁷ Pfahler, *Chem. Umschau*, 33, 65-70 (1926).

The actual percentage of these isomers which are inactive toward bromine is approximately 10 to 15% in excess of the usual amount. In some cases the percentage may be lower than this. It is perhaps fortunate that these values are not high, because such substances in oils would be very energetic toward oxygen and thus cause too rapid drying of the oil.

Further evidence to support the authors' view of the presence of stereoisomers in linseed oil is the following.

Through the courtesy of H. A. Nelson and G. F. A. Stutz of the New Jersey Zinc Company, a sample of raw linseed oil was exposed to ultraviolet light in the presence of a dry carbon dioxide atmosphere for eighteen hours. This sample after exposure showed an iodine number of 148 and a hexabromide number of 35. This confirms the work of G. F. A. Stutz,⁸ who has shown a marked decrease in the iodine number of raw linseed oil after exposure to ultraviolet light in the presence of nitrogen gas.

However, when this sample of oil was brominated in the presence of ultraviolet light for thirty minutes, the total bromine absorbed was equivalent to an iodine number of 190, as against 180 for the original raw, unexposed oil.

In the first exposure of the raw oil in the presence of carbon dioxide, the ultraviolet rays caused a mutation of the stable isomers to labile isomers. This is in accordance with the views of Stoermer⁹ and others.

In the second exposure, where the pre-exposed oil was brominated, the action of the ultraviolet rays stimulates the addition of halogen to the isomers which were stereomuted in the first exposure. It is known that labile isomers react very slowly with halogen and, furthermore, they react easily with oxygen. This too was found to be the case, for the oil from the first exposure (iodine No. 148) dried more rapidly than the raw, unexposed oil.

It is apparent, therefore, that the ultraviolet rays in thirty minutes' time could hardly have changed the labile form to that which required eighteen hours to accomplish in the other direction, but that they simply stimulated the absorption of the halogen.

Our experiments so far indicate that the optimum condition for bromination under the influence of ultraviolet light is attained just at the point where substitution begins. A small substitution value is discernible in practically all glycerides which represents hydroxy acids, even before exposure, so that this value must be considered first before assuming substitution by ultraviolet light.

Conclusions

The rate of bromination of oleic, linolic and linolenic acids is in inverse ratio to the number of double bonds, that is, oleic acid reacts the most rapidly and linolenic acid the least.

⁸ Stutz, *Ind. Eng. Chem.*, **18**, 1238 (1926).

⁹ Stoermer, *Ann.*, **342**, 1 (1905).

The rate of bromination of the mixed fatty acids of poppy seed, soya bean, linseed and perilla oils is in direct relation to the acid constituents.

Under the influence of ultraviolet light the bromination of both the so-called pure acids and the mixed fatty acids proceeds beyond the bromination in the dark, which indicates the presence of unsaturated isomers which are not shown by present methods of analysis.

THE CONSTITUTION OF ORTHO-NITROBENZALDEHYDE AND THE INTERFERENCE OF NITRO AND NITROSO GROUPS ON THE ZEREWITINOFF METHOD FOR THE QUANTITATIVE ESTIMATION OF ACTIVE HYDROGEN

BY HENRY GILMAN AND ROBERT E. FOTHERGILL¹

RECEIVED JUNE 18, 1927

PUBLISHED NOVEMBER 5, 1927

Introduction

In connection with a study of the mechanism of the photochemical reactions of *o*-nitrobenzaldehyde and some of its condensation products, Tanasescu² has suggested recently that *o*-nitrobenzaldehyde is very probably an equilibrium mixture of the following forms:

The chief evidence brought forward in support of the cyclic hydroxy formula (II) is the quantity of methane evolved when *o*-nitrobenzaldehyde is treated with methylmagnesium iodide according to the method of Zerewitinoff.³ This quantitative method for the estimation of active hydrogens has been used very extensively and, on the whole, is eminently satisfactory.

However, Tanasescu is probably quite wrong in suggesting that *o*-nitrobenzaldehyde has the cyclic hydroxy formula (II) because the compound evolves methane when treated with methylmagnesium iodide. We do not say that a formula like (II) is impossible. If it is a likely formula it must find support in evidence other than that given by the Zerewiti-

¹ A preliminary report on this work was presented at Iowa City, May 7, 1927, before the Organic Division of the Iowa Academy of Science.

³ Zerewitinoff, *Ber.*, 40, 2023 (1907), and numerous succeeding papers. The most recent reference is the *Z. anal. Chem.*, 68, 321-327 (1926) [*C. A.*, 21, 153 (1927)]. See also Chugaev, *Ber.*, 35, 3912 (1902), for earlier experimental work on the same method.

noff method. The present quantitative studies on the gases evolved show that the phenomenon of gas evolution is essentially an inherent property of the nitro and nitroso groups.

Tanasescu used methylmagnesium iodide in his studies and, as well as can be ascertained from his data, the gas evolved was merely measured and not analyzed to ascertain whether it was pure methane or a mixture of hydrocarbons. Such analyses have been carried out in our work and although the gas evolved when methylmagnesium iodide is used is largely methane, as one would expect if any hydroxyl group were present, the same is not true with other alkylmagnesium halides like the ethyl-, propyl- and butylmagnesium bromides. With these other alkylmagnesium halides varying amounts of unsaturated and R. R. hydrocarbons are evolved in addition to ethane, propane and butane.

Experimental

All of the experiments were carried out under the standard conditions of earlier workers. A few of the compounds were studied in *n*-butyl ether according to Zerevitinoff's⁴ technique. Most of the determinations, however, were made by the revised method of Moureu and Mignonac,⁴ in which ethyl ether is used as the medium. Ciusa⁵ also used the technique of Moureu and Mignonac. Blank runs with pure benzoic acid were made in both methods in order to assure ourselves of correct manipulation.

The compounds used were of the highest purity commercially available and in a few cases additional special purification processes were used.

The gases evolved were analyzed by standard methods of combustion, preceded by removal of ether, unsaturated hydrocarbons and oxygen.

An experiment with nitrobenzene and methylmagnesium iodide in *n*-butyl ether showed that most of the gas was evolved at room temperature during the first ten minutes.⁶ However, in order to displace any dissolved gas and to expedite the several determinations, the reaction flask was immersed in a beaker of water at 60–70°. It was allowed to stand under these conditions for fifteen minutes, after external heat was removed. At the end of this period the water-bath was removed, the flask cooled to room temperature and a reading was then made of the volume of gas evolved.

The analysis of the saturated gas by the explosion method followed by measurement of carbon dioxide and water showed that the quantity of saturated hydrocarbon that might have been formed by a coupling reaction (for example, ethane when methylmagnesium iodide was used) was generally quite small and did not exceed several per cent. In order to verify this, two large runs were made with *n*-butylmagnesium bromide and cyclohexylmagnesium bromide. Forty-nine and two-tenths g. (0.4 mole) of nitrobenzene dissolved in 100 cc. of dry ether was added slowly to 2.25 moles of *n*-butylmagnesium bromide—an amount which was sufficient to give a positive color test for RMgX compound. After hydrolysis, careful fractionation gave about 2 g. (1.6%)

⁶ About 0.8 active hydrogen equivalent of gas was evolved during the first ten minutes. At the end of two hours, the equivalent of active hydrogen increased to 0.99. Finally, in this particular experiment, heating for fifteen minutes at 60–70° increased the active hydrogen equivalent to 1.35. This particular determination was the last of those made in the present study.

of *n*-octane and 6.0 g. or 3.6% of *n*-butyl alcohol. The reaction mixture of 0.17 mole of nitrobenzene and 0.4 mole of cyclohexylmagnesium bromide gave 2.4 g. or 3.6% of di-cyclohexyl.

TABLE I
RESULTS

No.	Compound	G. of compound	Grignard reagent	Gas evolved, (Cc stand. cond.)	No. of active hydrogens

		.2214		41.7	1.03
		.1993		34.4	0.95
		.4849		87.2	.99
3	Benzoic acid	.5206	C ₂ H ₅ MgBr	96.5	1.01 ^b
4	Nitrobenzene	.6004	C ₂ H ₅ MgBr	170.8	1.56
		.5724		155.7	1.50
5	<i>o</i> -Nitrotoluene	.6871	C ₂ H ₅ MgBr	180.0	1.60
		.3412		98.7	1.77 ^c
6	<i>p</i> -Nitrotoluene	.5872	C ₂ H ₅ MgBr	158.5	1.65 ^d
7	1,3,5-Trinitrobenzene	.1992	C ₂ H ₅ MgBr	31.2	1.49 ^e
8	<i>o</i> -Nitrobenzaldehyde	.5007	C ₂ H ₅ MgBr	121.9	1.65 ^f
		.5005		124.9	1.68
9	<i>m</i> -Nitrobenzaldehyde	.5297	C ₂ H ₅ MgBr	112.0	1.43 ^g
10	Nitrosobenzene	.4020	C ₂ H ₅ MgBr	91.8	1.09 ^h
11	<i>p</i> -Nitrosodiethylaniline	.5012	C ₂ H ₅ MgBr	46.4	0.74 ^h
12	Nitrobenzene	.6184	<i>n</i> -C ₄ H ₉ MgBr	213.8	1.90 ⁱ
13	Nitrobenzene	.7228	<i>n</i> -C ₄ H ₉ MgBr	221.6	1.68 ⁱ

^a When carried out at room temperature the number of active hydrogen was 0.98. However, when the reaction flask was heated to from 60–70° for fifteen minutes, then cooled and the gas measured, the number was 1.03. This slight increase was undoubtedly due to the expulsion of some dissolved gas. Accordingly, all other experiments with *n*-butyl ether were heated in like manner. With ethyl ether as the solvent the temperature of the water-bath was 40–45°.

^b This gas contained 0.5% of unsaturated compounds. Very probably this is due to a small quantity of ethylene formed in the preparation of ethylmagnesium bromide.

^c Included in this gas was 13% of unsaturated compounds.

^d There was 16.5% of unsaturation in this gas.

^e This includes 5.9% of unsaturation.

^f This includes 10.5% of unsaturation, and the other run giving 1.68 active hydrogen showed 8.0% unsaturation. The authors wish to thank the Eastman Kodak Company for the sample of *o*-nitrobenzaldehyde used in this study.

^g This includes 12.2% of unsaturation.

^h Includes 12.6% unsaturation, whereas the *p*-nitrosodiethylaniline has 9.6% unsaturation.

ⁱ Includes 10.8% unsaturation, whereas the experiment with *n*-butylmagnesium bromide gave 12.9% unsaturation.

Discussion of Results

The results in Table I show that all the nitro and nitroso compounds studied evolve varying amounts of gas when treated with alkylmagnesium

halides having an alkyl group of low molecular weight. In a way it is largely fortuitous that nitrobenzene shows but one active hydrogen when treated with methylmagnesium iodide;⁶ for, had ethylmagnesium bromide been used—a reagent which in the hands of others⁴ has given good results in estimating active hydrogen in a miscellany of compounds—the number of active hydrogens would have been about 50% greater. In this connection it is to be noted that *n*-propyl- and *n*-butylmagnesium bromides also give higher results than those obtained with methylmagnesium iodide.

The gas evolved from the two nitrobenzaldehydes studied is probably independent of the aldehyde group present, because benzaldehyde under corresponding conditions evolves no gas.

Tanasescu² got about one active hydrogen equivalent with *o*-nitrobenzaldehyde and less than one-third of an active hydrogen with *p*-nitrobenzaldehyde. He used methylmagnesium iodide, but on the basis of our results with different alkylmagnesium halides it is obvious that had he used a higher alkylmagnesium halide he would have found more active hydrogen. In this way he might have avoided the error of advancing formula (II), which is postulated as having one hydroxyl group largely because it evolves one equivalent of gas with methylmagnesium iodide.

Summary

The cyclic hydroxy structure proposed for *o*-nitrobenzaldehyde has no support on the basis of gas evolved when treated with an alkylmagnesium halide of low molecular weight. Gas evolution has been shown to be an inherent property of nitro and nitroso groups, and the Zerewitinoff method cannot be used with substituted aromatic nitro and nitroso compounds unless corrections are made for the gas evolved because of the nitro or nitroso group.

PARA-CYME NE STUDIES. VIII. A. PARA-CYMYLENE-2,5-DIAMINE. B. NEW DYES DERIVED FROM 2-AMINO- AND 2-AMINO-5-BROMO-*p*-CYME NE

BY ALVIN S. WHEELER AND LILLIE F. P. CUTLAR¹

RECEIVED JUNE 20, 1927

PUBLISHED NOVEMBER 5, 1927

In order to obtain cymylene-2,5-diamine we first acetylated 2-aminocymene (an Eastman Kodak product) but in view of the difficulty encountered in purifying the acetate we examined the statement of Wallach and Schrader² that a di-acetyl derivative, melting at 66°, may be prepared. We carried out six experiments, as follows: (1) boiled one mole of aminocymene (A) with one mole of acetic anhydride (B); (2) boiled A with a large excess of B; (3) one mole of A with one mole of acetyl chloride (C) in ether; (4) one mole of A with two moles of C in ether; (5) two moles of A with one mole of C in ether; (6) A with large excess of C in ether. In all cases the mono-acetyl compound, melting at 71°, was obtained. Our own method was to treat an acetone solution of aminocymene with a large excess of acetyl chloride, pouring the mixture into a large quantity of water. The acetate was nitrated as described by Andrews,³ modifying the process by pouring the nitration mixture into a sodium hydroxide solution containing ice. Even so the product was purified with difficulty. Its acetone solution was boiled many times with kelp char before the product could be recrystallized from alcohol. The nearly white needles melted at 168°. The location of the nitro group was proved by converting it into di-acetylcymylene-2,5-diamine prepared by Kehrmann and Messinger⁴ and by Wallach,⁵ these authors giving 260° as the melting point. The usual reducing agents failed to give a product which could be purified, but success was obtained with titanium trichloride and hydrochloric acid in an atmosphere of carbon dioxide, with the assistance of H. A. Ljung in this Laboratory. The desired compound, melting at 260°, was obtained on acetylating the reduction product with acetic anhydride and sodium acetate. Kehrmann and Messinger obtained it from thymoquinonedioxime. We then obtained this diacetate by a very different method. Aminocymene was coupled with diazotized sulfanilic acid. The dye produced was reduced with stannous chloride and the diamine ob-

tained was acetylated. This method also indicates that the second amino group is in position 5 and also the nitro group because the coupling must take place in a position para to the amino group.

Three new salts of aminocymene were prepared: the nitrate, the hydrobromide and the trichloro-acetate. Two new dyes were prepared by coupling aminocymene with sulfanilic acid and with *p*-nitrosodimethylaniline, the latter dye being of the Eurhodine type. The sulfanilic acid dye furnishes a splendid raw material for the preparation of cymylene-2,5-diamine.

The bromination of aminocymene was first carried out by the method used by one of us and Smithey⁶ in which a carbon tetrachloride solution of aceto-amidocymene is treated with bromine, the product then being hydrolyzed. But since the hydrobromide of aminobromocymene was needed for most of the work, the acetylation step was omitted and the aminocymene directly brominated. Apparently the only product of the reaction was the hydrobromide of 2-amino-5-bromo-*p*-cymene. It will be recalled that Kekulé⁷ brominated aniline directly and obtained a bad mixture of aniline hydrobromide, monobromo-, dibromo- and tribromo-aniline. As two more hydrogen are substituted in aminocymene than in aniline we have a very different situation. Azo dyes were obtained by coupling aminobromocymene with *o*-cresol, catechol, phloroglucinol, carvacrol and *p*-toluidine. In addition sulfanilic acid and anthranilic acid were diazotized and coupled with aminobromocymene.

Their color reactions with sulfuric acid were noted. The names given to the colors are based on Ridgway's Standards.⁸

Experimental Part

Salts of 2-Amino-*p*-cymene

The three salts described below were made by mixing the constituents in the cold. They were recrystallized from a mixture of ether and petroleum ether. All are soluble in water, alcohol, acetone and ether and melt with decomposition. Analysis was made by titration with potassium hydroxide, using methyl red as indicator

Summary

1. The nitrate, hydrobromide and trichloro-acetate of 2-amino-*p*-cymene were prepared.
2. Aminocymene gave dyes with sulfanilic acid and with *p*-nitrosodimethylaniline, the latter being a Eurhodine.
3. The sulfanilic acid dye is an excellent raw material for making cymylene-2,5-diamine.
4. The sulfate of 2-amino-5-bromo-*p*-cymene was prepared.
5. New azo dyes were prepared by coupling 2-amino-5-bromo-5-cymene with *o*-cresol, catechol, phloroglucinol, carvacrol and *p*-toluidine. Sulfanilic and anthranilic acids were diazotized and coupled with aminobromocymene.

CHAPEL HILL, NORTH CAROLINA

[CONTRIBUTION FROM LABORATORIES OF THE NEW YORK STATE COLLEGE OF FORESTRY
AND THE CHEMICAL DEPARTMENT OF SYRACUSE UNIVERSITY]A NOTE CONCERNING A NEW METHOD FOR THE PRODUCTION
OF CELLOBIOSE FROM CELLOBIOSE OCTA-ACETATE

BY F. C. PETERSON AND C. C. SPENCER

RECEIVED JUNE 22, 1927

PUBLISHED NOVEMBER 5, 1927

Cellobiose (or cellulose as it was formerly called) is a disaccharide sugar obtained by partial hydrolysis or acetolysis of either cotton or wood cellulose. It is also the product of the action of certain microorganisms on cellulose.

Cellobiose is at present attracting considerable interest in the field of bacteriology. It has been found that cellobiose may be used as a test for the separation of two types of bacteria commonly found in water. Previously the identification of these two types of organisms has been the result of data compiled from correlated tests. Cellobiose, however, is utilized by *A. aerogenes* with acid and gas formation, whereas no changes

are brought about by any strains of *B. coli*. This test is, therefore, specific in differentiating these two types of organisms. When applied to public health work it may thus be used to indicate the presence or absence of fecal pollution.

The literature at present reveals two procedures for the preparation of this sugar. The method given by Skraup and König¹ and published in 1899 is the older of the two, and the second, described by Maquenne and Goodwin² and published in 1904, is really a modification of the former method. Both of them depend on the saponification of the octa-acetate of the sugar by means of alcoholic potassium hydroxide, with subsequent isolation of the sugar from the potassium salt by means of an acid (aqueous acetic acid was used by Skraup and König; perchloric acid was used by Maquenne and Goodwin). In either case the solutions after acid treatment were concentrated *in vacuo* to a sirup or solid and the sugar was purified by repeated crystallization from methanol or ethanol.

Experiments in our Laboratories have shown that either of the methods gives satisfactory yields in the preparation of this sugar. Yield figures of purified cellobiose up to 75% were obtained. The procedures involved are, however, long and tedious and cellobiose if prepared commercially in this manner would necessarily have to be quoted at \$3.00 or \$4.00 per gram. In order that the time factor might be reduced and the yield increased, if possible, other means of preparation were sought.

A procedure has been developed which reduces the time of preparation to approximately one-half that formerly required and yields up to 85% of purified cellobiose have been obtained. Quantitative studies of the method have been confined to the preparation of several batches of this sugar.

The procedure for the newly developed method was as follows.

A 10% solution of sodium ethylate was prepared in 95% alcohol. Ten grams of finely pulverized cellobiose octa-acetate were incorporated into 85 cc. of this solution during a period of one hour. The mixture was constantly agitated by a mechanical stirrer. The reaction took place rapidly, as evidenced by the strong odor of ethyl acetate which was given off almost immediately after the addition of the first portions of the acetate, and was complete in less than one hour. The time limit of one hour was allowed in order that any small lumps of the acetate (resulting from improper pulverization) might be completely saponified. The sodium salt was then collected by filtration, washed with absolute alcohol and dissolved in a minimum volume of water and again filtered. To the resulting aqueous solution glacial acetic acid was slowly added until a precipitate began to form.

Very frequently complete crystallization of the cellobiose took place

¹ Skraup and König, *Monatsh.*, 22, 1011 (1901).

² Maquenne and Goodwin, *Bull. soc. chim.*, 31, 854 (1904).

within 10 or 15 minutes after the addition of sufficient glacial acetic acid. In other cases it was necessary to allow the mixture to stand overnight in order that complete crystallization might be effected. Apparently somewhat decreased yields result when it becomes necessary to adopt the latter procedure.

The crude cellobiose was collected by filtration, washed with ether and dried at 65°. Purification of the crude sugar was accomplished by dissolving it in a minimum volume of water, filtering and adding acetone to the aqueous solution until reprecipitation was complete. A product of sufficient purity was usually obtained after two such recrystallizations from acetone. Approximately 80% of the acetone was recoverable by fractional distillation. Yields of crude cellobiose as high as 95% have been obtained by the use of this method. Yields of purified sugar as high as 85% have also been obtained. The purified sugar melted at 225° (uncorr.) and gave satisfactory results when analyzed for carbon and hydrogen. Its rotation (in water) was 24.4° at the end of fifteen minutes and 35.2° at the end of 27 hours.

The advantages derived through the use of this method over those previously employed for the preparation of cellobiose from its acetate are as follows:

(1) Yield figures of both crude and purified cellobiose are materially higher than those by the methods of Skraup and König and Maquenne and Goodwin. The yield of purified sugar melting at 225° (uncorr.) has been increased approximately 10%.

(2) The crude cellobiose as it crystallizes from glacial acetic acid is free from any gummy, foreign material. When using the methods employed by the former investigators some gummy material is always associated with the crude cellobiose. Contamination of the crude sugar by this gum increases the number of recrystallizations necessary in order that a product of sufficient purity may be obtained. Inasmuch as each recrystallization is accompanied by a decrease in yield and inasmuch as the number of recrystallizations is less by the use of our method than by those previously employed, this may explain in part the higher yields which we were able to obtain.

(3) The time consumed in the preparation of cellobiose is reduced approximately one-half and in some cases three-quarters of that formerly required.

(4) Needle-shaped crystals of purified cellobiose measuring approximately two millimeters or over in length are consistently obtained. Upon only one occasion during a period of two years have crystals of this size been obtained when following the methods of Skraup and König or Maquenne and Goodwin. These latter methods usually yield needle-shaped crystals of approximately $\frac{1}{10}$ of one millimeter in length.

(5) Both labor and cost of materials are reduced. This allows cellobiose to be prepared commercially at a figure which is not prohibitive to those laboratories desiring to use it in public health work.

HYDROXYNAPHTHOQUINONE STUDIES. VII. THE BROMINATION OF NAPHTHAZARIN

BY ALVIN S. WHEELER AND B. G. CARSON¹

RECEIVED JUNE 25, 1927

PUBLISHED NOVEMBER 5, 1927

The first study of the bromination of naphthazarin was carried out by one of us and Edwards.² The constitution of naphthazarin was regarded at that time as 5,6-dihydroxy-1,4-naphthoquinone but it has now been proved to be 5,8-dihydroxy-1,4-naphthoquinone. Dimroth and Ruck³

have shown that pyroboro-acetate reacts with naphthazarin to form a di-boro-acetate. Therefore, the two hydroxyl groups must be para to each other and not ortho, since this reaction occurs between carbonyl and hydroxyl groups ortho to each other. Pfeiffer⁴ has shown that tin tetrachloride forms an addition product with loss of one molecule of hydrochloric acid, such a reaction occurring with hydroxyquinones where the carbonyl is ortho to the hydroxyl group. Many formulas in the literature are now affected by this new formula for naphthazarin.

Bromination of Naphthazarin

Naphthazarin takes up a maximum of four atoms of bromine in hot glacial acetic acid solution. Positions 2, 3, 6 and 7 are undoubtedly occupied (Formula II). This tetrabromo naphthazarin gives a diacetyl derivative (III) and a dianilide (IV) on boiling with aniline. In the latter reaction the aniline may have reacted with the bromine atoms of the quinone ring or with those of the phenol ring. The same doubt exists in regard to the relative mobility of the hydrogen atoms of the two rings in naphthazarin. When two chlorine or bromine atoms are taken up, which ring do

¹ This paper is an abstract of a thesis submitted in partial fulfilment of the requirements for the degree of Doctor of Philosophy, at the University of North Carolina, in June, 1927.

Experimental Part

2,3,6,7-Tetrabromonaphthazarin (II).—Five g. (1 mole) of pure sublimed naphthazarin was dissolved in 139 cc. of glacial acetic acid and treated with 15.9 g. of bromine (a little less than four moles). The mixture was boiled under a reflux for eight hours. The product separated on cooling the solution. It was recrystallized from glacial acetic acid, using 35–45 cc. of acid for each gram of product. The crystals are slender, flat, bronze-colored needles, melting at 300°. The compound is insoluble in ether, difficultly soluble in hot alcohol and acetone but easily soluble in hot chloroform, carbon tetrachloride and glacial acetic acid. It is very soluble in toluene. This derivative may also be prepared by allowing the brominating mixture to stand for three weeks at room temperature.

Anal. Subs., 0.1195: AgBr, 0.1772. Calcd. for $C_{10}H_4O_4Br_4$: Br, 63.24. Found: 63.11.

Acetylation yields a diacetate and aniline a dianilide derivative. The bromine is removed by boiling the compound with a 2% hydrochloric acid solution of stannous chloride.

Diacetate (III).—The diacetate was best prepared by first making the sodium salt of the tetrabromonaphthazarin by the ether-sodium carbonate method and then treating the salt with a mixture of equal parts of acetyl chloride and acetic anhydride. Enough of the liquid mixture was used to act as a solvent. It was heated until no further change took place in color, which passed from blood-red to yellow. The product was precipitated with water. It is easily soluble in glacial acetic acid, acetone, chloroform and benzene but difficultly soluble in alcohol and ether. It is best recrystallized from boiling chloroform. It forms light yellow, granular crystals, melting at 262°. It can also be prepared from tetrabromodiquinone by simultaneous reduction and acetylation.

Anal. Subs., 0.1714: AgBr, 0.2185. Calcd. for $C_{10}H_6O_6Br_4$: Br, 54.24. Found: 54.25.

Dianilide (IV).—Two g. (1 mole) of tetrabromonaphthazarin was dissolved in 250 cc. of alcohol and 1 g. of aniline added. The mixture was refluxed for eight hours when, judging from the color of the solution, the reaction was complete. The solution was concentrated to 25 cc. and cooled. The product was recrystallized three times from glacial acetic acid. It consisted of microscopic bronze-colored needles, melting at 251°. There were some red fumes about twenty degrees below the melting point; weight, 2.3 g. It is easily soluble in benzene, alcohol and glacial acetic acid. It dissolves in sodium carbonate solution.

Anal. Subs., 0.1626: AgBr, 0.1200. Calcd. for $C_{22}H_{14}O_4N_2Br_2$: Br, 31.83. Found: 31.41.

2,3,6,7-Tetrabromodiquinone (V).—Five g. of naphthazarin was dissolved in 150 cc. of glacial acetic acid and treated with 30 g. of bromine, nearly double the amount required to make tetrabromonaphthazarin. The mixture was allowed to stand for five weeks at room temperature. At the end of this period a yellow product had settled out. Under the microscope the crystals were found to be yellow platelets, highly refractive and mixed with some red needles. The latter were probably naphthazarin since, on heating the product, red fumes began to appear at 180°. Purification was accomplished by recrystallizing from boiling glacial acetic acid, ethyl acetate or toluene. The quinone is difficultly soluble in glacial acetic acid, acetone, chloroform and benzene; nearly insoluble in alcohol. When recrystallized from acetic acid or ethyl acetate, the color changes from yellow to red and the crystalline form from platelets to microscopic needles. The pure substance sublimates at 275–280°. It is insoluble in sodium carbonate solution. Its preparation can be carried out in hot solution.

Anal. Subs., 0.2538: AgBr, 0.3760. Calcd. for $C_{10}O_4Br_4$: Br, 63.46. Found: 63.04.

The diquinone can be reduced and acetylated in one operation using zinc dust and acetic anhydride, yielding diacetyltetrabromonaphthazarin (III).

Dianilide (VI).—This product was prepared in the same manner as (IV), glacial acetic acid, however, being used as solvent. One g. of the diquinone gave 0.7 g. of product. On recrystallizing from glacial acetic acid, it formed brown needles with a metallic luster, subliming at 220–225°. It is easily soluble in alcohol, benzene and glacial acetic acid, less soluble in ether, nearly insoluble in petroleum ether and insoluble in sodium carbonate solution.

Anal. Subs., 0.3062: AgBr, 0.2288. Calcd. for $C_{22}H_{14}O_4Br_2$: 31.97. Found: 31.78.

2,3-Naphthazarin Dichloride (X).—This compound was obtained by Zincke and Schmidt⁷ by chlorinating naphthazarin. We obtained it from tetrahydroxynaphthalene. Two and one-half g. of the latter compound was dissolved in 30 cc. of chloroform and cooled with ice. Dry chlorine was passed in slowly for ten hours. The solution at the end of this time was red, due to a small amount of impurity. The solution was concentrated by blowing off some of the solvent with air. The product was filtered and a small quantity of red crystals was dissolved out on the filter by dropping cold acetone upon the material while the suction was on. The product became pure yellow and melted at 220°.

2,3-Dibromonaphthazarin (VII).—This compound was first made by one of us and Edwards⁸ from tetrahydroxynaphthalene. This preparation was made from naphthazarin. One g. (1 mole) of naphthazarin was dissolved in 25 cc. of glacial acetic acid and treated with 1.5 g. of bromine (slightly less than 2 moles). The solution was boiled for four hours. The product, recrystallized from glacial acetic acid, consisted of red leaves of a metallic luster, melting at 258°; weight, 1.3 g. This product will sublime. The reaction may also be carried out at 70°. No anilido derivative could be obtained. An attempt was made to prepare a Eurhodol. A mixture of 1.75 g. of dibromonaphthazarin and 0.60 g. of *o*-phenylenediamine was dissolved in 200 cc. of absolute alcohol and refluxed for eight hours; 1.5 g. of a purplish-blue compound was obtained. It was nearly insoluble in the usual organic solvents. As it dissolved slightly in glacial acetic acid, large amounts of this were used in an attempt to purify the product. It decomposes at about 225°. The substance was not pure, as the content of bromine was 3% low.

Other Reactions

Action of Phosphorus Trichloride.—Two g. of naphthazarin was mixed with 5 g. of dry sodium carbonate and 75 cc. of phosphorus trichloride and refluxed for thirteen hours. The solution became yellow and some yellow substance collected in the condenser. It was poured into sodium carbonate solution. The dirty red precipitate was insoluble in the usual organic solvents. Its sodium hydroxide solution was intensely blue.

Nitration.—Three methods of nitration were tried: (1) a mixture of boric, sulfuric and nitric acids; (2) sulfuric and nitric acids; (3) acetic and nitric acids. The reactions were carried out at 5°. In each case the product was reduced with stannous chloride and diquinol, melting at 154°, obtained.

Coupling with Amines.—*p*-Chloro-aniline was diazotized and coupled

with naphthazarin. The analysis showed a deficiency of 1.4% of chlorine. We were unable to purify the product further.

We hereby wish to thank the Badische Anilin und Soda-Fabrik of Ludwigshaven on the Rhine for a very generous supply of sublimed naphthazarin.

Summary

1. Recent work shows that the hydroxyl groups in naphthazarin are para to each other and not ortho.

2. The following new derivatives of naphthazarin were prepared: 2,3,6,7-tetrabromonaphthazarin, its diacetate and dianilide; 2,3,6,7-tetrabromodiquinol and its dianilide.

3. The known dichloride of naphthazarin was also made from diquinol and likewise the known dibromonaphthazarin.

4. Certain unsuccessful reactions are noted.

CHAPEL HILL, NORTH CAROLINA

[COMMUNICATION NO. 311 FROM THE RESEARCH LABORATORY OF THE EASTMAN KODAK COMPANY]

THE LOWER FATTY ACIDS OF COCONUT OIL

By E. R. TAYLOR AND H. T. CLARKE

RECEIVED JUNE 27, 1927

PUBLISHED NOVEMBER 5, 1927

The analysis of coconut oil has been carried out in a variety of ways, each of which has led to a widely different result. A full discussion of the subject is to be found in the paper of Armstrong, Allan and Moore,¹ in which it was clearly shown by these authors that fractionation of the esters of the acids can yield significant results only when the separation of the various components has been so complete as to yield these in substantially pure form, so that the saponification values of the intermediate fractions may legitimately be employed for the estimation of their composition. These authors conducted their fractionation on the ethyl esters obtained from not more than one kilo of coconut oil, and were unable to detect any acid lower than caprylic acid.

We have carried out a systematic fractionation on approximately 130 kilos of methyl esters obtained from commercial coconut oil² by a modification of the method of Haller and Youssoufian.³ The fractionation was carried out repeatedly and systematically until the total amount of fractions intermediate between those of the pure components amounted to

¹ Armstrong, Allan and Moore, *J. Soc. Chem. Ind.*, **44**, 63T (1925).

² This material was stated by its manufacturers (the Procter and Gamble Company) to have been prepared from copra of mixed origin but to be of representative quality.

³ Haller and Youssoufian, *Compt. rend.*, **143**, 803 (1906).

less than 5% of the entire amount. No attempt was made to separate the esters of acids higher than myristic.

Distributing the components of the intermediate fractions pro rata according to the weights and boiling ranges of these, the results indicate the following composition: methyl caproate, 0.48%; methyl caprylate, 8.9%; methyl caprate, 5.7%; methyl laurate, 45.2%; methyl myristate, 16.5%; higher esters, 23.4%. The value for methyl myristate should be slightly higher than is indicated since its separation from the higher esters was not carried to completion. The above percentages are based on the final total weight, which was about 3% lower than that of the weight of the crude ester. The losses, which may be partially accounted for by the presence of alcohol, have thus been distributed through the series.

The purity of the individual esters was checked by determining the melting points of the acids prepared by hydrolysis of the appropriate fractions; in all cases satisfactory agreement with recorded values was obtained.

Attention is drawn to the presence of methyl caproate. Its identity was established by conversion of the free acid through its chloride into the amide, which possessed the same melting point as the amide prepared from synthetic caproic acid and showed no change of melting point on mixing with an authentic sample. The anilide also possessed the melting point recorded in the literature.

Since only 3 g. of distillate passed over below 151° (corr.), it may confidently be asserted that butyric acid is not present in detectable amounts in coconut oil.

Experimental

In 22-liter flasks were placed 8 kg. of coconut oil, 9600 g. of methyl alcohol and 500 g. of sulfuric acid. The mixture was refluxed for forty-eight hours on the steam-bath, allowed to cool to room temperature and the top layer of esters separated. The mixture of esters was placed in a 15 gal. crock and made just neutral to methyl orange with sodium carbonate solution, when 6 liters of a saturated salt solution was stirred into the mixture and allowed to settle. The bottom layer was siphoned off and discarded.

The crude ester (130 kg. from 136 kg. of coconut oil) was distilled under reduced pressure in 7-8 liter portions from a 12-liter flask fitted with a 24cm. column, dividing the distillate into five fractions. Fractionation of these was systematically carried out until the distribution of the various fractions shown in the table was reached. The final distillations of the lowest fractions were carried out under atmospheric pressure.

Samples of the esters were saponified; the resulting free acids showed the following constants: caproic acid, b. p. 204-206° (corr.); caprylic acid, m. p. 14-15°; capric acid, m. p. 30-31°; lauric acid, m. p. 42-43°; myristic

acid, m. p. 53-54°. A sample of the caproic acid was converted by means of thionyl chloride into the acid chloride and the crude product so obtained was added with stirring to concentrated ammonia held below 0° by the addition of ice. The precipitated amide, after washing with dilute ammonia and drying in air, melted at 93-95° and possessed a distinct odor of caproic acid. On recrystallization from toluene the odor was removed and the melting point rose to 98-99°. A sample of authentic caproic acid (prepared from *n*-butyl bromide by the malonic ester synthesis) yielded an amide which also melted at 98-99°.⁴ A mixture of these two amides showed no change in melting point. Another portion of the chloride was converted into the anilide by adding it to a benzene solution of aniline. The benzene solution was washed with dilute acid and dilute alkali and concentrated, when it deposited crystals of the anilide which melted at 94.5-95.5°.⁵

Summary

Systematic fractionation of about 130 kilos of methyl esters of coconut oil acids has been carried out; the results give definite information as to the quantitative distribution of the various lower acids in the original oil. The following acids have been isolated: caproic acid (0.46%), caprylic acid (8.7%), capric acid (5.6%), lauric acid (45.0%), myristic acid (16.5-18%).

PARA-CYME NE STUDIES. IX. THE NITRATION OF 2-AMINO-*p*-CYME NE¹

BY ALVIN S. WHEELER AND F. P. BROOKS

RECEIVED JUNE 29, 1927

PUBLISHED NOVEMBER 5, 1927

The nitration of 2-amino-*p*-cymene or carvacrylamine has not hitherto been undertaken. A pure acetyl derivative was difficult to obtain if the aminocymene was boiled with glacial acetic acid. A quicker and better method recently noted in this Laboratory is to treat an acetone solution of aminocymene with acetyl chloride. The acetyl derivative was nitrated at 0° in sulfuric acid solution with nitric acid. Hydrolysis of the nitro compound gave an aminonitrocymene which is a liquid. Its hydrochloride turns purple readily in the light. The benzoyl derivative of aminocymene was prepared with the hope of more readily obtaining a pure compound for nitration. A nitro derivative was obtained from the benzoate but its hydrolysis was impossible in open vessels. Its reduction gave benzamido-aminocymene. The acetyl derivative and the hydrochloride of the latter were prepared.

Two dyes were obtained by coupling diazotized aminonitrocymene with 2-naphthol and with Neville-Winther's salt.

Experimental Part

2-Aceto-amido-5-nitro-*p*-cymene, $C_9H_7CH_2C_6H_7NHCOCH_3NO_2$.—Nineteen parts of acetyl cymidine, m. p. 71°, was dissolved in 84 parts of sulfuric acid (1.84), cooled to 0° and treated dropwise with 10 parts of 70% nitric acid. The nitration mixture was poured into ice water. The solid product was filtered and washed with much water. It was then broken up into small pieces, washed with sodium hydroxide and recrystallized from hot alcohol. It is usually difficult to get the product into crystalline form; pale yellow prisms, m. p. 148°, very soluble in chloroform, fairly soluble in alcohol, benzene and acetic acid and insoluble in petroleum ether.

Anal. Subs., 0.1816: N_2 , 19.4 cc. (20°, 745 mm.). Calcd. for $C_{12}H_{16}O_4N_2$: N, 11.87. Found: 12.23.

2-Amino-5-nitro-*p*-cymene, $C_9H_7CH_2C_6H_7NH_2NO_2$.—The aceto-amido compound was hydrolyzed with boiling concd. hydrochloric acid. The free base was thrown out with alkali and extracted with ether. The orange-colored oil left after evaporation of the ether was steam distilled. The distillate was saturated with salt and extracted with ether. The yellow liquid left after evaporation of the ether was distilled at atmospheric pressure, a considerable portion decomposing. The pure nitro-amine distilled above 250° and possessed a sweet taste.

Anal. Subs., 0.2009: N_2 , 25.8 cc. (23°, 752 mm.). Calcd. for $C_{10}H_{14}O_2N_2$: N, 14.43. Found: 14.24.

¹ This paper is an abstract of a thesis submitted to the faculty of the University of North Carolina in partial fulfilment of the requirements for the degree of Doctor of Philosophy, in June, 1926.

Hydrochloride.—The hydrochloride crystallizes in clusters of white needles which turn purple in the light. It is quickly hydrolyzed by alcohol or the moisture of the air, turning yellow. It was recrystallized from alcohol containing hydrochloric acid. It was rapidly dried and analyzed by titration, using phenolphthalein as indicator.

Anal. Subs., 0.1000, 0.1000: 21.44, 21.44 cc. *N*/50 NaOH. Calcd. for $C_{10}H_{14}O_2N_2 \cdot HCl$, 15.81. Found: 15.71, 15.71.

2-Benzamido-5-nitro-*p*-cymene, $C_6H_2CH_2C_6H_7NHCOC_6H_5NO_2$.—Aminocymene was benzoylated in the usual way. The melting point of the product remained at 90.5° after repeated recrystallizations from hot alcohol although Andrews² gives 96.5°. The product was nitrated by dissolving 10 g. in 50 cc. of concd. sulfuric acid, cooling to 0° and slowly adding 10 g. of concd. nitric acid, holding the temperature at 0°. The mixture was poured into 600 cc. of water containing ice. The yellow precipitate was filtered, well washed with water and dried on a porous plate; weight, 36 g. A preparation with 30 g. gave a yield of 95 g. These are very high yields but recrystallizing from alcohol brings the yields down at once to expected figures. About 16 g. dissolve in 100 cc. of boiling alcohol and 2 g. remain in solution at room temperature. The crystals are very pale yellow, six-sided prisms which melt at 215–218°.

Anal. Subs., 0.2516: N_2 , 21.2 cc. (23°, 754 mm.). Calcd. for $C_{17}H_{18}O_2N_2$: N , 9.39. Found: 9.39.

2-Benzamido-5-amino-*p*-cymene, $C_6H_2CH_2C_6H_7NHCOC_6H_5NH_2$.—Ten g. of benzamidonitrocymene was reduced in alcoholic solution with tin and hydrochloric acid. The alcohol was evaporated off, the residue taken up with water and the solution made strongly alkaline. The solution was extracted with ether, the latter evaporated off and the yellow residue dissolved in hydrochloric acid and the solution filtered and treated with ammonia. The free base was purified by reprecipitating several times. It is a pale yellow solid, melting at 115°. It is soluble in alcohol and acetic acid, less soluble in ether and insoluble in water. The yellow alkaline solution rapidly becomes bluish. The ether solution is yellow with a bluish fluorescence.

Anal. Subs., 0.2333: N_2 , 23 cc. (29°, 757 mm.). Calcd. for $C_{17}H_{18}ON_2$: N , 10.53. Found: 10.66.

Hydrochloride.—Hydrogen chloride was passed into an ether solution of the amine, giving pale yellow crystals which deepen in color on drying. It melts with decomposition above 200°.

Anal. Subs., 0.1000: 33 cc. of *N*/10 NaOH. Calcd. for $C_{17}H_{20}ON_2HCl$: HCl , 11.97. Found: 12.03.

2-Benzamido-5-aceto-amido-*p*-cymene was prepared by boiling the 5-amino compound with glacial acetic acid for ten hours. The solution was concentrated and the acid neutralized. The precipitate was dissolved in ether, from which it separated as a yellow powder, melting at 120°. Analysis for nitrogen gave 8.11% against a theoretical value of 9.04%, showing the compound to be impure, but scarcity of material prevented further purification.

New Azo Dyes

1-(5-Nitrocarvacrylazo)-2-naphthol, $C_6H_2CH_2C_6H_7NO_2N_2C_{10}H_6OH$.—Diazotized nitro-aminocymene was coupled with 2-naphthol in the usual way. The dye was recrystallized from glacial acetic acid. It formed well-shaped deep red prisms melting at 245°.

Anal. Subs., 0.2145: N_2 , 23.4 cc. (20°, 752 mm.). Calcd. for $C_{20}H_{19}O_2N_2$: N , 12.04. Found: 12.30.

² Andrews, *J. Ind. Eng. Chem.*, 10, 453 (1918).

2-(5-Nitrocarvacrylazo)-1-naphthol-4-sulfonic Acid, $C_{16}H_9CH_3C_2H_4NO_2N_3C_{10}H_7OHSO_3ONa$.—Nitro-aminocymene was diazotized and coupled with Neville-Winther's salt. The product was salted out of solution. It is a red dye, soluble in water and alcohol and was recrystallized from alcohol.

Anal. Subs., 0.1511: N_3 , 13 cc. (24°, 753 mm.). Calcd. for $C_{26}H_{19}O_4N_3SNa$: N, 9.33. Found: 9.51.

The Constitution of Aminonitrocymene

It is possible for the nitro group to enter any of the vacant positions, 3, 5 and 6. Position 6 is eliminated because the nitro compound does not correspond to the 2-amino-6-nitro-*p*-cymene described by one of us and Harris.³ Its acetyl derivative melts at 115° and not 148°. Similarly the benzoyl derivatives are wide apart in melting points. The expectation is that the nitro group will enter para to the amino group, that is, Position 5. That this is the case is indicated by our conversion of the acetyl derivative into 2,5-diaceto-amido-*p*-cymene, described by Kehrmann and Messinger,⁴ who obtained it from thymoquinonedioxime. We reduced aceto-amidonitrocymene with tin and hydrochloric acid and purified the hydrochloride of 2-aceto-amido-5-amino-*p*-cymene.

Anal. Subs., 0.1000: 44.9 cc. *N*/10 NaOH. Calcd. for $C_{17}H_{18}ON_2HCl$: HCl, 16.09. Found: 16.35.

It is white but readily turns pink. The free base quickly turns to a blue compound. The diacetyl derivative was obtained by boiling with acetic anhydride and sodium acetate. The product, recrystallized from alcohol, melted at 260°, which is the melting point given by Kehrmann and Messinger for 2,5-diacetylamido-*p*-cymene.

Summary

1. 2-Amino-5-nitro-*p*-cymene was obtained by the nitration of 2-aceto-amido-*p*-cymene.
2. Its constitution was determined by its conversion into 2,5-diaceto-amido-*p*-cymene, previously made from thymoquinonedioxime.
3. The following new compounds were made: 2-aceto-amido-5-nitro-*p*-cymene and its hydrochloride; 2-benzamido-5-nitro-*p*-cymene; 2-benz-amido-5-amino-*p*-cymene, its hydrochloride and acetate; the hydrochloride of 2-aceto-amido-5-amino-*p*-cymene.
4. Two azo dyes were made by coupling the aminonitrocymene with 2-naphthol and with 1-naphthol-4-sulfonic acid.

PIPERIDINE DERIVATIVES

IV. SUBSTITUTED PIPERIDINE-ALKYL BENZOATES AND PARA-AMINOBENZOATES

By S. M. McELVAIN

RECEIVED JUNE 29, 1927

PUBLISHED NOVEMBER 5, 1927

The numerous investigations of the amino-alkyl benzoate type of local anesthetics have produced a few compounds in which the piperidine nucleus comprises the amino group. Pyman¹ prepared piperidyl² ethylbenzoate. It was found to have local anesthetic properties but a rather high toxicity. Brill³ prepared N-piperidinopropylbenzoate and mentioned that it had local anesthetic properties. Recently the piperidino-ethyl esters of propylaminobenzoic acid and methoxy-ethylaminobenzoic acid have been described⁴ as local anesthetics. Since the completion of the work described below, Barnes and Adams⁵ have described the *p*-aminobenzoates of N-(β -hydroxy-ethyl)-piperidine, N-(γ -hydroxypropyl)-piperidine, β -(β -carbomethoxypiperidyl)-ethyl alcohol and γ -(β -carbomethoxypiperidyl)-propyl alcohol. They were local anesthetics, the substituted piperidine derivatives being less effective than the unsubstituted.

It seemed probable that the presence of certain substituent groups in the piperidine nucleus of such compounds would produce a definite effect on their physiological properties. Accordingly, a number of substituted piperidino-alkylbenzoates were prepared and submitted for pharmacological study. These compounds do not form a well-defined series, but are merely some of the possible types that offered a particular preparational advantage on account of the availability of the necessary substituted piperidines. Work is at present under way which will, it is hoped, sufficiently complete the various indicated series to point to some fairly definite conclusions relative to the effect of structure on physiological action.

This paper deals with the preparation and the preliminary pharmacological study of the following compounds: γ -piperidinopropylbenzoate (I), γ -2-methylpiperidinopropylbenzoate (II), γ -2-propylpiperidinopropylbenzoate (III), γ -3-methylpiperidinopropylbenzoate (IV), β -3-methylpiperidino-ethylbenzoate (V), γ -3-carbethoxypiperidinopropylbenzoate (VI),

¹ Pyman, *J. Chem. Soc.*, 93, 1793 (1908).

² The nomenclature used in this paper is that suggested by Meyer and Jacobson and designates as "piperidino" the radical formed by dropping the hydrogen from the nitrogen atom of piperidine and as "piperidyl" the radical formed by dropping a hydrogen from one of the carbon atoms of piperidine. By this nomenclature Pyman's compound would be "piperidino-ethyl benzoate."

³ Brill, *THIS JOURNAL*, 47, 1134 (1925).

⁴ Brit. pat. 241,767; *C. A.*, 20, 3539 (1926).

⁵ Barnes with Adams, *THIS JOURNAL*, 49, 1307 (1927).

γ -piperidinopropyl-*p*-aminobenzoate (VII), γ -3-methylpiperidinopropyl-*p*-aminobenzoate (VIII), γ -3-carbethoxypiperidinopropyl-*p*-aminobenzoate (IX). The unsubstituted piperidino derivatives (I and VII) were included in the above list for comparison. All of these substances were isolated and used as the hydrochlorides.

The benzoates were most conveniently prepared by the condensation of the substituted piperidine with a chloro-alkylbenzoate. The *p*-aminobenzoates were prepared by first condensing the piperidine with trimethylene chlorohydrin, acylating the resulting piperidinopropyl alcohol with *p*-nitrobenzoyl chloride, and finally reducing the resulting *p*-nitrobenzoate catalytically to the *p*-aminobenzoate. These reactions are represented with 3-methylpiperidine, thus

A marked difference in the reactivity of the 2 substituted piperidines and the 3 substituted piperidines was noted in the above condensation. The 3-methyl- and 3-carbethoxypiperidines reacted practically completely with γ -chloropropylbenzoate when heated for twenty to thirty minutes at 100°. The amount of reaction was determined by the quantity of the hydrochloride of the secondary amine that was obtained when the reaction mixture was diluted with ether. Under the same conditions there was hardly any reaction between the 2-methyl- or 2-propylpiperidine and the chloro ester. It was found necessary to heat these reactants for one to three hours at temperatures of 125–150° in order to produce a satisfactory reaction.

Experimental

3-Carbethoxypiperidine (ethyl nipecotate).—This compound was prepared by the procedure described by McElvain and Adams.⁶

⁶ McElvain and Adams, *THIS JOURNAL*, **45**, 2745 (1923).

3-Methylpiperidine.—3-Methylpyridine (β -picoline) was prepared from glycerol ammonium phosphate and phosphorus pentoxide according to the method of Schwarz.⁷ The hydrochloride was prepared and reduced catalytically, using the same procedure as that employed for the preparation of 3-carbethoxypiperidine. The 3-methylpiperidine so obtained boiled at 123–126°.

2-Methylpiperidine.—2-Methylpyridine (α -picoline) was isolated from the picoline fraction of coal tar bases which boiled at 127–132° by the method of Heap, Jones and Speakman.⁸ It was reduced in a manner similar to that used for 3-methylpyridine. The 2-methylpiperidine boiled at 114–116°.

2-Propylpiperidine.—This base was obtained by the action of aqueous sodium hydroxide on a sample of Merck's coniine hydrobromide. After drying it boiled at 164–166°.

Substituted Piperidino-alkylbenzoate Hydrochlorides.—The general procedure for the preparation of these compounds consisted of heating together 2 molecular equivalents of the secondary amine (a substituted piperidine) and 1 molecular equivalent of the chloro-alkyl benzoate. The reaction mixture was cooled, diluted with several volumes of ether and the precipitated secondary amine hydrochloride filtered off. From the ether solution the tertiary amine was precipitated with dry hydrogen chloride as the hydrochloride, which was further purified by recrystallization from an alcohol-ether mixture.

There was a marked difference between the condensations of the 2 substituted piperidines and those of the other piperidines which were used with the chloro ester. It was found that the unsubstituted piperidine and 3 substituted piperidines condensed quite completely with the chloro ester in twenty to thirty minutes at 100°, while the 2 substituted piperidines required temperatures of 125–150° for two to three hours. Even under these conditions the condensations of the 2 substituted piperidines were sufficiently incomplete to cause considerable secondary amine hydrochloride to be mixed with the tertiary amine hydrochloride. In such cases it was necessary to treat the mixed hydrochlorides with dilute aqueous sodium hydroxide and shake the resulting aqueous suspension of the free bases with benzoyl chloride. The tertiary amine was then extracted from this

γ -3-Carbethoxypiperidinopropyl	161–163	10.01	10.10

^a Brill (ref. 3) describes this compound as melting at 192°.

⁷ Schwarz, *Ber.*, 24, 1676 (1891).

⁸ Heap, Jones and Speakman, *This Journal*, 43, 1936 (1921).

reaction mixture with ether and reprecipitated as the hydrochloride. This treatment, followed by recrystallizations from an alcohol-ether mixture, gave quite pure products. The yields of the recrystallized products in the case of the 2 substituted piperidino compounds were 35-40%, while in the case of the piperidino and 3 substituted piperidino compounds they amounted to 60-65%.

γ -Substituted Piperidinopropyl-*p*-nitrobenzoate Hydrochlorides.—Two molecular equivalents of the piperidine and 1 molecular equivalent of trimethylene chlorohydrin were heated together at 100° for thirty minutes. The reaction mixture was cooled, treated with several volumes of ether and the precipitated secondary amine hydrochloride filtered off. The piperidinopropyl alcohol was precipitated from the ether solution as the hydrochloride, the ether decanted off and the precipitate, a sirupy, amorphous mass, dried under diminished pressure at 150° for twenty minutes. To this dried hydrochloride 1.5 molecular equivalent of *p*-nitrobenzoyl chloride was added and the mixture heated until the evolution of hydrogen chloride had ceased. The reaction mixture was cooled, diluted with ether and the precipitate allowed to crystallize. Recrystallizations from an alcohol-ether mixture gave pure products. The yields were 50-63%.

Pharmacological Report

These anesthetics are being studied pharmacologically by Mr. Charles L. Rose of the Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana. A brief report of a portion of this work is included in this paper.

The anesthetic efficiencies were determined in the usual way by the application of a 2% solution of the anesthetic to the rabbit's cornea and

⁹ McElvain, *THIS JOURNAL*, **48**, 2240 (1926).

noting the duration of anesthesia. The toxicities were determined by subcutaneous injection into white mice and also by intravenous injection into white rats. The toxicity values for the maximum tolerated dose and the minimum lethal dose are expressed in milligrams per kilogram body weight of the animals. The results of these pharmacological studies are summarized in Table IV and the various anesthetics are designated by the Roman numerals which accompany them in the introductory portion of the paper. The corresponding values for cocaine and procaine are included for comparison.

TABLE IV
PHARMACOLOGICAL DATA

Compound	Average duration of anesthesia, min.	Subcutaneous toxicity to white mice (mg./kg.)			Intravenous toxicity to white rats (mg./kg.)		
		M. T. D.	M. L. D.	No. of mice used	M. T. D.	M. L. D.	No. of rats used
I	0	400	450	8	15	17.5	10

Cocaine	29	200	250	18	15	17.5	12
Procaine	0	900	1000	17	45	50	10

Discussion of the Pharmacological Data

It is interesting to note that the only compounds in the above group that show any mucous membrane anesthesia are those in which an alkyl group is substituted in the piperidine nucleus. Those compounds (VI and IX), containing a carbethoxy substituent in the piperidine nucleus show no anesthetic action towards mucous membranes. These findings correspond to those of Barnes and Adams⁵ for the analogous 3-carbomethoxypiperidino derivative. The difference between the anesthetic action of Compounds IV and V is striking. Compound IV, which is γ -3-methylpiperidino-propylbenzoate, possesses distinct local anesthetic action, while the β -3-methylpiperidino-ethylbenzoate (V) shows no such action. Apparently this loss of anesthetic effect is caused in V by decreasing the number of methylene groups between the nitrogen and the benzoyl group from three to two.

Very few generalizations can be made from the toxicity data for this group of compounds. It is apparent that the substituted piperidino derivatives are less toxic than the corresponding unsubstituted piperidino derivatives. With the exception of IX, the *p*-aminobenzoates are more toxic subcutaneously than the corresponding benzoates. The same difference

was observed between the 1-alkyl-3-carbethoxy-4-piperidylbenzoates and *p*-aminobenzoates.¹⁰ In the above data there does not seem to be much correlation between the subcutaneous and absolute (intravenous) toxicities.

Summary

1. Several substituted piperidino-alkylbenzoates and *p*-aminobenzoates have been prepared and described.

2. The alkyl substituted piperidino compounds which contain three methylene groups between the piperidine nitrogen and the benzoyl group possess local anesthetic action, while the corresponding unsubstituted and carbethoxy substituted piperidino derivatives show no local anesthetic activity.

3. In general, the substituted piperidino derivatives are less toxic than the corresponding unsubstituted piperidino derivatives.

THE MERCURATION OF *o*-NITROPHENOL

BY HERBERT HENRY HODGSON

RECEIVED JULY 2, 1927

PUBLISHED NOVEMBER 5, 1927

Iodination of *o*-nitrophenol by the aid of yellow mercuric oxide was found by the author¹ to take place preferentially in the 4 as compared with the 6 position whether the medium employed was alcohol or glacial acetic acid, and in addition considerable di-iodination took place even when a deficiency of iodine was used. In consequence it became of interest to ascertain whether mercuration would exhibit a like preference.

Previous work on this subject by Hantzsch and Auld² established that when an alcoholic solution of *o*-nitrophenolate (1 mole) and aqueous mercuric acetate (1 mole) were boiled together, the mono-mercuri product formed yielded *p*-bromo-*o*-nitrophenol when brominated, thereby establishing mercuration in the 4 position. Later Raiziss and Proskouriakoff³ proved that considerable dimercuration occurred under the above conditions and, although the various products were not orientated by them, tacit assumption of mercuration in the 4 position was made for the mono-mercuri products.

In the present investigation mercuration has been effected both by fusion of *o*-nitrophenol with mercuric acetate and also according to the directions of Raiziss and Proskouriakoff. In the former case marked

¹⁰ McElvain, *THIS JOURNAL*, **48**, 2184, 2241 (1926).

¹ Hodgson, *J. Chem. Soc.*, 1927, 1141.

² Hantzsch and Auld, *Ber.*, **39**, 1105 (1906).

³ Raiziss and Proskouriakoff, *THIS JOURNAL*, **44**, 787 (1922).

preference was shown for mercuration in the 6 position and practically no dimercuration occurred, whereas in aqueous alcoholic solution substitution in the 4 position accompanied by considerable dimercuration took place.

Orientations were established by conversion of the mercured products into the corresponding iodonitrophenols.

The 6- and 4-acetoxymercuri-2-nitrophenols were readily converted into the 6- and 4-fluoro-, chloro-, bromo- and iodomercuri-2-nitrophenols, all of which were lighter in color than *o*-nitrophenol itself, the depths of shade increasing gradually from fluoro (almost colorless) to chloro (very pale brownish-yellow), bromo (pale yellow) and iodo (almost as deep a yellow as *o*-nitrophenol). Further, the 6-acetoxy- and 6-halogenomercuri-2-nitrophenols appear to be somewhat paler than the 4 substituted isomerides and, moreover, possess lower melting points and lesser solubilities in alcohol and acetic acid.

Experimental

6-Acetoxymercuri-2-nitrophenol.—An intimate mixture of *o*-nitrophenol (15 g.) and mercuric acetate (3 g.) was heated gradually to 150° during one hour, and kept at 140–150° for four hours with frequent shaking. The reaction product was mixed with a saturated solution of sodium chloride and steam distilled, when unchanged *o*-nitrophenol was recovered (12 g.) and a non-volatile residue (2 g.) obtained from which 6-chloromercuri-2-nitrophenol was removed by repeated extraction with boiling alcohol. The light brown almost colorless residue was dissolved as completely as possible in dilute sodium hydroxide, the solution filtered, reprecipitated by acetic acid and the product crystallized from glacial acetic acid, in which it is only moderately soluble, giving pale brownish-yellow, almost colorless micro clusters which do not appear to melt below 300°.

Anal. Calcd. for $C_6H_5O_2NHg$: N, 3.5. Found: 3.6.

When an aqueous suspension of 6-acetoxymercuri-2-nitrophenol is gently warmed for about 30 minutes with excess iodine dissolved in aqueous potassium iodide, almost the whole is converted into 6-iodo-2-nitrophenol (1 g. gives 0.62 g.; calcd. 0.71 g.), which is removed by steam distillation and crystallized from dilute alcohol, giving characteristic plates, m. p. 110°.

Anal. Calcd.: I, 47.9. Found: 47.7.

This product, when treated in glacial acetic acid solution with iodine and yellow mercuric oxide, was converted quantitatively into 4,6-di-iodo-2-nitrophenol. When the steam-volatile product was collected in small fractions, the first one had a melting point of 102° and appeared to contain a certain amount of 4-iodo-2-nitrophenol, recognized by microscopic examination. A negligible amount of 4,6-di-iodo-2-nitrophenol was detected in the iodination experiment above, which indicated that almost no dimercuration had taken place.

4-Acetoxymercuri-2-nitrophenol, prepared according to the directions of Raiziss and Proskouriakoff,³ was treated with iodine as above and afforded a mixture of 4,6-di-iodo- and 4-iodo-2-nitrophenols, with a little 6-iodo-2-nitrophenol. The former, which was present in considerable amount, thus confirms Raiziss and Proskouriakoff's observation³ with respect to the fairly extensive dimercuration which takes place under these conditions. The two latter products were separated by steam distillation, fractionally crystallized from alcohol and identified by microscopic examination, confirma-

tion forthcoming by iodination of all the fractions to 4,6-di-iodo-2-nitrophenol, exclusively.

6- and 4-Halogenomercuri-2-nitrophenols.—These products were precipitated by the addition of the requisite halogen acid to solutions of the sodium 6- and 4-hydroxymercuri-2-nitrophenols prepared according to the directions of Raiziss and Proskouria-koff³ except in the cases of the 6- and 4-iodomercuri-2-nitrophenols, which were precipitated by the addition of dilute sulfuric acid to solutions of the above sodium salts in which a large excess of potassium iodide had been dissolved. The 4-halogeno-mercuri compounds were all slightly deeper in color and more soluble in alcohol and acetic acid than the 6 isomerides and all possessed higher melting points where these existed.

For convenience and to abbreviate description the crystalline form, color and melting points of the 6 and 4 compounds are given in Table I below. Both sets were crystallized from alcohol.

Sodium-6-hydroxymercuri-2-nitrophenolate gives scarlet-red crystals, while the crystals of the 4 compound are a deeper red.

Anal. Calcd. for $C_6H_4O_4NNaHg$: N, 3.7. Found: 3.8.

TABLE I
HALOGENO-MERCURI-2-NITROPHENOLS

Name	M. p., °C.	—6 Isomer—		M. p., °C.	—4 Isomer—		Composition, % Calcd. Found	
		Color	Crystal form		Color	Crystal form		
Fluoro	187	Pale yellow	Plates	195	...	Micro plates	N = 3.9	4.0
Chloro	185*	Pale yellow- ish-brown	Rect. plates	205	Creamy yellow	Micro clusters	Cl = 9.5	9.5
Bromo	177	Pale yellow	Plates	236	...	Needles	Br = 19.1	18.9
Iodo	215	Deep yellow	Needles	>300	Bright yellow	Micro needles	I = 27.3	27.0

* Crude product, m. p. 175°; contained some of the 4 isomer as shown by its reaction with iodine, etc. The pure product, m. p. 185°, gave only the 6 isomer.

Summary

Fusion of *o*-nitrophenol with mercuric acetate gives mainly 6-acetoxymercuri-2-nitrophenol. When solvent media are employed, 4-acetoxy-2-nitrophenol is formed preferentially, accompanied, however, by appreciable amounts of 4,6-diacetoxymercuri-2-nitrophenol.

THE FORMATION OF TRIPHENYLMETHYL PEROXIDE FROM CARBON DIOXIDE AND PHENYLMAGNESIUM BROMIDE

BY F. F. BLICKE

RECEIVED JULY 5, 1927

PUBLISHED NOVEMBER 5, 1927

Several years after the discovery by Grignard¹ that carboxylic acids can be prepared from carbon dioxide and alkyl magnesium halides Meyer and Tögel² undertook a detailed study of the action of carbon dioxide on phenyl magnesium bromide. They obtained benzoic acid and triphenylcarbinol as principal products and, in addition, varying amounts of benzene, biphenyl, triphenylmethane and phenol. Furthermore, a small amount of a colorless, crystalline, ether-insoluble material was found. This substance melted at 186° and remained unidentified. Meyer and Tögel also stated that their reaction mixtures were colored. Schroeter³ was able to show that benzophenone is another product formed in this synthesis and he too obtained the ether-insoluble product. From the data which were given we suspected that the unidentified compound might have been triphenylmethyl peroxide, formed by oxidation of triphenylmethyl present in the reaction mixture.

We allowed carbon dioxide to react with phenylmagnesium bromide according to the directions of the above-mentioned investigators and proved conclusively that triphenylmethyl peroxide was present among the reaction products.

A number of unsuccessful experiments were performed in the attempt to discover the reaction by which triphenylmethyl was formed. For example, $C_6H_5COOMgBr$ and $(C_6H_5)_3COMgBr$ were heated, respectively, with phenylmagnesium bromide in ether and the effects of small amounts of magnesium and iodine⁴ upon the reaction mixtures were tested. Although we were unable to determine just how the free radical was formed, it seems probable that triphenylmethyl was produced in some way from triphenylcarbinol, or rather from its $MgBr$ derivative.⁵

By the interaction of carbon dioxide and a cold ether solution of α -naphthylmagnesium bromide, α -naphthoic acid was obtained in good yield. By the use of a hot solution of the Grignard reagent, we hoped that the reaction would proceed further with the formation of the tertiary carbinol

⁴ (a) Gomberg and Bachmann, *THIS JOURNAL*, 49, 236 (1927); (b) Boyd and Hatt, *J. Chem. Soc.*, 131, 904 (1927).

⁵ Stadnikoff, *Ber.*, 57, 5 (1924), obtained triphenylmethyl peroxide from the interaction of the $MgBr$ derivative of triphenylcarbinol and ethyl formate. The exact mechanism of this reaction has not been established.

and possibly the free radical. A compound claimed to be tri- α -naphthylcarbinol has been described by Schmidlin and co-workers⁶ and also by Tschitschibabin;⁷ the former investigator allowed naphthoyl chloride to react with more than two equivalents of naphthylmagnesium bromide, the latter added naphthylmagnesium bromide to dinaphthyl ketone. However, judging from the remarkable properties ascribed to this compound, it seems to us that these investigators could not have had the pure carbinol. Schmidlin and Massini state that the compound contains a very unreactive hydroxyl group and that the usual reagents which convert tertiary carbinols into their respective chlorides are without action. Tschitschibabin maintains that at ordinary temperature the carbinol spontaneously absorbs oxygen and is oxidized by potassium permanganate to α -naphthyl-di- α , α -naphthofluoryl alcohol. When treated with iodine the carbinol iodide is said to have been formed. As Schmidlin⁸ himself points out it is strange that it was found impossible to convert the carbinol iodide, or bromide, into either the original carbinol or into the free radical. Judging from the properties of diphenyl- α -naphthylcarbinol⁹ and phenyl-di- α -naphthylcarbinol,¹⁰ it might be predicted that tri- α -naphthylcarbinol would possess a very reactive hydroxyl, so reactive, in fact, that the carbinol as well as its derivatives such as $(C_{10}H_7)_3COMgBr$, a compound which would result from the Grignard synthesis, would tend to undergo very readily various types of changes, especially fluorenation. The absorption of oxygen and iodine and the decolorization of potassium permanganate at ordinary temperature are reactions which are foreign to any simple tertiary aromatic carbinols hitherto described. Finally, tri- α -naphthylcarbinol might be expected to yield an intense blue or violet solution when treated with concentrated sulfuric acid; Schmidlin and Tschitschibabin state that their compounds are colored orange-red or yellow by this reagent.

From the interaction of carbon dioxide and a hot ether solution of α -naphthylmagnesium bromide we obtained naphthoic acid and a red oil from which no crystalline products could be obtained.

We then attempted to prepare the carbinol from naphthylmagnesium bromide and di- α -naphthyl ketone. After decomposition of the reaction mixture with ice and ammonium chloride, a colorless material quickly deposited from the ether layer. This substance decolorized solutions of iodine and of potassium permanganate at ordinary temperature and dissolved in sulfuric acid with the formation of a red solution. These ob-

servations correspond to those of Tschitschibabin but in our opinion the material is not tri- α -naphthylcarbinol, or it contains only very little of this substance.

Since further work on this compound seems impossible at present we are obliged to present our results in an unfinished state.

Experimental Part

The Formation of Triphenylmethyl Peroxide.—Phenylmagnesium bromide was prepared from 6.2 g. of magnesium turnings, 40 g. of bromobenzene, 120 cc. of ether and a crystal of iodine. A rapid stream of dry carbon dioxide was then passed through the solution. At first no noticeable change took place; later the mixture became somewhat warm and colorless crystals were deposited upon the walls of the flask. After one and one-half hours a considerable amount of gummy precipitate had formed. The mixture was then decomposed with ice and slightly more than the calculated amount of dilute hydrochloric acid. After decomposition had been effected a deep orange ether layer was obtained. A small amount of crystalline substance floated between the ether and water layers. When the clear ether solution was separated and shaken with air it became noticeably lighter in color and a colorless, crystalline material precipitated. This was washed with ether and recrystallized twice from xylene; m. p. 184°. A portion of this substance was mixed with triphenylmethyl peroxide obtained from triphenylchloromethane, silver and air; the mixture melted at 185–186°. The largest yields of peroxide were obtained when the solution of phenylmagnesium bromide was heated during the addition of carbon dioxide; the reaction mixture then turned a permanganate color during the course of the reaction. The crude peroxide, varying in weight from 1 to 2 g., contained a considerable amount of magnesium salts which could only be removed by several recrystallizations. When the solution of the Grignard reagent was cooled with ice, the mixture remained colorless during the reaction with carbon dioxide, and upon the addition of water and dilute mineral acid, benzoic acid and some triphenylcarbinol were obtained as the principal reaction products but no peroxide seems to have been formed.

α -Bromonaphthalene.—The bromonaphthalene used in our experiments was carefully purified material. At first a technical grade of this substance was purchased and subjected to several fractional distillations. However, the separation of the monobromonaphthalene from naphthalene, dibromonaphthalene and bromine and hydrogen bromide addition products which were present in the technical product required considerable time. We finally prepared the bromonaphthalene by the following method which differs in several essential respects from the methods commonly used.¹¹ Carbon tetrachloride was substituted for the poisonous and inflammable carbon disulfide; $\frac{3}{4}$ of a molecular equivalent of bromine was used instead of one whole equivalent; the crude bromonaphthalene was fractionated under ordinary pressure instead of under diminished pressure. The use of carbon tetrachloride as a solvent enabled us to brominate in a one-phase system, hence mechanical stirring was unnecessary. By the use of the above amount of bromine the yield of monobromonaphthalene, based on bromine, was as large as that obtained in other processes in which

¹¹ "Organic Syntheses," John Wiley and Sons, Inc., 1921, Vol. I, p. 36.

one whole equivalent of bromine is used; moreover, dibromonaphthalene, a product which represents a loss of both bromine and naphthalene, was formed only in negligible amount. The bromine and hydrogen bromide addition products formed during bromination are surprisingly difficult to decompose; the desired decomposition of these products is always effected by distillation under ordinary pressure but they often remain undecomposed, to some extent at least, during distillation under diminished pressure.

One thousand g. of technical naphthalene and 1500 cc. of carbon tetrachloride were put into a 5-liter flask, the stopper of which was fitted with a reflux condenser and a dropping funnel. The hydrogen bromide evolved during the reaction was led through the condenser into water. One hundred and fifty cc. of bromine was added in 25cc. portions during the course of two hours and the flask was shaken occasionally. A slow, regular evolution of hydrogen bromide began and all of the naphthalene soon dissolved. The remainder of the bromine, 150 cc., was added in 25cc. portions during the course of twenty-four hours. After all of the bromine had been added the mixture was allowed to stand for one day. Two hundred g. of technical sodium hydroxide dissolved in 400 cc. of hot water was then added and the alkaline mixture subjected to steam distillation. After the solvent had been removed, the oily residue was separated and dried with solid sodium hydroxide. The crude product was fractionated under ordinary pressure into four portions and, since hydrogen bromide and bromine were evolved, each fraction was treated with hot concentrated sodium hydroxide solution and then refractionated several times. Most of the unchanged naphthalene was removed from the lowest-boiling portion by filtration. The fourth fractionation of the portion which had boiled at 270–275° under 740 mm. yielded 730 g. of monobromonaphthalene which was collected at 271–274°. From other experiments the yields of bromonaphthalene were 755 g. and 760 g., respectively. Small fractions of low- and high-boiling material obtained from three experiments were united and refractionated. One hundred and fifty g. of pure bromonaphthalene was obtained. The yields given above, therefore, are increased by approximately 50 g., respectively, and correspond to 63, 65 and 65%, respectively, of the calculated amounts based on bromine.

α -Naphthoic Acid.—Acree¹² claims to have obtained an almost theoretical yield of α -naphthoic acid from naphthylmagnesium bromide and carbon dioxide but gives no experimental details regarding the process. According to Gilman and co-workers¹³ α -naphthylmagnesium bromide is formed only to the extent of 70% under optimum conditions. We have prepared α -naphthoic acid a great many times and found that the yields of crude acid, which had been washed free from inorganic salts and thoroughly dried, varied from 65–70% of the calculated amount.

Naphthylmagnesium bromide was prepared from 18 g. of magnesium, 156 g. of α -bromonaphthalene, 400 cc. of ether and a crystal of iodine. The oily Grignard reagent¹⁴ and the supernatant ether were poured into a 2-liter, wide-mouthed bottle the stopper of which was fitted with a stirrer, a wide carbon dioxide inlet tube which extended almost to the bottom of the bottle and a reflux condenser to which a calcium chloride tube was attached. During the reaction with carbon dioxide the bottle was immersed in ice water but the Grignard reagent should not be cooled before the addition of

¹² Acree, *Ber.*, 37, 627 (1904).

¹³ (a) Gilman and McCracken, *THIS JOURNAL*, 45, 2462 (1923); (b) Gilman and Parker, *ibid.*, 46, 2822 (1924).

¹⁴ This material tends to solidify readily if allowed to stand at ordinary temperature.

carbon dioxide or the naphthylmagnesium bromide will solidify to a hard cake which reacts very slowly with the gas. A brass rod, bent in a zig-zag form was found to be much more satisfactory than a stirrer made from glass. The Grignard reagent was stirred very vigorously and the gas, dried by passing it through three wash bottles filled with sulfuric acid, was led through it at a rapid rate. The reaction mixture became more and more viscous and at the end of one and one-half hours the mixture was decomposed in the usual manner. The naphthoic acid was extracted from the ether layer with dilute sodium carbonate solution.

If the ether suspension of naphthylmagnesium bromide was refluxed during the addition of carbon dioxide the yield of naphthoic acid was decreased to about 35% of the calculated amount.

Di- α -naphthyl Ketone.—For the preparation of large amounts of this ketone the method of Schmidlin and Massini¹⁵ is unsatisfactory, but we found that their method could be modified with advantage as follows. Naphthylmagnesium bromide, which had been freed from traces of unchanged magnesium by the subsequent addition of a small amount of α -bromonaphthalene, was added slowly, with stirring, to excess (2 equivalents) of cold naphthoyl chloride¹⁶ dissolved in ether. In this way the possible production of the tertiary carbinol was prevented to a considerable extent and the formation of the red impurity mentioned by Schmidlin and Massini was eliminated entirely. In spite of the fact that carefully purified materials had been used, the yield of pure ketone never exceeded 40% of the calculated amount. It was finally found that di- α -naphthyl ketone could be prepared easily, in large amounts, from the interaction of naphthylmagnesium bromide and naphthyl cyanide.

Naphthylmagnesium bromide (1.4 equivalents) was prepared in a liter flask from 45.5 cc. of α -bromonaphthalene, 7.5 g. of magnesium and 300 cc. of ether. Any unchanged magnesium was brought into solution by the subsequent addition of a few drops of bromonaphthalene. Thirty-three g. of naphthyl cyanide dissolved in ether was then added. Since the Grignard reagent had precipitated to a large extent in the form of a viscous oil, intimate contact of this substance with the cyanide was obtained by refluxing the mixture vigorously on a steam-bath. After a short time a granular precipitate began to form. The mixture was then heated for eight hours longer at a less vigorous rate. The ether, which contained binaphthyl, was decanted from the precipitate and the latter decomposed with ice and ammonium chloride. The ketone imine was extracted with ether, the solvent removed and the imine, in order to hydrolyze it to the ketone, was refluxed for twenty-four hours on a steam-bath with a mixture composed of 50 cc. of acetone, 100 cc. of water and 30 cc. of hydrochloric acid. After removal of the acetone by evaporation the granular product, which had been well washed with water, was dissolved in the least possible amount of hot alcohol. Upon cooling a brown oil was deposited. The alcoholic solution was decanted from this material and upon further cooling the ketone (23 g.) precipitated in crystalline form and in a quite pure state. The ketone was finally recrystallized from ether. From the brown oil, which soon solidified, a further amount (23 g.) of material was obtained which was recrystallized successively from acetic acid, alcohol and ether. The total yield of ketone was 75% of the calculated. Schmidlin and Massini¹⁵ state that di- α -naphthyl ketone, recrystallized from ether, is a colorless substance which melts at 103°. Tschitschibabin,⁷ who prepared the ketone by oxidation of the corresponding secondary carbinol, reported that the material, recrystallized from acetic acid, melted at 98°. We found that the ketone was often slightly yellow even after several recrystallizations

¹⁵ Ref. 6 a, p. 2388.

¹⁶ In order to prepare pure naphthoyl chloride, naphthoic acid was refluxed with 6 equivalents of thionyl chloride for two hours.

from ether and frequently yielded a deep yellow solution; in other instances the compound was obtained in a colorless condition after only one recrystallization and melted at 99–100°. The yellow color of the ketone is undoubtedly due to some impurity which is removed with difficulty.

α -Naphthoic Anhydride.—To a mixture of 4 g. of thoroughly dried, anhydrous sodium carbonate and 8 g. of naphthoyl chloride, there was added 2.5 cc. of pure pyridine. Apparently no reaction took place even when the mixture was warmed. However, upon the addition of a few drops of water to the cold mixture a vigorous reaction began. The mass was stirred thoroughly and then allowed to cool. After the addition of water the insoluble residue was dried and recrystallized from benzene. The compound melted at 145–146°. This anhydride had previously been prepared from calcium naphthoate and naphthoyl chloride.¹⁷ The yield of pure product was 5.3 g. or 80% of the calculated.

α -Naphthyl Cyanide.— α -Naphthoyl chloride was added to cold, concentrated ammonia water which was stirred vigorously and the acid amide formed was dried and then warmed gently for a short time with one equivalent of phosphorus pentachloride. The phosphorus oxychloride was removed by distillation; the residue was poured on ice, pulverized and thoroughly washed with water to remove phosphorus compounds. The crude cyanide was purified by distillation under ordinary pressure. The yield was practically quantitative.¹⁸

Di- α -naphthylcarbinol.—In the preparation of this carbinol according to the directions given in the literature,¹⁹ difficulty was encountered because of the formation of oily by-products; the use of excess ethyl formate seemed to be responsible for the formation of the oily material. Since naphthylmagnesium bromide can be obtained only in 70% yield,¹⁸ 0.7 of an equivalent of the ester (instead of 1 equivalent) should be used for 2 equivalents of the Grignard reagent. The Grignard reagent was prepared from 69 g. of bromonaphthalene, 7.2 g. of magnesium, 200 cc. of ether and a crystal of iodine. Seven and eight-tenths g. of freshly-distilled ethyl formate was added, a few drops at a time, during the course of half an hour and the mixture was thoroughly shaken and cooled after each addition of the ester. The carbinol, in the form of its magnesium bromide addition product, precipitated almost completely. After twenty-four hours the ether was decanted and the precipitate decomposed with ice and the calculated amount of dilute hydrochloric acid. The crystalline product was washed with a small amount of dilute hydrochloric acid, dried and then triturated with a small quantity of ether several times. The yield of pure product was 22 g.; m. p. 144°.

The carbinol can be converted easily into di- α -naphthylmethane as follows. Three g. of the carbinol was dissolved in 60 cc. of hot acetic acid and 25 g. of hydriodic acid (sp. gr. 1.96) was added to the hot solution, a small amount at a time. The mixture was then boiled for a few minutes. After twelve hours the methane, which had separated in the form of colorless needles, was filtered. The compound melted at 107–108° after recrystallization from alcohol.

Summary

It has been shown that under certain conditions triphenylmethyl is formed in the interaction of carbon dioxide and phenylmagnesium bromide.

THE POLARITY OF THE CARBON-HALOGEN BOND

I. DEVELOPMENT OF A QUANTITATIVE METHOD FOR THE DETERMINATION OF RELATIVE RATES FOR THE ACID HYDROLYSIS OF POSITIVE HALOGENS

BY JOHN R. SAMPEY

RECEIVED JULY 5, 1927

PUBLISHED NOVEMBER 5, 1927

Recently Nicolet and collaborators¹ have studied the different degrees of polarity that are shown by halogens attached to carbon in the aromatic series. The present investigation was undertaken with a two-fold purpose: to develop a more quantitative method for the determination of the rate of removal of positive halogens and to determine to what extent halogens in halogen naphthols show different degrees of polarity. The reaction which Nicolet has found useful as a preliminary test for positive halogens, that of the action of stannous chloride in acid solution on the organic halide, is one which has been applied in a qualitative way to the removal of halogen atoms from halogen amines and phenols² and to a less extent to the removal of bromine from bromo- β -naphthols and bromo- β -naphthylamines.³ The method described below differs from those referred to in that the hydrolysis was carried out in an oxygen-free atmosphere, and that the amount of halogen removed was determined by titration of the excess stannous chloride solution with standard iodine solution.⁴ It is thus considerably more convenient and rapid.

Method of Hydrolysis

The standard solution of stannous chloride was prepared by dissolving 60 g. of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ in 1000 g. of hydrochloric acid (37%) and the solution was diluted to 3700 cc. with 95% alcohol (the alcohol was added to make the organic halides soluble). This solution was stored in an atmosphere of hydrogen to prevent oxidation; after twenty-four hours the oxygen in the gases above the solution had disappeared and the stannous chloride maintained its strength unaltered during the time required to make the hydrolyses. The apparatus used for the storage of the solution and for the titration was

⁴ Treadwell and Hall, "Analytical Chemistry," John Wiley and Sons, Inc., New York City, 1919, p. 698.

similar to that described by Thornton.⁵ The standardization of the stannous chloride solution against a 0.1 *N* solution of iodine was done in an atmosphere of nitrogen.

Briefly, the procedure as finally adopted in the method of hydrolysis was as follows. A weighed sample of the organic halide was placed in an Erlenmeyer flask and, after sweeping out the air with a stream of nitrogen, an excess of the stannous chloride solution was introduced. The flask was placed under a reflux condenser in a thermostat heated to 70° and the temperature of the thermostat was kept constant within $\pm 0.01^\circ$. A layer of oil over the surface of the water in the thermostat prevented evaporation and made it easier to maintain a constant temperature. The solution was kept in an atmosphere of nitrogen at all times and at the end of a definite length of time the flask was removed from the thermostat to a pail of water where it was cooled for one minute. The amount of halogen removed from the organic halide by the hydrolysis was determined by titration of the excess of stannous chloride with 0.1 *N* iodine solution. The calculation of the amount of halogen removed was based on the number of cubic centimeters of stannous chloride solution consumed in the removal of all of the bromine and iodine from the halogen phenols and naphthols; as was expected, it was found that one mole of stannous chloride was required in every case for the complete removal of each atom of bromine or iodine; for example, exactly half a gram of 1-bromo-2-hydroxynaphthalene, when heated until all the bromine was removed, oxidized as much stannous chloride solution as did 43.80 cc. of 0.1 *N* iodine. This would be equivalent to the presence of 0.3504 g. of molecular bromine, but there are only 0.1750 g. of bromine in the 0.5 g. sample used. This is further evidence that the halogen when removed is positive.^{1a}

Several sources of error in the hydrolysis were examined. It was possible that some iodine substitution might have taken place during the titration with the standard iodine solution; no evidence of interaction of the iodine solution with the halogenated or unhalogenated phenols and naphthols was found when titrations were made. Care was taken to recrystallize several times all compounds used in order to free them from adsorbed halides and other impurities. A considerable error in the rate measurement was introduced by the method of heating the stannous chloride solution from room temperature to 70° after the introduction of the organic halide. Except in the cases of those compounds which lost their halogen rapidly, this error was found to be less than that caused by the entrance of atmospheric oxygen when attempts were made to introduce the halide into the stannous chloride solution after it had reached a constant temperature of 70°. It was not possible to remove portions of the solution from time to time for titrations without greatly increasing the difficulty of manipulation in keeping out the oxygen of the atmosphere. Efforts were made to keep the error introduced by the method of heating constant by the use of the same volume of stannous chloride solution in all the hydrolyses; in some cases this was not possible because of the insolubility of several of the compounds.⁶

⁵ Thornton, *THIS JOURNAL*, 43, 91 (1921).

⁶ In the next article it will be seen that the errors in the method of hydrolysis were further reduced by (a) heating the compounds which lose the halogens rapidly in a solution of lower hydrogen-ion concentration, (b) increasing the amount of alcohol for the highly insoluble compounds and (c) introducing the organic halide after the stannous chloride solution has reached 70°.

The results of the hydrolyses are summarized in the following table.

TABLE I
ACID HYDROLYSIS OF HALOGEN PHENOLS AND HALOGEN NAPHTHOLS

Compounds	Weight g.	Time of hydrolysis, min.	Cc. of SnCl ₄ soln. introduced	Cc. of 0.1 N iodine consumed in titrations	G. of halogen removed	Total halogen removed, %

2,4-Dibromophenol	.3	60	20.00	27.45

Discussion of Table I

The most striking result shown in Table I is the remarkable reactivity of the halogen atoms in halogen naphthols. On the basis of the Lewis definition of a bond, the significance of the fact is that the bonding pair of electrons in the carbon-halogen bond of halogen naphthols is drawn further from the halogen nucleus and nearer the carbon than is the case with halogen phenols. Identification of the organic products of the reaction showed, however, that halogens in the 6 and 7 positions did not respond to the test for positive halogens, for they were not removed even on prolonged heating. 6-Bromo-2-hydroxynaphthalene was isolated after the reduction of the 1,6-dibromo-2-hydroxynaphthalene had gone as far as it would under the experimental conditions, and 6,7-dibromo-2,3-dihydroxynaphthalene was identified after the reduction of the tetra-bromo derivative. These results lend further support to the explanation^{1c} for the mechanism of the removal of positive halogens through quinone formation, for Vesely and Jokes⁷ have shown that of the six naphthoqui-

⁷ Vesely and Jokes, *Bull. soc. chim.*, 33, 955(1923).

nones of Willstätter, the two which are the most readily formed possess an intact benzene nucleus.

Preparation of Compounds

In the preparation of the compounds studied in Table I it was found necessary in several cases to modify the procedure as described in the literature. Attempts to prepare 2,3-dihydroxynaphthalene from "R-salt" by the method of Friedländer⁸ were so unsuccessful that considerable time was consumed in the development of a satisfactory method of preparation. When the reaction was carried out as described the chief product was β -naphthol. This indicated that the alkali fusion of the "R-salt" had failed to replace the 3-sulfonic acid group by an hydroxyl group and that the subsequent bomb reaction had removed both the 3- and 6-sulfonic acid groups. An increase in the temperature of the fusion resulted in considerable charring; varying the amount of water added to the fusion failed to produce the desired result. A potassium hydroxide fusion was substituted for the sodium hydroxide fusion and the temperature was raised to 300°; no water was added. When this fusion was acidified, much sulfur dioxide was liberated, indicating the removal of a sulfonic acid group. The bomb reaction proved that the 3-sulfonic acid group had been replaced with the hydroxyl group. The conditions under which the bombs were heated were also changed, for after more than twenty trials in which the temperature, the concentration of the sulfuric acid and the time of heating were varied, it was found that there was less charring when the strength of the acid was reduced from one-to-three to a concentration of one-to-four. This made it necessary to increase the time of heating to fourteen hours at 165–175°. The 2,3-dihydroxynaphthalene was brominated according to Fries.⁹ Attempts to prepare an iodo-derivative by direct iodination of the 2,3-dihydroxynaphthalene resulted in the formation of a dark, amorphous mass with the disappearance of little of the iodine.

Armstrong⁹ mentions the fact that 1,6-dibromo-2-hydroxynaphthalene can be prepared by bromination of β -naphthol in acetic acid; no details are given. The following procedure gave a yield of 90%: 25 g. of β -naphthol was dissolved in 150 cc. of acetic acid; to the solution was added slowly two moles (55.5 g.) of bromine in 35 cc. of acetic acid. The solution was heated almost to boiling for twenty minutes in order to expel the hydrogen bromide; it was cooled and water was added slowly to precipitate the dibromonaphthol. The solution was filtered and the product dried and recrystallized from hot alcohol.

In following out the procedure of Jackson¹⁰ for the preparation of tetrabromocatechol so much difficulty was experienced in keeping the products in solution during the bromination that a solvent other than chloroform was sought. When the bromination was made in acetic acid, there was no precipitation of the partially brominated products.

Summary

1. A quantitative method is described for the determination of relative rates of acid hydrolysis of positive halogens.
2. The test for positive halogens has been extended to halogen naphthols.
3. Improved methods of preparation are given for several halogen phenols and naphthols.

THE POLARITY OF THE CARBON-HALOGEN BOND

II. THE KINETICS OF THE ACID HYDROLYSIS OF HALOGEN PHENOLS AND HALOGEN NAPHTHOLS

BY JOHN R. SAMPEY

RECEIVED JULY 5, 1927

PUBLISHED NOVEMBER 5, 1927

The development of a quantitative method for the determination of relative rates of acid hydrolysis of positive halogens¹ has opened the way for a study of the kinetics of the reaction. In the present article an investigation is made on the effect of a change in both the hydrogen-ion concentration and the stannous chloride concentration upon the velocity of the reaction that has been used as a test for the determination of the degree of polarity of the halogen atoms in halogen phenols and halogen naphthols.

Effect of Hydrogen-Ion Concentration

The effect of a change in the hydrogen-ion concentration of the solution was first investigated. The total acidity of the stannous chloride solution used in Table I of the preceding article was determined by titration against a normal sodium hydroxide solution: 5.0 cc. of the stannous chloride solution neutralized 14.6 cc. of the normal sodium hydroxide. A solution of about one-seventh this total acidity was prepared by making up 50 g. of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ and 80 g. of hydrochloric acid (37%) to 2960 cc. with 95% alcohol; 20.0 cc. of this solution neutralized 8.5 cc. of normal sodium hydroxide. The stronger acid solution removed 0.0260 g., or 14.85%, of the bromine from 1-bromo-2-hydroxynaphthalene in twenty minutes; the weaker acid solution removed 0.0072 g., or 4.1%, of the bromine in the same length of time.

It is not justifiable to draw any conclusions of a quantitative nature from these data on the relation between the hydrogen-ion concentration and the speed of the reaction, because the relation of the total acidity as determined to the actual hydrogen-ion concentration of the solutions is unknown. By taking advantage, however, of the qualitative relation, we were able to slow down the hydrolysis of the more positive halogen compounds found in Tables II, IV, VII and VIII, and to speed up the removal of the bromine from the less positive halogen compounds found in Tables III, V, VI and IX.

A possible mechanism for the acid hydrolysis of positive halogens has been formulated;² the role of the hydrogen ions in the reaction, however, is very likely catalytic. According to the theories of Lapworth³ and more

recently Rice,⁴ it is the unhydrated hydrogen ions that catalyze reactions of this type. Experiments are planned to determine the effect of moisture on the rate of removal of the halogens by acids.

Effect of Stannous Chloride Concentration

The hydrolysis was further studied to determine the effect of a change in the concentration of the stannous chloride. In order to increase the acidity of the solution and at the same time not add so much water that half a gram of the organic halides would not dissolve readily, dry hydrogen chloride gas was passed into a solution containing 200 cc. of the 37% hydrochloric acid and two liters of 95% alcohol; 5.0 cc. of this solution neutralized 22.3 cc. of normal sodium hydroxide. This high concentration of acid caused more rapid hydrolysis. The following constants were obtained when the data were substituted in the equation for a first-order reaction: $1/t \times \log a/(a-x) = 0.4343k$, where a is the amount of removable bromine in the sample, and x is the amount of bromine removed.

The rate of removal of the halogens by the acid solution is apparently independent of the concentration of the stannous chloride; the evidence therefor is still more conclusive in Tables IV-IX below, where the range of concentration over which the reaction is studied is wider. Nicolet³ has used in his interpretation of the mechanism of the removal of positive

⁴ Rice, *THIS JOURNAL*, 45, 2808 (1923).

halogens this significant fact of the independence of the concentration of the stannous chloride on the rate of hydrolysis.

If we wish to determine how far, relatively, the bonding pair of electrons has been drawn from any positive halogen, it is more significant to use that weight of each compound which will lose the same weight of halogen on complete hydrolysis than it is to employ the same weight of each halogen phenol and naphthol. In the next two tables of data the halogen atoms that were not removed were not counted in when determining the equivalent weights to be used; for instance, 0.25 g. of 2,4-dibromo-1-hydroxynaphthalene was taken and 0.5 g. of 1,6-dibromo-2-hydroxynaphthalene, because in the latter only one bromine atom is removed. The weight of bromine lost on complete hydrolysis of 1,6-dibromo-2-hydroxynaphthalene was taken as the standard in the calculations for the amount of other halogens to be used. Due to the large differences in the rates of hydrolysis of the compounds, as shown in the preceding article of this series, it was necessary to prepare two stannous chloride solutions with different hydrogen-ion concentrations; the solution with the weaker hydrogen-ion concentration was used with those compounds whose halogens were more positive. The solution used in Table II was prepared by passing dry hydrogen chloride gas into 95% alcohol; 30 g. of SnCl_2 -

By the use of equivalent quantities the interesting fact appears in Table II that the 1,4-bromine atoms in the two dihydroxynaphthalenes are removed at approximately the same rate; such a relation could not be drawn from any preceding results. In view of this relation, it is surprising to find in Table III that the bromine atom in the 6 position of 1,6-dibromo-2-hydroxynaphthalene exerts a decided influence upon the bromine in the 1 position.

In the final series of runs⁵ the effect of a wide range of concentration of the stannous chloride was determined. The method of hydrolysis was slightly changed: in each case 25.0 cc. of stannous chloride solution was

⁵ The results set forth in Tables IV-IX were obtained in the Chemical Laboratory of Howard College.

heated to the temperature of the thermostat before the organic halide was introduced. The oxygen of the atmosphere was kept out by keeping the tube from the cylinder of nitrogen below the neck of the Erlenmeyer flask when the sample was introduced. In order to control the rate of the hydrolysis a stannous chloride solution of different hydrogen-ion concentration was used for each compound; for the more positive halogens a solution of low acidity was used. The weight of organic halide used first in Tables IV-VI was sufficient to oxidize on complete hydrolysis 25.0 cc. of 0.1 *N* stannous chloride solution; in the last three tables that weight of sample was used which would oxidize all of the stannous chloride present on complete removal of the positive halogens. The solutions used in Tables IV-IX were made as follows.

Table IV: 160 g. of HCl (37%) and 14 g. of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ made up to a volume of one liter with 95% alcohol.

Table V: 435 g. of HCl (37%) and 25 g. of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ made up to one liter with 95% alcohol; 5.0 cc. of this solution neutralized 23.0 cc. of *N* NaOH.

Table VI: 175 g. of HCl (37%) and 15 g. of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ made up to one liter with 95% alcohol; 5.0 cc. of this solution neutralized 10.4 cc. of *N* NaOH.

Table VII: 135 g. of HCl (37%) and 26 g. of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ made up to one liter with 95% alcohol; 5.0 cc. of this solution neutralized 7.7 cc. of *N* NaOH.

Table VIII: 160 g. of H_2SO_4 (concentrated) and 30 g. of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ made up to one liter with 95% alcohol; 200 cc. of water was added in an attempt to dissolve the heavy precipitate of tin salts; 5.0 cc. of this solution neutralized 12.6 cc. of *N* NaOH.

Table IX: 435 g. of H_2SO_4 (concentrated), 35 g. of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ and 150 cc. of water were made up to a volume of one liter with 95% alcohol.

Summary

1. The rate of removal of positive halogens from halogen phenols and halogen naphthols increases strikingly with the acid concentration.
2. The rate of hydrolysis in acid solution is independent of the concentration of the stannous chloride.

THE SOLUBILITY OF BARIUM *n*-BUTYRATE^{1,2}

BY HENRY J. WING

RECEIVED JULY 11, 1927

PUBLISHED NOVEMBER 5, 1927

In 1887 Sedlitzky³ determined the solubilities of the calcium salts of isovaleric, isobutyric and methylacetic acids. In 1902 Lumsden⁴ determined the solubilities of a number of calcium salts of the acetic acid series. In 1903 Walker and Fyffe⁵ studied the solubility of barium acetate. In 1926 the solubility of barium propionate was reported.⁶ Since some of these later determinations are at variance with those of the earlier investigators, the determination of the solubility of barium *n*-butyrate was undertaken, although it had been reported by Desz thy in 1893.⁷

While Desz thy's curve for the solubility of barium *n*-butyrate, as shown by the dotted line in Fig. 1, is somewhat similar to that obtained in this investigation, yet there is a distinct difference in the values obtained.

Experimental Part

Preparation of the Salt.—The barium *n*-butyrate was prepared by treating c. p. barium hydroxide with a slight excess of *n*-butyric acid (Eastman's, *n*-Butyric acid No. 60) and evaporating the solution to crystallization. The crystals were washed with alcohol and dried. The analyses in Table I show that the alcohol washing had no effect on the composition of the salt.

Determination of the Composition of the Hydrate.—Desz thy reported that the salt in contact with solution was the dihydrate over the entire temperature range.⁷

The salt crystallizes slowly from the solution in beautiful star-shaped clusters of slender crystals. Some individuals over two centimeters in length were obtained. As shown in Table I the salt is in the water-free form at 20° and washing with alcohol and drying at 60° have no effect on its composition. The analysis of the salt at 0° indicates that it is also anhydrous. A microscopic examination of these latter crystals showed them to be identical with those at 20°.

¹ This is the second of a series of determinations of the solubilities of the barium salts of the fatty acids.

² The early completion of this study was accomplished only by the assistance of one of our senior students, Mr. C. W. Eddy, which assistance it gives me great pleasure to acknowledge.

⁷ Desz thy, *Monatsh.*, **14**, 245 (1893).

TABLE I
DETERMINATION OF FORM OF SALT

Type of sample	Wt. of sample, g.	BaCrO ₄ found	BaCrO ₄ calcd. from Ba(but.) ₂	BaCrO ₄ calcd. from Ba(but.) ₂ .H ₂ O
Large crystals, H ₂ O washed, air dried at 20°	0.8609	0.6963	0.7003	0.6620
Small crystals, alc. washed, oven dried at 60°	.5500	.4452	.4474	.4229
Crystals at 20°, H ₂ O washed, air dried, 1 hour	.7737	.6205	.6294	.5950
Crystals at 0.3° for 60 hours, filtered and air dried, 1/2 hour	.5728	.5530	.5471	.5173

Determination of the Solubility.—The solubilities were determined by making up the solutions, with an excess of salt, in two large tubes. These were placed in a thermostat equipped with a thermo-regulator in which the mercury contact did not foul, although the current through the regulator was about one-half ampere.⁸ The regulation was within a 0.02° over the entire temperature range.

Fig. 1.

The solution in one tube was kept for half an hour at a temperature of from ten to twenty degrees above that of the observation and was then placed in the bath. The solution in the other tube was kept at a temperature below that of the observation until the experiment was ready to be carried out. The two solutions, placed in the bath at the required temperature, were stirred continuously for several hours, two to five, depend-

⁸ Wing and Thompson, *Ind. Eng. Chem.*, 17, 1242 (1925).

ing upon the temperature. Samples were then withdrawn by forcing the liquid through a filter and capillary tube into tared weighing bottles. The barium was precipitated in the form of the chromate and the amount of barium *n*-butyrate present was determined from this. Table II shows the results of these determinations and they are shown graphically by the solid line in Fig. 1.

The results of the determinations made by the supersaturation method and the undersaturation method were in very close agreement. In the average, the agreement was better than 0.2%. For example, by the undersaturation method, at 50.05° the test portion contained 26.50 g. of barium butyrate in 100 g. of solution, while at the same temperature, 26.53 g. of barium butyrate was found in 100 g. of solution by the supersaturation method. The values given in Table II are for the mean solubility at the various temperatures.

TABLE II
SOLUBILITY OF BARIUM BUTYRATE

Temp., °C.	0.06	9.92	19.86	26.50	33.00	39.98
Ba(but.) ₂ in 100 g. of soln., g.	27.0	26.5	26.1	25.9	25.9	26.0
Ba(but.) ₂ in 100 g. of water, g.	37.0	36.1	35.4	34.9	34.9	35.2
Temp., °C.	50.05	59.97	70.08	80.05	90.27	94.96
Ba(but.) ₂ in 100 g. of soln., g.	26.5	27.1	28.0	29.5	31.3	32.5
Ba(but.) ₂ in 100 g. of water, g.	36.1	37.2	39.0	41.7	45.5	48.1

Summary

1. The solubility of barium *n*-butyrate is a minimum at about 30°.
2. Over the entire temperature range, the salt in equilibrium with the solution is the water-free salt.
3. The solubility curve of barium *n*-butyrate is convex to the temperature axis.

PIPERIDINE DERIVATIVES. V. THE PREPARATION AND REDUCTION OF CERTAIN PHENYL SUBSTITUTED 3-CARBETHOXY-4-PIPERIDONES. 1-CYCLOHEXYL- AND 1-PHENYLETHYL-3-CARBETHOXY-4-PIPERIDYL-PARA-AMINO BENZOATES¹

BY J. R. THAYER AND S. M. McELVAIN

RECEIVED JULY 14, 1927

PUBLISHED NOVEMBER 5, 1927

In an earlier communication by one of us² the preparation of a series of 1-alkyl-3-carbethoxy-4-piperidyl-*p*-aminobenzoates of the formula

was described.

These substances showed very marked and unexpected physiological action. It was found that the size of the alkyl group in the 1 position had a pronounced effect on the physiological activity of the compounds, for, as the size of the alkyl group was increased, the subcutaneous toxicity was lowered and the efficiency for corneal anesthesia raised.

Because of this unexpected behavior, it seemed advisable to study the effect of substituting certain aryl and aryl-alkyl groups in the 1 position of the piperidine nucleus of the type compound shown above.

The preparation of such derivatives necessarily involved the synthesis of the corresponding piperidones by the same internal aceto-acetic ester condensation of the proper dicarbethoxy tertiary amines that was used for the 1-alkyl-3-carbethoxy-4-piperidones.³ The piperidones in which

R was the phenyl, benzyl and phenylethyl group were prepared. Very satisfactory yields (40–70%) of these piperidones were obtained, showing that the above condensation is of quite general application and is not materially affected by the nature of the R group.

The reduction of these phenyl substituted piperidones was interesting particularly as compared to the reduction of the 1-alkyl-3-carbethoxy 4-piperidones. When these latter compounds were reduced catalytically

¹ This paper is an abstract of a portion of the thesis submitted by J. R. Thayer to the Graduate School of the University of Wisconsin in partial fulfillment of the requirements for the Degree of Doctor of Philosophy in Chemistry.

² McElvain, *This Journal*, **48**, 2239 (1926).

with Adams' platinum-oxide platinum black catalyst it was found that 15-20 hours were required to reduce the ketone group to a point where it showed no coloration with ferric chloride. This reduction to a negative ferric chloride test generally required 10-20% excess of the theoretical amount of hydrogen necessary to convert the ketone into the secondary alcohol.

The 1-phenyl derivative, in the first three hours of the reduction, absorbed about 50% of the theoretical amount of hydrogen necessary to reduce both the ketone group and the benzene ring, and the reduction of the ketone group was not complete at this stage. The rate of reduction decreased somewhat after this rapid, initial absorption but at the end of twelve to fifteen hours the reduction was complete, as shown by the fact that approximately 15% excess of the hydrogen necessary to reduce both the ring and the ketone group had been absorbed and the reduction product gave no coloration with ferric chloride. Inasmuch as there was unreduced ketone present after hydrogen in excess of that required completely to reduce the ring had been absorbed, it is difficult to arrive at any conclusions as to the order in which the reduction took place. From the observations which were made, it may be that the ring and ketone group are reduced simultaneously, or that the ring was reduced before the reduction of the ketone began. In either case the final reduction product, as determined by derivatives, was 1-cyclohexyl-3-carbethoxy-4-hydroxypiperidine.

In the reduction of the 1-benzylpiperidone, there was no rapid initial absorption of hydrogen and both the ring and the ketone group seemed to reduce simultaneously. The reduction to a negative ferric chloride test took place in about 24 hours and required 65-75% of the theoretical amount of hydrogen necessary for the complete reduction of both the ring and ketone group. From this point the reduction was very slow but could be continued to a stage where an excess of 12-15% of the theoretical amount of hydrogen necessary to reduce both groups had been absorbed. It was not possible to isolate a crystalline derivative of the reduction product, either at the point where the ketone was completely reduced or at the point where more than sufficient hydrogen had been absorbed to reduce both the ketone and the ring. From the standpoint of producing a definite final product, the catalytic reduction of the 1-benzyl-3-carbethoxy-4-piperidone was unsuccessful, but it did show the effect of the separation of the aromatic nucleus from the amino nitrogen on the rate of nuclear hydrogenation.

In the case of the 1-phenylethyl-3-carbethoxy-4-piperidone, in which the aromatic nucleus is two carbon atoms removed from the amino nitrogen, the reduction proceeded in much the same manner as that of the 1-alkyl-3-carbethoxy-4-piperidones. A negative test for the ketone was obtained with ferric chloride after 10-12 hours of reduction and at this

point approximately 20% excess of the hydrogen necessary for the reduction of the ketone group had been absorbed. Thereafter there was practically no absorption of hydrogen even on prolonged exposure to reduction. As mentioned above, the 1-alkyl-3-carbethoxy-4-piperidones generally absorbed an excess of 10-20% of the hydrogen necessary for the reduction of the ketone to the secondary alcohol. From such data it is apparent that the reduction of the aromatic nucleus in the 1-phenylethylpiperidone does not take place to any marked extent, if at all.

The reduction products of these piperidones were acylated with *p*-nitrobenzoyl chloride. The derivative obtained from the 1-phenyl-3-carbethoxy-4-piperidone was assumed to be 1-cyclohexyl-3-carbethoxy-4-piperidyl-*p*-nitrobenzoate on account of (1) the amount of hydrogen absorbed during the reduction of the piperidone and (2) the absence of unsaturation in the *p*-nitrobenzoate as shown by dilute potassium permanganate solution.

It was not possible to isolate a crystalline *p*-nitrobenzoate from the acylation of the reduction product of the 1-benzylpiperidone. This reduction product showed a distinctly different behavior from the others with *p*-nitrobenzoyl chloride. There was very little evolution of hydrogen chloride when the reactants were heated together. Under the same conditions, the reduction products of the other piperidones gave a vigorous evolution of hydrogen chloride with *p*-nitrobenzoyl chloride. Such behavior would indicate that considerable reduction of the secondary alcohol group to a methylene group had taken place.

1-Phenylethyl-3-carbethoxy-4-piperidyl-*p*-nitrobenzoate was shown to be the derivative obtained from the acylation of the reduction product of the 1-phenylethyl-3-carbethoxy-4-piperidone by (1) the amount of hydrogen absorbed in the reduction of the piperidone and (2) the fact that benzoic acid was obtained by the oxidation of the reduction product.

The 1-cyclohexyl- and 1-phenylethyl-3-carbethoxy-4-piperidyl-*p*-nitrobenzoates were converted by catalytic reduction into the corresponding *p*-aminobenzoates, which were isolated as the crystalline dihydrochlorides

Experimental

β -Carbethoxyethylphenylamine.—This substance has been prepared by Harrie and Loth⁴ from aniline and β -iodopropionate. The following procedure was used in this work. A mixture of 180 g. (1 mole) of ethyl- β -bromopropionate and 190 g. (2 moles) of freshly distilled aniline was heated to 70-80° in an oil-bath with stirring. At this temperature a rather vigorous reaction took place, whereupon the heating was discontinued until this initial reaction had subsided. The mixture was then heated at 110-120° for two to three hours, after which it was cooled and the precipitated anilin hydrobromide filtered off by suction. The precipitate was washed with 200 cc. of ether. The ether was evaporated from the filtrate and the secondary amine distilled unde

⁴ Harries and Loth, *Ber.*, 29, 514 (1896).

diminished pressure. The yield was 140–145 g. (72–75% of the theoretical); b. p. 133–135° (2 mm.); n_D^{20} 1.5315; d_{20}^{20} 1.0709. The hydrochloride melted at 98–99°.

Anal. (of the hydrochloride). Subs., 0.2020: AgCl, 0.1261. Calcd. for $C_{11}H_{16}O_2 \cdot NCl$: Cl, 15.46. Found: 15.44 (of the free base).

Subs., 0.7972, 0.7169: 43.2, 40.4 cc. of 0.0911 *N* HCl. Calcd. for $C_{11}H_{16}O_2 \cdot N$: N, 7.25. Found: 6.91, 7.12.

β -Carbethoxyethylbenzylamine.—To a solution of 54 g. of benzylamine in 400 cc. of alcohol was added 90 g. (0.5 mole) of ethyl β -bromopropionate at such a rate that the temperature of the mixture did not exceed 50°. The mixture was then allowed to stand for about three hours. During this time it was shaken occasionally. Sixty g. of silver oxide was then added and the mixture shaken intermittently for two hours. The alcoholic solution of the amine was filtered with suction and the precipitate washed with 125–150 cc. of alcohol. The alcohol was removed from the filtrate by distillation and the amine dissolved in 400 cc. of ether. The ethereal solution was washed twice with 10% potassium cyanide solution, after which the solvent was removed and the amine distilled under diminished pressure. The yield was 63–68 g. (60–65% of the theoretical); b. p. 132–134° (2 mm.); n_D^{20} 1.5059; d_{20}^{20} 1.9126. The hydrochloride melted at 147–149°.

Anal. (free base). Subs., 1.1128, 1.2086: 56.77, 62.90 cc. of 0.0911 *N* HCl. Calcd. for $C_{12}H_{17}O_2 \cdot N$: N, 6.76. Found: 6.51, 6.64.

(Hydrochloride). Subs., 0.2700: AgCl, 0.1551. Calcd. for $C_{12}H_{17}O_2 \cdot NCl$: 14.58. Found: 14.20.

β -Carbethoxyethylphenylethylamine.—This amine was prepared in exactly the same manner as that described above for β -carbethoxyethylbenzylamine. The yields were 68–72 g. (62–65% of the theoretical); b. p. 145–147° (2 mm.); n_D^{20} 1.5040; d_{20}^{20} 1.0098. The hydrochloride melted at 161–163°.

Anal. (free base). Subs., 0.9994, 0.7326: 46.8, 36.3 cc. of 0.0911 *N* HCl. Calcd. for $C_{13}H_{19}O_2 \cdot N$: N, 6.33. Found: 5.97, 6.32.

(Hydrochloride). Subs., 0.2310: AgCl, 0.1277. Calcd. for $C_{13}H_{19}O_2 \cdot NCl$: Cl, 13.78. Found: 13.66.

β,β' -Dicarbethoxydiethylphenylamine.—A mixture of 195 g. (1 mole) of β -carbethoxyethylphenylamine and 90 g. (0.5 mole) of ethyl β -bromopropionate was heated at 110–120° for 36–40 hours. The reaction mixture was then treated with alkali solution and the free amines were extracted with three 200cc. portions of ether. The ether was removed by distillation and the amines were fractionally distilled under diminished pressure, the fraction boiling at 180–200° (2 mm.) being collected as the tertiary amine. The yield was 126–135 g. For analyses and physical constants this amine was further purified by shaking with an alkaline aqueous suspension of benzoyl chloride. On redistillation, the tertiary amine boiled at 182–184° (2 mm.); n_D^{20} 1.5176; d_{20}^{20} 1.0948.

Anal. Subs., 1.0248, 1.0295: 36.76, 37.47 cc. of 0.091 *N* HCl. Calcd. for $C_{16}H_{23} \cdot O_2N$: N, 4.78. Found: 4.58, 4.64.

β,β' -Dicarbethoxydiethylbenzylamine.—To 104 g. (0.5 mole) of β -carbethoxyethylbenzylamine in 100 cc. of alcohol was added 90 g. (0.5 mole) of ethyl β -bromopropionate. The mixture was allowed to stand for two and a half to three hours with occasional shaking and then heated to 100° for a half hour. The mixture was cooled to 20–30° and diluted with 300 cc. of alcohol. Sixty g. of silver oxide was then added and the mixture shaken intermittently for about two hours. The silver bromide was filtered off and the precipitate washed with 150 cc. of alcohol. The alcohol was removed from the filtrate, the amine dissolved in 400 cc. of ether and the ethereal solution washed twice with a dilute solution of potassium cyanide. After the removal of the ether the

amine was distilled under diminished pressure. The yield amounted to 92–95 g. (82–85% of the theoretical). The tertiary amine was freed from any secondary amine by treatment with benzoyl chloride. It then boiled at 181–183° (2 mm.); n_D^{20} 1.4942; d_{20}^{20} 1.0598.

Anal. Subs., 1.3649, 1.3025: 49.1, 46.5 cc. of 0.0911 *N* HCl. Calcd. for $C_{17}H_{23}O_4N$: N, 4.57. Found: 4.58, 4.56.

β,β' -Dicarbethoxydiethylphenylethylamine.—This amine was prepared according to the procedure given above for β,β' -dicarbethoxydiethylbenzylamine. The yield was 80–84 g. (50–52% of the theoretical); b. p. 190–193° (2 mm.); n_D^{20} 1.4990; d_{20}^{20} 1.0454.

Anal. Subs., 1.2533, 1.2248: 43.37, 40.80 cc. of 0.0911 *N* HCl. Calcd. for $C_{18}H_{17}O_4N$: N, 4.36. Found: 4.42, 4.25.

1-Phenyl-, 1-Benzyl- and 1-Phenylethyl-3-carbethoxy-4-piperidone Hydrochlorides.—These substances were prepared by the internal condensation of the corresponding dicarbethoxy tertiary amines with sodium in xylene and isolated by the procedure described by McElvain.^{3b}

TABLE I

1-Substituent	Formula	M. p., °C.	Yield, %	Analyses (%Cl) calcd.	found
Phenyl	$C_{14}H_{18}O_3NCl$	144–145	70	12.54	12.50
Benzyl	$C_{15}H_{20}O_3NCl$	170–172	50	11.93	11.84
Phenylethyl	$C_{16}H_{22}O_3NCl$	165–167	40	11.42	11.45

Reduction of 1-Phenyl-3-carbethoxy-4-piperidone Hydrochloride.—A solution of 20 g. of the piperidone in 125 cc. of alcohol was reduced catalytically using 0.5 g. of Adams' platinum-oxide platinum black catalyst, at room temperature and under a pressure of 2.5–3.5 atmospheres. The reduction of the ketone group was followed by testing portions of the solution for coloration with ferric chloride, and the reduction of the aromatic nucleus was estimated from the amount of hydrogen absorbed. Four molecular equivalents of hydrogen were necessary for the reduction of both the ketone group and the ring. In the first three hours of reduction approximately 2 molecular equivalents of hydrogen were absorbed. The absorption of hydrogen at the end of twelve hours amounted to 4.31 molecular equivalents, which was in excess of that theoretically necessary to reduce both groups. At this point a positive test for the ketone was obtained with ferric chloride. For complete reduction of the ketone it was necessary to continue the reduction for an additional six to eight hours, at the end of which time the ferric chloride test was negative and the total absorbed hydrogen amounted to 4.46 molecular equivalents. No attempt was made to isolate or purify the reduction product.

Reduction of 1-Benzyl-3-carbethoxy-4-piperidone Hydrochloride.—Twenty g. of this piperidone was reduced catalytically in the manner described above. In the first nine hours of reduction there was an absorption of 1.80 molecular equivalents of hydrogen and the ketone group was not completely reduced. In a series of six runs the minimum absorption of hydrogen necessary for the complete reduction of the ketone group was 2.51 molecular equivalents, while in the other cases it varied between 2.59 and 2.81 molecular equivalents. At the end of thirty-six to forty hours of exposure to reduction the amount of hydrogen absorbed amounted to 4.29–4.44 molecular equivalents.

Reduction of 1-Phenylethyl-3-carbethoxy-4-piperidone Hydrochloride.—The reduction procedure was the same as that outlined above for the 1-phenyl derivative. In the first twelve hours of reduction the amount of hydrogen absorbed was 1.49 molecular equivalents. This amount was approximately a 50% excess over that necessary for the ketone reduction. Upon exposure to reduction for an additional twenty-four

hours, there was practically no further absorption of hydrogen. This reduction product, after the removal of the solvent, yielded benzoic acid when oxidized with an aqueous potassium permanganate solution.

1-Cyclohexyl-3-carbethoxy-4-piperidyl-*p*-nitrobenzoate Hydrochloride.—The catalyst was filtered from the solution of the reduction product of the 1-phenyl-3-carbethoxy-4-piperidone and the alcohol removed by distillation under diminished pressure. After the complete removal of the solvent, 25 g. of *p*-nitrobenzoyl chloride was added and the mixture heated at 140–145° in an oil-bath until the evolution of hydrogen chloride ceased. The nitro ester was isolated by the same procedure as that used for the corresponding 1-alkyl compounds. The yield was 8–9 g. An aqueous solution of the hydrochloride of this *p*-nitrobenzoate gave no indication of unsaturation when treated with dilute aqueous potassium permanganate. The recrystallized *p*-nitrobenzoate hydrochloride melted at 188–190°.

Anal. Subs., 0.2530: AgCl, 0.0819. Calcd. for $C_{21}H_{27}O_6N_2Cl$: Cl, 8.05. Found: 8.00.

Attempted Acylation of the Reduction Product of 1-Benzyl-3-carbethoxy-4-piperidone Hydrochloride.—Several attempts were made to acylate the reduction product obtained when the reduction was stopped at the point where a negative test for the ketone was indicated. This product gave very little reaction with *p*-nitrobenzoyl chloride. The reduction product obtained when the reduction was continued to the point where an excess of hydrogen over that required to reduce both the ketone group and the ring had been absorbed, was treated with *p*-nitrobenzoyl chloride. In this case also there was very little evolution of hydrogen chloride. From neither of these attempted acylations was it possible to obtain a crystalline derivative of the reduction products. The lack of reaction with *p*-nitrobenzoyl chloride would indicate, it seems, that the ketone group had been converted, to a very large extent, to a methylene group.

1-Phenylethyl-3-carbethoxy-4-piperidyl-*p*-nitrobenzoate Hydrochloride.—The reduction product from the 1-phenylethyl-3-carbethoxy-4-piperidone, after the removal of the solvent, was treated with *p*-nitrobenzoyl chloride under the conditions described above. The reaction appeared to proceed normally and produced a copious evolution of hydrogen chloride. The hydrochloride of the *p*-nitrobenzoate crystallized well and behaved in all respects like the corresponding 1-alkyl derivatives. The yield was 15 g. of a product melting at 195–197°.

Anal. Subs., 0.2570: AgCl, 0.0805. Calcd. for $C_{23}H_{27}O_6N_2Cl$: Cl, 7.67. Found: 7.75.

1-Cyclohexyl- and 1-Phenylethyl-3-carbethoxy-4-piperidyl-*p*-aminobenzoate Dihydrochlorides.—Ten g. of the *p*-nitrobenzoate hydrochloride was dissolved in 250 cc. of absolute alcohol and reduced catalytically using 0.25 g. of Adams' platinum-oxide platinum black catalyst. The reduction was complete in twenty to thirty minutes and the *p*-aminobenzoates were isolated as the dihydrochlorides by the procedure that was used for the 1-alkyl-3-carbethoxy-4-piperidyl-*p*-aminobenzoate dihydrochlorides.²

TABLE II

1-Substituent	Formula	M. p., °C.	Analyses (% Cl)	
			Calcd.	Found
Cyclohexyl	$C_{21}H_{27}O_4N_2Cl_2$	220–222	15.85	15.47
Phenylethyl	$C_{23}H_{29}O_4N_2Cl_2$	215–218	15.12	14.85

Pharmacological Report

The authors are indebted to Mr. Charles L. Rose of the Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana, for this

pharmacological report on the 1-cyclohexyl- and 1-phenylethyl-3-carbethoxy-4-piperidyl-*p*-aminobenzoates.

The anesthetic efficiencies were tested by application of 1% solutions of the anesthetics ($P_H = 5$) to the rabbit's cornea and noting the duration of anesthesia. The toxicities were measured by subcutaneous injection into white mice. These data, together with comparative values for cocaine, are summarized in Table III.

TABLE III
PHARMACOLOGICAL DATA

1-Substituent	Duration of anesthesia in minutes with 1% solution (aver. for 5 rabbits)	Toxicity to white mice mg. per kg.	
		M. T. D.	M. L. D.
Cyclohexyl	26.1	100	150 (28 mice used)
Phenylethyl	46.4	1150	1200 (40 mice used)
Cocaine	20.4	200	250

The above data indicate that the 1-cyclohexyl-3-carbethoxy-4-piperidyl-*p*-aminobenzoate is somewhat more efficient than cocaine in producing corneal anesthesia, while the corresponding 1-phenylethyl derivative is over twice as efficient as cocaine. The toxicity of the cyclohexyl derivative is slightly greater than that of cocaine, while the toxicity of the 1-phenylethyl derivative is approximately one-fifth that of cocaine.

The toxicity of the cyclohexyl derivative is interesting when compared with the corresponding 1-alkyl derivatives. In the case of these latter compounds it was found that the subcutaneous toxicity to white mice decreased as the size of the alkyl group in the 1 position was increased. The 1-methyl and 1-*iso*-amyl derivatives had values of 100 mg. per kg. and 550 mg. per kg., respectively, as the minimum lethal doses for white mice. It is seen from Table III that the 1-cyclohexyl derivative is approximately equivalent to the 1-methyl derivative in toxicity. It might have been expected that the presence of a group of such a carbon content as the cyclohexyl group in the 1 position would have produced a physiological effect of the order of that shown by the higher alkyl radicals, such as the *iso*-amyl radical. Since this expected similarity in behavior between the cyclohexyl group and the higher alkyl groups was not found to exist, it appears that the abnormal action of the former is due to its cyclic structure. The toxicity of the phenylethyl derivative is exceptionally low and, since at the same time its anesthetic efficiency is quite high, it indicates that phenyl-alkyl radicals may be very desirable N-substituent groups in local anesthetics.

Summary

1. The preparation of some 1,3,4-tri-substituted piperidines and the reduction of the corresponding 4-piperidones have been described.
2. A preliminary pharmacological report on the 1-cyclohexyl- and

1-phenylethyl-3-carbethoxy-4-piperidyl-*p*-aminobenzoates has been included.

3. This pharmacological report indicates that the cyclohexyl group does not correspond to the higher alkyl groups in its physiological effect and is a much less desirable N-substituent group than the phenylethyl group for this particular type of local anesthetic.

AZO DYES CONTAINING ANTIMONY. II

By FITZGERALD DUNNING AND E. EMMET REID

RECEIVED JULY 21, 1927

PUBLISHED NOVEMBER 5, 1927

In a previous paper,¹ the preparation of a series of azo dyes containing antimony has been described. These compounds were prepared for a study of their possible therapeutic action. Since that time another series of dyes and several miscellaneous antimonials have been prepared. These compounds have been tested as to their activity against trypanosomes and as to their toxicities. The pharmacological findings, which are summarized here, will be published more fully elsewhere.

As these compounds are, for the most part, dyes, it was thought of interest to ascertain the effect of the antimony group on the color. Dyes containing the group $\text{—SbO}_3\text{H}_2$ have been contrasted with those having the SO_3H group and with some containing neither.

Results

The compounds which have been prepared are for the most part derivatives of stibanilic acid, *p*-aminophenylstibinic acid $\text{—H}_2\text{NC}_6\text{H}_4\text{SbO}_3\text{H}_2$. The method of preparation of this compound has been further improved. This consists in breaking down the molecular compound formed by diazotized *p*-amino-acetanilide and antimony trichloride with hot sodium hydroxide. Thus stibanilic acid is obtained from the molecular compound in one step.

The first series of compounds, Nos. I to VI, described in the previous paper, were obtained by coupling diazotized stibanilic acids with substituted phenols. In the second series, diazotized stibanilic acid has been coupled with dimethyl- and diethylaniline to form *p*-dimethylamino-azobenzene-4'-stibinic acid and the corresponding diethyl compound (Nos. VII and VIII). The disodium salts, $\text{Na}_2\text{O}_3\text{SbC}_6\text{H}_4\text{N:N:C}_6\text{H}_4\text{N(R)}_2$, are normally formed and are readily soluble in water. The solutions are comparatively stable.

The third series has been prepared by coupling diazotized stibanilic acid with various substituted naphthalene sulfonic acids.

¹ Dunning and Reid, *THIS JOURNAL*, **48**, 2959 (1926).

The intermediates used were as follows: 1,8-naphthylamine-3,6-disulfonic acid (H-acid); 1-naphthol-4-sulfonic acid (Neville and Winther's acid); 5,2-naphthylamine-7-sulfonic acid (J-acid); 2-naphthol-3,6-disulfonic acid (R-salt); 2-naphthylamine-3,6-disulfonic (amino R salt); 1,8-dinaphthol-3,6-disulfonic acid (chromotrope), to form compounds XII, XIII, XIV, XV, XVI and XVII, respectively. The structural formulas are

Methylantranilate, *p*-aminodimethylaniline and benzidine have also been diazotized, coupled with antimony trichloride and treated with sodium hydroxide to give the following compounds: methyl *o*-stibono-benzoate, *p*-dimethylaminophenylstibinic acid and *p,p'*-dibenzenestibinic acid.

The sodium salts of all the compounds described have been tested as to their effectiveness against trypanosomiasis. For this purpose the white (albino) rat infected with *Trypanosoma equiperdum* has been used. All of the compounds of the first and second series have proved to be totally ineffective. With the third series, however, positive results have been obtained. Compound XII (as indicated above) has proved to be the most effective and compounds XVI and XIV follow in order.

The compounds which have been found to be effective possess approximately the same structural formulas, as the pharmacological table of findings will show. The presence of one amino group and one sulfonic acid group, and preferably two sulfonic acid groups, in the naphthalene intermediate, seems to be necessary, as an inspection of the formulas of compounds XII, XIV and XVI will show. These findings are in keeping with the conclusions of Ehrlich² and of Nicolle and Mesnil³ working with benzidine dyes.

That antimony is necessary is witnessed by the fact that analogous dyes made from sulfanilic acid have no trypanocidal action.

² Ehrlich, *Berl. klin. Wochschr.*, **44**, 233, 280, 310, 341 (1907).

³ Nicolle and Mesnil, *Ann. inst. Pasteur*, **20**, 417, 513 (1906).

Experimental

In following any of the general methods^{4,5} for the preparation of stibanilic acid, several difficulties are encountered.

Not only is the material hard to handle mechanically, but the yields are generally low. In the first place, on treating the diazotized amine solution with antimony trichloride, the oxychloride of antimony precipitates out unless the solution is strongly acid. When a strong sodium hydroxide solution of antimony oxide is used, the oxide precipitates. The greatest difficulty, however, is caused by the production of a stiff foam which prevents thorough mixing of the reactants and causes much trouble mechanically. This foam subsides only after standing for a considerable length of time (24 hours) and occasions much decomposition. To overcome this, we experimented with various foam-breakers such as ether, alcohol, acetone, etc., but these all seemed to cause decomposition and were discarded. We have developed, however, two methods which have proved fairly successful. One, a modification of the method of Schmidt, was reported previously. The other is shorter, in that two steps are combined.

A mixture of *p*-amino-acetanilide (150 g.), recrystallized after boiling with charcoal, and antimony trioxide (145 g.) in one liter of water containing sufficient 33% hydrochloric acid to dissolve the trioxide (600 cc.) was warmed until everything dissolved. On cooling, white crystals of the hydrochloride of the amine separated out. This mixture was cooled to 0° and diazotized with a solution of 69 g. of sodium nitrite in 460 cc. of water. The nitrite solution was introduced through a capillary at the bottom of the beaker, with mechanical stirring. During this slow addition a yellow, crystalline (rectangular plates) compound formed. This is the double salt of the type described by May.⁶

These diazonium chloride antimony trichloride complex salts are very stable and their formation is almost quantitative. As the product formed here, $\text{CH}_3\text{CONHC}_6\text{H}_4\text{-N}_2\text{Cl}\cdot\text{SbCl}_3$, is somewhat soluble in hydrochloric acid, the yield of this reaction is only about 90%.

This compound was filtered off, suspended in water and the suspension was added slowly to a 10% solution of sodium hydroxide heated to 90°, the solution being stirred mechanically. This method gave good results and the time of the procedure was considerably shortened. The evolution of nitrogen was comparatively rapid and the foam formed on each addition of the molecular compound subsided rapidly. The addition usually takes from one to two hours. After all the suspension was added, the solution was heated at the same temperature until a test filtered portion precipitated and redissolved in excess dilute hydrochloric acid. The solution was then nearly neutralized and saturated with carbon dioxide to precipitate impurities. It was filtered, and from the filtrate stibanilic acid, $\text{NH}_2\text{C}_6\text{H}_4\text{SbO}_2\text{H}_2$, precipitated by acetic acid, the acetyl group having been removed during the procedure. The crude stibanilic acid is removed from the liquid by centrifuging and is then ready for use. The yield varies but is generally about 50%, figured on the crude acid.

The breaking down of the molecular compound was also effected by ammonium hydroxide, sodium carbonate solutions and solutions of sodium hydroxide of varying strengths. The effect of copper powder, mild oxidizing agents, etc., was also tried with no success.

As the crude product has been found to be sufficiently pure for our purpose, it has been used without further purification. This has been

⁴ Ger. pat. 254,421 (1912); 261,825 (1913); 220,488 (1913).

⁵ Schmidt, *Ann.*, **421**, 174 (1920).

⁶ May, *J. Chem. Soc.*, **101**, 1037 (1912).

particularly fortunate as stibanilic acid is far from being a stable compound, decomposing rapidly on keeping. For this reason, we have prepared our acid as we needed it and have made no attempt to keep it in solid form.

Preparation of Dyes

The second and third series of dyes were made after the same general method described previously.¹ For the preparation of the second series, substituted anilines were utilized as intermediates. Dimethyl-, diethyl-, dipropyl- and dibutylaniline were used but, unfortunately, compounds were formed only by dimethyl- and diethylaniline. These were made as follows.

A calculated amount of stibanilic acid was diazotized with 10% sodium nitrite solution in the customary manner. This was poured into hydrochloric acid solutions containing calculated quantities of dimethyl- and diethylaniline. These solutions were allowed to stand for some time, filtered and made alkaline. The alkaline solutions were clear at first but on standing precipitates formed. These proved to be the *p*-nitroso derivatives of the substituted anilines used. Their formation is due to an excess of nitrous acid in the diazotized stibanilic acid solution, which is difficult to avoid. The solutions were filtered from these impurities and the acid dyes were precipitated by hydrochloric acid. These precipitates were collected by centrifuging and were dried and then washed with hydrochloric acid to remove any phenylstibinic acid or similar by-product and any excess of the intermediate.

The resulting *p*-dimethyl- (VII) and *p*-diethylamino-azobenzene (VIII) were, respectively, dull brown and dull purple in color and both were insoluble in water and organic solvents and soluble in sodium and ammonium hydroxide.

Anal. Calcd. for $C_{14}H_{16}O_2N_2Sb$: Sb, 30.7. Found: 29.9.

Calcd. for $C_{16}H_{20}O_2N_2Sb$: Sb, 28.7. Found: 27.5.

The third series of dyes has been prepared after the following general scheme. Calculated amounts of diazotized stibanilic acid were added to slightly alkaline solutions of various substituted naphthalene sulfonic acids in theoretical amounts. These solutions were warmed and allowed to stand for several hours and then filtered. The filtered solutions were evaporated to small volume on a water-bath. At this point the procedure of preparation differed according to the nature of the dye. If it was possible to precipitate by acid, the solution was acidified, the precipitate collected by centrifuging and dried. The dried, powdered precipitate was thoroughly washed with hydrochloric acid and then with water. This removed any excess intermediate or breakdown products of stibanilic acid. It was again dried and analyzed for antimony. The following compounds were prepared by this method.

Diazotized stibanilic acid was coupled with Neville and Winther's acid, J-acid and amino R salt, respectively, to give compound XIII, dark red; compound XIV, light red brown; and compound XVI, dark brown. Compounds XIII and XIV were insoluble in water. Compound XVI was moderately soluble. All were insoluble in organic solvents but soluble

in sodium and ammonium hydroxides and concentrated sulfuric acid. Sodium salts of all were prepared.

Analyses of the dyes and their sodium salts.

Calcd. for $C_{16}H_{10}O_9N_2Na_4Sb$: Sb, 18.2. Found: 19.5.

The preparation of compounds of Series III which could not be precipitated with acid occasioned much difficulty. By concentrating to very small volume and making the solution very strongly acid with hydrochloric acid, small yields could be obtained. Several methods were attempted in order to isolate the dye. A concentrated solution of the dye was treated with a saturated solution of sodium chloride in an effort to salt out the dye. This method was not very satisfactory as the precipitate contained much salt and, in addition, a large amount of the dye remained in solution. Fractional precipitation from alcohol-water mixture gave fair results but the method was very tedious and the yields were poor.

The method finally adopted was the precipitation of the barium salt of the dye by treating the solution with a solution of barium chloride. The barium salts of the dyes separate out as apparently amorphous precipitates. These precipitates are collected by filtering the solution or by centrifuging, washed thoroughly and dried. Fortunately, the barium salts of the intermediates used to make these dyes are relatively soluble in water and if any of them precipitate with the dye, washing with water removes them. The dried compounds were weighed and then suspended in water. To these suspensions a dilute solution containing sufficient sodium sulfate to precipitate the barium was added. In fact, it is better to add a slight excess of sodium sulfate to prevent the presence of the highly toxic barium ion in the final product. The mixtures were warmed and stirred vigorously. Barium sulfate was thrown down and the sodium salts of the dyes went into solution. A small amount of the dyes is adsorbed on the precipitates, coloring them highly. The barium sulfate was filtered off and the resulting solutions of the sodium salts of the various dyes were evaporated to dryness either on a water-bath or "in vacuo." It is better to dry in a vacuum. Each was tested for barium to insure its absence.

Diazotized stibanilic acid was coupled with H-acid, R-salt and chromotrope, respectively, to give compounds XII, brilliant purple; XV, orange brown; and XVII, purple. These are all soluble in water, insoluble in organic solvents and soluble in concentrated sulfuric acid. They decompose on heating.

Analyses:(XII) Calcd. for $C_{10}H_{10}O_{10}N_3S_2Na_4Sb$: Sb, 17.9. Found: 19.5.(XV) Calcd. for $C_{10}H_9O_{10}N_3S_2Na_4Sb$: Sb, 18.2. Found: 17.2.(XVII) Calcd. for $C_{16}H_{10}O_{11}N_3S_2Na_4Sb$: Sb, 17.8. Found: 16.9.

For comparison, the analogs of all of these dyes were prepared from diazotized sulfanilic acid and the same intermediates. These were isolated as the sodium salts. They have been utilized as dyes for the dyeing of woolen skeins and have also been tested pharmacologically on rats infected with *Trypanosoma equiperdum*.

Miscellaneous

Several antimony compounds which do not belong to any of these classes of dyes have been prepared. The general method of preparing these derivatives has been the application of the diazo reaction for introducing the stibinic acid group. As a consequence, various aromatic amines have been the starting-point for all of the subsequent syntheses.

May found that a double salt of diazotized sulfanilic acid and antimony trichloride could not be prepared, due in all probability to the strong acidic character of the sulfonic acid group. This has been confirmed and also has been found to apply to diazotized anthranilic acid. That the formation of the double salt is prevented by the presence of the acidic groups seems to be indicated strongly by the fact that we have been able to prepare antimony trichloride molecular double salts with diazotized methyl anthranilate and with *p*-aminobenzoic acid. The latter compound is formed with some difficulty. These double salts have been broken down with sodium hydroxide to form the corresponding stibinic acid derivatives.

Antimony compounds have also been prepared from diazotized benzidine, *p*-aminodimethylaniline and *p*-aminodiethylaniline.

The method of preparation has been the same in every case. Tenth molar proportions of the amine and antimony trioxide were dissolved in 100 cc. of water and 60

TABLE I
ANTIMONY COMPOUNDS

Molecular compound	Stibinic acid	Analysis, % Sb, Calcd. Found

^a These crystals were contaminated with the *p*-nitroso-di-alkyl aniline, which gave them a greenish tinge.

cc. of concentrated hydrochloric acid. This solution was cooled to 0° and a 10% water solution of 6.9 g. of sodium nitrite was added through a capillary at the bottom of the beaker, the contents being stirred rapidly. The crystalline double salts, being comparatively insoluble in hydrochloric acid of this concentration, settled out. These were filtered off and suspended in water and this suspension was added slowly to 10% sodium hydroxide at 90°. During the addition the mixture was stirred mechanically and a brisk evolution of nitrogen took place. After this reaction was over, the by-products were precipitated by making the solution almost neutral and passing in carbon dioxide. The sodium salts of the various aromatic stibinic acids were then precipitated by adding alcohol. These salts were obtained by filtering and were dissolved in water and the acid form of the compounds precipitated by dilute acetic acid.

These products were insoluble in water and the usual organic solvents but soluble in sodium and ammonium hydroxides. They decomposed on heating (see Table I).

Analytical

The analyses of these compounds occasioned some difficulty and many methods were tried. The method of Schmidt with a slight modification was used with fair success. After the sample had been burned down with 5 g. of sodium bisulfate and 10 cc. of concentrated sulfuric acid and diluted tartaric acid was added, sulfur dioxide was passed through to insure the reduction of all pentavalent antimony. The excess sulfur dioxide was removed by boiling, preferably in an atmosphere of carbon dioxide. The solution after cooling was neutralized with sodium bicarbonate and then titrated with 0.1 *N* iodine solution.

The method of Macallum works satisfactorily for the water-soluble compounds.

The use of the Parr bomb for oxidation of the sample with sodium peroxide was attempted. The subsequent procedure was: acidification with hydrochloric acid, filtering, adding cooled solution to a solution of 5 g. of potassium iodide in 100 cc. of water and titrating liberated iodine with 0.1 *N* thiosulfate. The results, using this method, were low.^{7,8,9,10}

Pharmacological

All the derivatives of these three series of antimony dyes have been tested against a virulent strain of *Trypanosoma equiperdum*. The white albino rat has been used as a test animal. One per cent. solutions of the dyes were utilized and the results are summarized in Table II.

A more complete report on the pharmacology of these compounds will appear elsewhere.

Antimony and the Color of Dyes

In view of the fact that the compounds described are dyes, it was thought of interest to ascertain the effect of the antimony group as an auxochrome.

XIV	19.4	.4	.09	4-5	8	3	Cures with treatment give promise.
XV	17.3	.4	.1	...	5	0	Effective with mild infection.
XVI	17.5	.4	.08	4-5	10	6	
XVII	16.9	.4	5	0	Effective with mild infection.

Accordingly, dyes were made for this purpose by coupling diazotized stibanilic acid with various intermediates, and for comparison diazotized sulfanilic acid was coupled with the same intermediates. The intermediates used for this purpose were as follows: H-acid, Neville and Winther's acid, J-acid, R-salt, G-salt, Armstrong's acid, Epsilon acid, Schaeffer's salt, chromotrope, phenol, chlorophenol, *o*-cresol, *o*-nitrophenol and salicylic acid.

Woolen and cotton skeins, five grams in weight, were utilized for application of the dyes. Solutions of each dye were prepared in such a manner as to give a 1% dyeing, based on the weight of the skein. Calculated quantities of solutions containing known amounts of diazotized stibanilic and sulfanilic acids, respectively, were pipetted into beakers containing dilute solutions of the requisite amounts of the various intermediates, these solutions being alkaline with sodium carbonate. The technique of the ensuing manipulations is that described by Waldron and Reid¹¹ for the dyeing of woolen and cotton skeins, respectively.

It was found that the antimony dyes had the property of being direct

 TABLE III
 COLOR OF DYES

Intermediate	Auxochrome groups		
	—SO ₂ H (wool)	—SbO ₂ II ₂ (wool)	—SbO ₂ II ₂ (cotton)
H-acid	Bordeaux *	Reddish violet	Light violet
Neville and Winther's acid	Bright reddish orange	Light red	Dull pink
R-salt	Light dull reddish orange	Dull yellowish red	Pale dull reddish orange
G-salt	Very light buff	Pale dull yellowish orange	Very pale, dull reddish orange
Epsilon acid	Bright yellowish brown	Bright yellowish brown	Dull reddish orange
Chromotrope	Cerise	Dull reddish violet	Light bluish violet
Schaeffer's salt	Dull reddish yellow	Orange	Very dull reddish orange
Chlorophenol	Dull yellow	Light dull yellow	Dull cream
Cresol	Greenish yellow	Dull yellow	Cream

¹¹ Waldron and Reid, *THIS JOURNAL*, **45**, 2412 (1923).

dyes for cotton, whereas the sulfanilic acid derivatives were not fast to cotton and were completely washed out.

The colors of the resulting skeins indicate that the antimony group (the stibinic acid group) is more strongly auxochromic in character than is the sulfonic acid group. Table III lists the colors of the various dyes.

Our thanks are extended to Dr. R. E. Rose, of the Technical Laboratory of E. I. du Pont de Nemours and Co., who kindly furnished the skeins for this work and the color designations of the finished products, and also to Mr. C. Slagle of this Laboratory who assisted in preparing the dyed skeins.

Summary

1. The method of preparing stibanilic acid has been improved.
2. Three series of azo dyes containing antimony have been made and tested against trypanosomiasis in the white rat.
3. The effect of antimony on color has been ascertained.
4. Several other antimonials have been described.

VARIOUS EFFECTS PRODUCED BY THE ACTION OF LIGHT UPON THE ISOMERIC MODIFICATIONS OF CERTAIN POLYPEPTIDE-HYDANTOINS

BY DOROTHY A. HAHN AND JANET EVANS

RECEIVED JULY 23, 1927

PUBLISHED NOVEMBER 5, 1927

As a result of the investigation of a fairly large number of pairs of geometrical isomers corresponding to different derivatives of benzal¹ and anisalhydantoin,² the interesting observation has frequently been made that during the process of preparation and purification of these substances, minute quantities of very high-melting and very insoluble compounds were formed. These substances were markedly different in their properties from any of the major products taking part in the particular transformations but were never formed in quantities sufficient to admit of a study of their properties or even of their analysis. Recent work on the isomeric modifications of methyl-N-3-methylbenzalhydantoin-N-1-acetate and of the corresponding acids,¹ has at last made it possible to arrive

¹ Hahn and Evans: The preparation and properties of these substances have been described in a paper which was received by THIS JOURNAL, July 23, 1927.

² Hahn and Gilman, THIS JOURNAL, 47, 2953 (1925).

at a definite and more or less detailed knowledge of some of the conditions which favor the formation of these very insoluble and high-melting compounds. The phenomenon has, for example, now been shown definitely to involve either a polymerization or an intramolecular rearrangement of a single pure substance and to be accelerated if not induced by the action of light. The changes which take place occur slowly in the presence of ordinary daylight, are hastened by bright sunlight and are very markedly accelerated under the influence of ultraviolet light from a mercury arc lamp. Certain of these compounds have been observed to suffer these changes when exposed to light in the *solid* state but the transformation is distinctly favored by the solution of the substance either in alcohol or ether. In particular, ether solutions which contain minute traces of iodine as a catalyst have been observed to give very satisfactory results under the action of ultraviolet light. The rate of transformation varies to a marked degree under what appear to be the same conditions in the case of different substances. The changes which are produced by the action of light are not limited to the formation of the above-mentioned high-melting and insoluble compounds but are fairly complex, as will be apparent from a consideration of the following examples.

I (a) The lower-melting ester, m. p., 65.5–66.5°, whether present in solid crystalline form or when partially dissolved and partially suspended in alcohol or ether, is transformed under the action of light in the following three ways: (i). It isomerizes to give the corresponding higher-melting modification. This was identified by a mixed melting-point determination with an analyzed specimen, m. p., 98.5–99.5°, which had been obtained by synthesis.³ (ii) It decomposes with the splitting off of benzaldehyde. This product was identified by its odor, its reaction with Tollens' reagent and finally by its conversion into benzoic acid. The benzoic acid which was produced in this way was identified by its properties and by a mixed melting-point determination with a pure laboratory specimen (Kahlbaum preparation). This decomposition takes place spontaneously even when pure, dry crystals are allowed to stand in stoppered glass containers, so that the substance cannot be kept unchanged under any conditions prevailing in the laboratory for periods of more than a few months. Incompletely purified specimens, m. p., 63–66°, begin to show signs of decomposition in the course of one week. The other product or products resulting from this decomposition have not been isolated. (iii) It polymerizes or isomerizes to form a substance which is very insoluble in all ordinary solvents and which melts at 278°.

I (b). The corresponding higher-melting ester, m. p., 98.5–99.5°, behaves in much the same way as the lower-melting ester under the action

³ The same change is produced very rapidly and quantitatively in alcohol solution under the action of hydrogen chloride gas. Compare Ref. 1.

of light but is distinguished by the fact that it is relatively much more stable and that its rate of transformation is relatively slower.

(i) It isomerizes to give the corresponding lower-melting modification, m. p., $65.5-66.5^{\circ}$, which was identified by comparison with the analyzed specimen. (ii) It decomposes with the formation of benzaldehyde, which latter was identified as described above. (iii) It polymerizes or isomerizes to give the same insoluble product, m. p., 278° , that was obtained in the case of the lower-melting isomer. The identity of the product which was obtained in the two cases was established by analyses and by means of a mixed melting-point determination.

II (a). The lower-melting corresponding acid, m. p., $186.5-187.5^{\circ}$, appears to be extremely stable under the action of light and suffered no appreciable change in its melting point on standing and no precipitation of an insoluble compound from its solutions even after these had been exposed to radiation from a mercury arc lamp over a period of many weeks.⁴

II (b). The higher-melting isomer suffers the following transformations under the action of light:

(i) It isomerizes to give the lower-melting modification, which was identified by means of a mixed melting-point determination with a pure analyzed specimen. (ii) It has not been observed to decompose with the splitting off of benzaldehyde. (iii) It polymerizes or isomerizes to give an acid which melts with decomposition at $290-294^{\circ}$. This substance is extremely insoluble in all ordinary solvents, but may be recrystallized from boiling acetic acid. It is not identical with the insoluble product which was obtained from the corresponding esters, since a mixture of the two products melted at $265-288^{\circ}$. The product from the esters is neutral to litmus and phenolphthalein, while the product from the above acid shows distinctly acid properties.

A comparison of these results shows that two different insoluble and high-melting rearrangement products are formed by the action of light upon the isomeric modifications of methyl-N-3-methylbenzalhydantoin-N-1-acetate (I, a and b) and upon the corresponding higher-melting acid (II, b), respectively. This is significant in that it suggests at once that the $-\text{COOCH}_3$ and $-\text{COOH}$ groups are still intact in the final product of the reaction. A comparison of the results which were obtained from the analysis of the two products, moreover, approximates very closely to the results obtained from the analysis of the original ester and acid, respectively. Further, the insoluble acid product, m. p., $290-294^{\circ}$, exactly neutralizes one equivalent of base, the reaction being accompanied by the

⁴ It is, however, rapidly and quantitatively transformed into the corresponding higher melting isomer when its acetic acid solution is boiled with hydrochloric acid. Compare Ref. 1.

complete solution of the substance. These facts admit of the assumption that the transformation has been of the nature either of a polymerization (which could be accounted for by the presence of unsaturated ethylene linkages in the original esters and acid) or of an isomerization reaction. The possibility that the reaction is one of polymerization cannot, unfortunately, be settled by means of molecular weight determinations, since the products under consideration are too insoluble to admit of laboratory manipulation by either boiling- or freezing-point methods.

In the event of isomerization two possible rearrangements might be conceived to take place:⁵

The corresponding acid might in either case be assumed to behave similarly. If a compound of the first type were formed, it should show basic properties as it contains a CH_2NH group. Since, however, neither of the high-melting products is soluble to any extent in concentrated hydrochloric acid, the possibility of a rearrangement of this kind would seem to be discounted. On the other hand, the rearrangement of the hydantoin to a pyrimidine would, according to advices from Dr. Johnson, be in general agreement with the observed solubilities of the new products, and if, by any chance, such a transformation can actually be demonstrated it would represent a new generic relationship between hydantoins and pyrimidines and would be of immediate biochemical interest. Typical illustrations of the procedures which have been employed will now be given.

Experimental

The tendency of methyl-N-3-methyl-4-benzalhydantoin to undergo decomposition under the action of light was first noticed when a pure, dry, crystalline specimen, m. p., $65.5\text{--}66.5^\circ$, which had been analyzed and left in a stoppered glass specimen bottle was found after the lapse of three

⁵ These two possible configurations have been suggested by Professor Treat B. Johnson and it now seems probable that the synthesis of a pyrimidine corresponding to the second formula (B) will be attempted next year by Miss Evans at Yale University under the direction of Dr. Johnson.

months to have passed into an oil. When the stopper of the container was removed a strong odor of benzaldehyde was detected. Other specimens were later observed to behave in the same way, the period of time required for liquefaction varying from two weeks to six months under different conditions. Specimens which were less pure, m. p., 63–66°, liquefied very rapidly. The process was also found to be accelerated by radiations from a quartz mercury arc lamp.⁶ The oily products which were obtained in a series of experiments were combined and distilled with steam. The steam distillate yielded a small amount of solid material which was removed by filtration. It melted at 115–118° and after recrystallization from water was identified as benzoic acid by means of a mixed melting point with a pure specimen of benzoic acid of known constitution. Samples of the aqueous filtrate from this substance when treated with 'Tollens' reagent gave a silver mirror. The main portion of the distillate was, therefore, oxidized with permanganate, neutralized with sodium hydroxide and evaporated to small volume. The clear solution which was obtained in this way, when acidified with hydrochloric acid, gave a precipitate of benzoic acid which was identified by comparison with a pure specimen of this substance. An oily residue which remained in the distilling flask after the steam distillation was separated from the supernatant aqueous layer and treated with alcohol. This procedure resulted in its partial solution and the simultaneous separation of an insoluble substance which melted at 276–278°. The alcohol filtrate from the latter was found to contain a mixture of the two isomeric esters II and III. These were partially separated by a process of fractional crystallization.

When the ester, m. p., 65.5–66.5°, was dissolved in alcohol or ether and the clear solution allowed to stand in diffused daylight, it gradually became cloudy and a fine, white, crystalline precipitate was observed to settle on the bottom and walls of the containing vessel. The formation of this precipitate was greatly accelerated by subjecting the solution to the radiations from a mercury lamp. Under this treatment, continued over a period of two weeks in the presence of a trace of iodine as a catalyst, 1.0 g. of ester, m. p., 65.5–66.5°, yielded approximately 0.1 g. of insoluble precipitate, m. p., 276–278°. The alcohol filtrate from this substance smelled strongly of benzaldehyde and on evaporation yielded 0.4 g. of a substance melting at 94–98°. This after recrystallization from alcohol was identified as the higher-melting, isomeric modification of the original ester by comparison with a pure specimen of known constitution. The alcohol filtrates from this substance when combined and evaporated yielded an oil which did not crystallize.

The ester (III), m. p., 98.5–99.5°, was observed to behave similarly. Thus, pure crystalline analyzed specimens which had stood in glass-stoppered containers for a period of one year were found to have become opaque and to have suffered a change in melting point to 97–245°. When recrystallized from boiling alcohol, this mixture was readily

⁶ 220-volt, direct current type, manufactured by the Hanovia Chemical and Manufacturing Company, Newark, N. J.

resolved into an insoluble substance, m. p., 276–278°, which was removed by filtration, and the original ester, m. p., 94–98°. The same effect was produced in ten weeks by exposing a sample of the ester to the action of radiations from a mercury lamp. In this case the product melted at 90–235°, while a sample of the same specimen which was kept in the dark showed no appreciable change in its melting point. The formation of the insoluble substance, m. p., 276–278°, was still further accelerated by partly dissolving and partly suspending the ester, m. p., 98.5–99.5°, in alcohol or ether and subjecting the mixture to the action of radiations from a mercury lamp. Thus 5 g. of ester suspended in 80 cc. of alcohol-free ether and exposed in this way for three weeks yielded 0.2 g. of an insoluble substance melting at 274–278°. In this case 3.6 g. of the original ester, m. p., 94–98°, was recovered and in addition to this 0.2 g. of the lower-melting isomer, m. p., 65.5–66.5°, was isolated as the result of fractional recrystallization of the resulting mixture from alcohol. Traces of benzoic acid were also separated and identified. The formation of the insoluble substances, m. p., 274–278°, appears to represent a time reaction. Thus, in general a clear ether solution becomes cloudy in the course of about a week and in two weeks an appreciable precipitate has formed. If this is removed by filtration and the clear filtrate exposed to the further action of light an *immediate* cloudiness becomes apparent. It should be noted that invariably at the beginning of any experiment there appears to be an appreciable period of time (usually about one week) which is required for the initial reaction. In one case 1.7 g. of ester, m. p., 98.5–99.5°, dissolved in 80 cc. of cold methyl alcohol became slightly turbid after a lapse of 15 hours and yielded 0.2 g. of a precipitate, m. p., 274–277°, after an exposure of three weeks.

The insoluble products, m. p., 274–278°, which were obtained as the result of these experiments were found to be identical whether formed from the lower- or higher-melting esters. This material as obtained from all sources was combined and purified by recrystallization from boiling benzene. The process was an extremely tedious one because of the very slight solubility of the substance (0.3 g. in 600 cc.) but was satisfactory in so far that a pure product melting sharply at 278° was finally obtained.

Anal. Calcd. for $C_{14}H_{14}O_4N_2$: N, 10.21. Found: 10.26.

This composition is the same as that found in the case of the original esters⁷ m. p., 65.5–66.5° and 98.5–99.5°, respectively.

The corresponding isomeric acids, m. p., 186.5–187.5° and 198.5–199.5°, respectively, were observed to differ from each other very considerably in their behavior under the action of light. The former appears to be remarkably stable both in the solid state and in solution. Some action takes place as shown by a change in melting point to 150–180° after an exposure of five months. The change was, however, not sufficient to allow of the separation and identification of any of the transformation products and no trace of an insoluble residue was detected in recrystallizing the above mixture.

The higher-melting isomeric acid, m. p., 198.5–199.5°, was readily transformed into a mixture having a melting point of 190–285° under the action of light. This very definite change was observed in the case of pure, dry, crystalline specimens which had been allowed to stand in stoppered glass containers in ordinary daylight for about a year, but a sample of the same specimen showed an appreciable though smaller change in melting point (to 197–200°) during the course of a month. Both products when treated with alcohol were only partially dissolved and when the resulting solution was filtered an insoluble residue melting with decomposition at 292–294° was obtained.

When the acid, m. p., 198.5–199.5°, partially dissolved and partially suspended in either methyl alcohol or ether, was placed in a quartz bottle and subjected to the action

⁷ Compare Ref. 1.

of radiations from a mercury lamp, the same transformation took place much more rapidly. Thus 5.0 g. of acid gave a precipitate of 0.05 g. of insoluble material, m. p. 292–294°, during the course of two days and the amount of this product increased to 0.3 g. at the end of six weeks. The filtrate from this, on evaporation, yielded 2 g. of a substance which melted at 186–188.5° and which was identified as the corresponding lower-melting isomer after recrystallization and comparison with an analyzed specimen of this compound which had been obtained by synthetic methods. No benzaldehyde was detected as a by-product in any of these transformations. The initial reaction required approximately the same time as was observed in the case of the corresponding esters.

The product melting at 292–294° was not identical with the high-melting and insoluble product which was obtained from the corresponding esters since a mixture of the two substances was found to melt at 265–288°. This new compound is, moreover, an acid which is slightly soluble in water and quickly decolorizes aqueous alkaline solutions containing phenolphthalein. It was, moreover, obtained by boiling 0.1 g. of the product, m. p., 278°, with a mixture of 5 cc. of glacial acetic acid and 10 cc. of concentrated hydrochloric acid for twenty-four hours. The substance is almost insoluble in alcohol, ether and chloroform and so very slightly soluble in benzene that it was not practicable to recrystallize it from this solvent. In this respect it differs markedly from the product, m. p., 278°, which was obtained by the action of light on the corresponding isomeric esters. It is somewhat more soluble in boiling glacial acetic acid (0.5 g. in 1000 cc.), from which it separates in the form of a white, crystalline powder, but unfortunately its melting point was not noticeably improved as a result of this treatment.

Anal. Calcd. for $C_{13}H_{12}O_4N_2$: N, 10.77. Found: 9.97, 10.17.

These results correspond closely with those which were obtained in the case of the original acid, m. p., 198.5–199.5°, namely, 10.65 and 10.63. The fact that the values found are so much lower than the calculated might be accounted for by assuming that traces of an impurity are present which could not be removed by recrystallization from acetic acid.

This new acid exactly neutralizes one equivalent of potassium hydroxide as calculated for its simplest molecular formula. Thus, when 0.0346 g. is suspended in 40 cc. of water, to which a drop of phenolphthalein has been added, and titrated against standard potassium hydroxide, it passes into solution and an end-point is reached when 0.0086 g. of base or an equivalent of 0.0059 g. of potassium has been added. The calculated amount of potassium required to neutralize an acid having the formula $C_{13}H_{12}O_4N_2$ is equal to 0.0052 g.

Summary

Certain types of hydantoin derivatives which contain unsaturated ethylene linkages and which exist in geometrically isomeric modifications undergo three distinctly different types of rearrangement and decomposition when subjected to the action of light. While the exact nature of these changes is not known in all cases, the phenomena would seem to be of definite importance from the standpoint of biochemistry.

THE OCCURRENCE OF CALCIUM CITRATE CRYSTALS IN CULTURES OF BUTYRIC ACID-FORMING BACTERIA AND THE WATER OF CRYSTALLIZATION OF CALCIUM CITRATE

BY W. H. PETERSON, P. W. WILSON,¹ ELIZABETH MCCOY¹ AND E. B. FRED

RECEIVED JULY 25, 1927

PUBLISHED NOVEMBER 5, 1927

When milk or potato to which calcium carbonate has been added is fermented by certain strains of butyric acid bacteria, white granules varying in size from 0.1 to 1 mm. in diameter appear in the medium. These granules have been analyzed and found to be calcium citrate. Somewhat similar crystals have been reported by Sato² to occur in sweetened condensed milk. The granules are formed by both groups of anaerobic butyric acid bacteria; those that form butyl alcohol (*e. g.*, *Clostridium acetobutylicum*, Weizmann) and those that do not (*e. g.*, *B. saccharobutyricus*, von Klecki).

Experimental

Preliminary Examination.—The granules were removed by diluting the medium with water and picking out the particles with a pair of forceps. Under the microscope they appeared to be snow-white, crystalline balls from which little, blunt, prism-like needles projected in all directions. The crystals were practically insoluble in water but could be dissolved by acidifying slightly with hydrochloric acid and boiling. A small quantity of organic debris remained undissolved. The crystals gave strong positive tests for citric acid with Denigès',³ Kunz's³ and Naüssler's⁴ reagents.

Analysis of the Crude Crystals.—The crystals were dried at 110° and analyzed, with the following results: ash, 23.0%; calcium, 17.5–18.2%; phosphorus, 0.11%. A small percentage (1.90) of the ash was insoluble in hydrochloric acid diluted with an equal volume of water.

Purification and Analysis of the Salt.—The crude salt was dissolved in dilute hydrochloric acid, the solution was filtered, neutralized with calcium hydroxide and calcium citrate precipitated by heating to boiling. The precipitate was filtered off and dried to constant weight in a desiccator and then dehydrated by heating at 110° for forty-eight hours.

Anal. Subs., 0.1348: loss (110°) 0.0164. Calcd. for $\text{Ca}_2(\text{C}_6\text{H}_5\text{O}_7)_2 \cdot 4\text{H}_2\text{O}$: H_2O , 12.63. Found: 12.17.

The calcium in the anhydrous salt was as follows.

Origin of Citric Acid.—In order to determine if the citric acid in this compound was that occurring naturally in the media or was formed by the organism in the fermentation of the sugar, a number of milk cultures were fermented. All of the flasks contained granules but the number and size varied. The granules were dissolved by adding glacial acetic acid and boiling. An equal quantity of acid was added to the control flasks. After making up to their original volume, the citric acid in the control and fermented samples was determined by Denigès's method. As a check on the method, known quantities of citric acid were added to certain aliquots before analysis. Complete recovery of the added citric acid was obtained. The unfermented milk contained 0.21% of citric acid and the fermented milk from 0.04 to 0.17%. Cultures that showed a small number of granules were low in citric acid, while cultures that contained a large number of granules were correspondingly high.

These results indicate that the bacteria as such are not directly concerned with the formation of the crystals but bring about changes in the composition of the milk that favor the formation of the crystals from the calcium and citric acid normally present. The action of the bacteria was duplicated by acidifying the milk with an amount of acetic and butyric acids equivalent to that formed by the bacteria (100 cc. of 0.1 *N* per 100 cc. of milk). Better results were obtained by first digesting the milk with trypsin and then acidifying. Under these conditions the crystals were larger and more numerous than in the fermented milk. In the untreated milk, crystals eventually appeared but these were small in comparison to those formed in the treated samples. The size and rate of formation of the crystals appear to be dependent on the colloidal properties and hydrogen-ion concentration of the milk.

Water of Crystallization of Calcium Citrate.—In discussing the composition of the granules, it was stated that the calcium citrate was completely dehydrated at 110° and that at this temperature the theoretical water of crystallization and percentage of calcium were obtained. These results are not in agreement with the statements in Abderhalden,⁶ Meyer and Jacobson,⁷ Beilstein⁸ and other reference works which say that calcium citrate, $\text{Ca}_3(\text{C}_6\text{H}_5\text{O}_7)_2 \cdot 4\text{H}_2\text{O}$, loses 2 molecules of water between

110–130° and the other 2 molecules only when heated to 175–185°. These statements are apparently based on the work of Soldaini and Bertè.⁹ Perhaps Soldaini and Bertè were led to use these high temperatures because the earlier workers, Heldt¹⁰ and Kämmerer¹¹ had dried their salts at 200° and 210°, respectively. In a recent publication Chatterjee¹² concluded on the basis of the calcium content that the citrate when dried at 110° retained but one-half a molecule of water. As we had obtained close to the calculated values for 4 molecules of water of crystallization and calcium for the dehydrated compound by drying at 110°, it seemed necessary, therefore, to redetermine the loss of water of calcium citrate under varying conditions of pressure and temperature.

Calcium citrate was first prepared by neutralizing citric acid, using phenolphthalein, with lime water, filtering and boiling for a few minutes to precipitate the calcium citrate. After standing on the steam-bath for two to three hours, the precipitate was filtered off, washed with water, alcohol, and ether, and dried in the air for twenty-four hours. A second preparation was made by neutralizing the citric acid with sodium hydroxide, adding calcium chloride and boiling. The precipitate which formed was treated in the same manner as in the first method. This preparation was somewhat coarser than the first preparation and, as the table shows, contained less hygroscopic moisture. In all, seven preparations were made by the two methods. The loss of the water of crystallization under various conditions of temperature and pressure was determined. As a check on the results the dried samples were also analyzed for calcium. The samples were kept between watch glasses with tightly-fitting, ground-glass edges held in place by a spring clamp. The watch glasses could thus be opened during the drying and closed during the weighing. After each drying samples were taken for calcium analysis and the remainder again dried to constant weight before calculating how much sample had been taken. This procedure was found to be necessary owing to the great rapidity with which the dried salt took up water on exposure to the air. The calcium citrate was strongly ignited until the weight became constant and this weight was taken as that of the resultant calcium oxide. As a check on the result, the calcium in the calcium oxide was also determined by the permanganate method.

The data for 4 preparations are given in Table I. The amount of hygroscopic water held by the citrate varies with the fineness of division of the powder. The light, fluffy material, Preparation No. 1, contained more than twice as much water as the denser material, Preparation No. 2. A third preparation which was not washed with alcohol and ether but was air-dried for thirty-six hours contained over 12% of hygroscopic moisture.

Contrary to the statement of Soldaini and Bertè, calcium citrate may lose water of crystallization when dried in a vacuum over sulfuric acid. In eighteen hours the two preparations lost 4.36 and 4.88%, respectively. The loss is probably not a constant quantity but varies with the degree of vacuum, the physical state of the citrate and other factors.

3 and 4	Oven, 125°	25	585	0.0	0.0	24.02
3 and 4	Oven, 180°	10	389	0.0	0.0	24.07

^a Water of crystallization in $\text{Ca}_3(\text{C}_6\text{H}_5\text{O}_7)_2 \cdot 4\text{H}_2\text{O}$ is 12.63%.

^b Calcium in $\text{Ca}_3(\text{C}_6\text{H}_5\text{O}_7)_2 \cdot 4\text{H}_2\text{O}$ is 21.08%, and in $\text{Ca}_3(\text{C}_6\text{H}_7\text{O}_7)_2$ is 24.13%.

^c Loss in vacuum and at 110° calculated on desiccator-dried material is 12.1 and 12.0%, respectively.

The entire water of crystallization of these preparations was removed at 110° in eighteen hours. More than 90% of this water of crystallization was driven off during the first six hours of heating. The combined loss by drying in a vacuum over sulfuric acid and by heating at 110° is slightly lower than that required for $\text{Ca}_3(\text{C}_6\text{H}_5\text{O}_7)_2 \cdot 4\text{H}_2\text{O}$ but the calcium content of the dried citrate is that required for $\text{Ca}_3(\text{C}_6\text{H}_5\text{O}_7)_2$ and shows that the two drying treatments produced the anhydrous salt. No further loss in weight or change in the percentage of calcium occurred on drying the salt at 125° and at 180°.

In the second experiment the calcium citrate was made from sodium citrate and calcium chloride in the same manner as Preparation 2 in the first experiment. The percentages of hygroscopic moisture in Preparations 3 and 4 are about the same as that in No. 2. The calcium content of the air-dried samples is a little low for $\text{Ca}_3(\text{C}_6\text{H}_5\text{O}_7)_2 \cdot 4\text{H}_2\text{O}$ and agrees with the moisture determination in proving that the air-dried samples contained some hygroscopic moisture. After being dried in the desiccator over sulfuric acid the salts were found to contain the percentage of calcium required for $\text{Ca}_3(\text{C}_6\text{H}_5\text{O}_7)_2 \cdot 4\text{H}_2\text{O}$. When dried at 110° both preparations lost almost the calculated water of crystallization. That the salts were

completely anhydrous is shown by the figures for calcium: 24.26 and 24.06%. Further drying at 125 and 180° did not show any additional loss of weight nor did the percentage of calcium change. The data on these 4 preparations and those found for 3 others not given in Table I demonstrate that certain preparations of $\text{Ca}_3(\text{C}_6\text{H}_5\text{O}_7)_2 \cdot 4\text{H}_2\text{O}$ lose all 4 molecules of water at 110°. We do not take the position, however, that all preparations of calcium citrate will become completely anhydrous at 110°. Two other preparations which were digested for a longer period of time after precipitation retained small but varying amounts of water (1.20 and 1.88%) at 110° and lost this at 180°. It is possible that the conditions under which the crystals are formed is a factor in determining the firmness with which the water of crystallization is held. The data, however, indicate clearly that no particular number of molecules of water is retained at either 110 or 125°.

Summary

Crystals of calcium citrate appear in old milk cultures (and on potato slants to which calcium carbonate has been added) after fermentation by butyric acid bacteria. The crystals are formed during evaporation of the culture and originate from the calcium and citric acid of the milk. The bacteria hasten the formation of the crystals by digesting the casein and producing a more suitable hydrogen-ion concentration. The same results can be accomplished by digesting the milk with trypsin and acidifying with acetic and butyric acids.

Statements in the literature that $\text{Ca}_3(\text{C}_6\text{H}_5\text{O}_7)_2 \cdot 4\text{H}_2\text{O}$ retains 2 molecules of water at 125° are incorrect. Seven preparations of calcium citrate were found to lose all of their water of crystallization at 110°. Two preparations retained from 1 to 2% of water of crystallization at this temperature. Drying in a vacuum over sulfuric acid removed more than 35% of the water of crystallization in two instances.

THE REACTION OF CHLORO-ACETIC ACID WITH AMMONIA AND THE PREPARATION OF GLYCINE

BY G. ROSS ROBERTSON

RECEIVED AUGUST 1, 1927

PUBLISHED NOVEMBER 5, 1927

The classical synthesis of glycine¹ from chloro-acetic acid and ammonia has never given entire satisfaction despite various claims in the literature. Although the cost of materials is low, it is significant that Clarke and Taylor² have rejected the method in favor of a two-stage cyanide process involving some expensive reagents. While the latter method is probably the best one now in ordinary use, it affords only 20 to 27% yield, calculated on the basis of the original starting material.

Clarke and Taylor have made valid objection to the Kraut process on account of the trouble in separating the glycine as the copper salt and displacing the copper by hydrogen sulfide. Equally valid is their criticism that the product is contaminated with ammonia, evidently in some form not readily volatilized. It is known, however, that glycine is too weak to form a stable salt with ammonia and can be recrystallized in the free state from ammonium hydroxide. Ammonium chloride is not necessarily the offending impurity, as we have shown in this Laboratory by the preparation of chlorine-free glycine which was seriously contaminated with ammonia.

In the chloro-acetic process the reaction does not stop with glycine but proceeds³ in part to form iminodiacetic acid, $\text{NH}(\text{CH}_2\text{COOH})_2$ and trimethylene-aminetricarboxylic acid $[\text{N}(\text{CH}_2\text{COOH})_3]$ compounds obscurely named "glycollamic acids" in the literature. For brevity they are designated below as "di-acid" and "tri-acid." These acids bearing carboxyl groups in excess of amine nitrogen are strong enough to make fairly stable ammonium salts and thus may furnish the undesired ammonia contamination in a glycine preparation.

It seems reasonable also that either the di-acid or the tri-acid might make a mixed salt or amide with both glycine and ammonia, thus making the impurity persistent in material of low solubility. Several possibilities of cross combination appear in this way and may well account for the fact that in an actual synthesis of glycine the mother liquor, presumably including salts of the di-acid and tri-acid, is an almost uncrystallizable sirup and probably a complex mixture. The sirup does not necessarily contain either chloro-acetic acid or glycolic acid. It has a high content of organic ammonium salts and some residual glycine. Rough Kjeldahl analyses

¹ Kraut, *Ann.*, **266**, 292 (1891).

² Clarke and Taylor, "Organic Syntheses," John Wiley and Sons, New York, **4**, 31 (1924).

³ (a) Heintz, *Ann.*, **122**, 257 (1862); (b) **145**, 49 (1868).

showed that it contains nitrogen in excess of that accounted for as primary amine and ammonia. Its principal role is that of interfering with the crystallization of glycine and of contaminating the product.

The present investigation was first a study of the course of the chloro-acetic acid-ammonia reaction in the interest of increased production of the desired glycine in the original reacting solution. Secondly, the problem was to eliminate the ammonium chloride and organic by-products, thus isolating the crystalline product without resorting to copper compounds.

The first of these plans was tried with the realization that even a moderate increase in the content of glycine would eliminate a corresponding amount of sirupy by-products, particularly the most undesirable tri-acid. If this could be accomplished, there should be a sharp rise in the practical yield of crystalline glycine and a product of much higher purity.

In the second phase of the work, silver oxide was adopted as a reagent to eliminate the normal by-product of ammonium chloride. It was then an easy matter to isolate glycine as the one crystallizable substance remaining. In view of the cost of the silver oxide, a method is described for the easy recovery of the reagent.

The accompanying graph shows the rate of accumulation of glycine in comparison with that of ammonium chloride when a mixture of chloro-acetic acid and ammonia is made in proportions similar to those described in the literature. The period was three hours, with a final determination five days later when the reaction was complete. Production of chloride ion is obviously equivalent to transformation of chloro-acetic acid, and in an ideal case should equal production of glycine if no subsequent reaction took place.

Chloro-acetic acid, twice fractionally distilled and then once recrystallized from an excess of its own melt, was weighed into 15 molar equivalents of chilled conc. ammonium hydroxide (sp. gr. 0.90). The flask containing the mixture was fitted with a wired-in stopper carrying a stopcock and a thermometer. The outfit was immediately placed in a thermostat at 40°. Automatic shaking prevented temperature rise from the heat of the reaction. At intervals portions of the mixture were withdrawn, immediately diluted ten-fold and placed in an ice-bath.

The diluted solution was analyzed at once by the Volhard method for chloride ion, advantage being taken of the fact that unchanged chloro-acetic acid does not react with silver ion. As time permitted, an aliquot of each reaction sample was rapidly boiled with a moderate excess of sodium hydroxide until ammonia fumes could not be detected for a final ten minutes. The content of primary amine (glycine) was now estimated in each by the standard van Slyke de-amination method. The macro-apparatus was used with the customary corrections. From each numerical result 3%⁴ was deducted, to allow approximately for the abnormal evolution of gas in the de-amination of glycine. Finally, Volhard titrations repeated several hours after the samples went on ice showed no appreciable change.

While ammonia is being expelled from the analytical samples, two slight errors enter. A small amount of new glycine is formed before the ammonia

⁴ Van Slyke, *Ber.*, 44, 1684 (1911).

is gone and a small amount of glycine is eliminated by reaction with the excess chloro-acetic acid before the latter is all transformed by the alkali into sodium glycolate. Since these errors tend to compensate, as sodium hydroxide in boiling dilute solution does not hydrolyze glycine, and since the traces of residual ammonia would not vitiate the de-amination data to a significant extent, it is thought that the nitrogen values are reasonably accurate for the use in question.

Fig. 1.—Transformation of one mole of chloro-acetic acid into ammonium chloride and glycine.

Apparently glycine and chloride ion are produced at nearly the same rate as long as ammonia is in gross excess over glycine. After about 25% production is attained, the accumulated glycine goes astray so rapidly that nearly two-thirds of the subsequent product is lost before the final exhaustion of the chloro-acetic acid is accomplished.

When the above procedure was continued through the silver oxide process described below, only about 20 to 25% yields of glycine were obtained in a fair degree of purity. This material was still decidedly contaminated with ammonium salts.

The obvious moral of the rate experiment was to multiply the ammonia-chloro-acetic acid ratio by about four, thus making the final ratio of chloride ion to glycine more like that at the time of the first analysis (that is, at the 18-minute reaction period of the graph). When this change was made, the final accumulation of glycine at once rose to 86%, and of this 63% was isolated in crystalline form as described later.

Several mixtures of widely variant proportions were analyzed, after two days' standing, by the de-amination method.

Molar ratio, ammonia to chloro-acetic acid	2:1	4:1	6:1	15:1	24:1	60:1	220:1
Primary amine produced, % of theoretical	29	32	37	58	65	86	95

The 220:1 mixture was carried through the full process, yielding 3.0 g. of glycine, or 75% of theoretical. The amount of ammonium hydroxide required in this case is, however, excessive for practical work. As in other cases, the actual yield always falls 20% or more below the potential yield, probably on account of decomposition as well as loss in crystallization and filtration.

Experiments at high temperatures and runs made with 40% ammonia under pressure gave no promise of significant improvement except that derived from raising the ammonia-acid ratio. Experiments with dilute mixtures, those with alcohol as solvent and those with ammonium carbonate⁵ instead of ammonium hydroxide gave inferior results. With reduced-pressure evaporation of the reaction mixture, there were slightly improved yields but the improvement was not worth the trouble. Finally, the 60:1 ammonia ratio was chosen as the best compromise between two evils, namely, excessive volumes of ammonium hydroxide and excessive production of undesired salts.

Preparation of Glycine.—One mole of chloro-acetic acid (94.5 g.) is dissolved in 4 liters of ammonium hydroxide (sp. gr. 0.90) and set aside in a stoppered vessel for twenty-four hours in surroundings at about 30°, or for two or more days at about 20°, no attention being paid to the heat of the reaction. The mixture is then heated to recover the excess ammonia, which is received in a flask of distilled water cooled in running water.

One mole of silver nitrate (170 g.) is dissolved in about 500 cc. of water and converted into flocculent silver oxide by the addition of a slight excess of clear, technical sodium hydroxide solution. The oxide is washed by decantation, collected on a Büchner filter and washed free of sodium compounds.

The glycine reaction mixture is evaporated to about 500 cc., during which time nearly all free ammonia escapes. The silver oxide is then stirred into the solution until no lumps of unchanged reagent can be detected, all residual solid being in the form of

⁵ Nencki, *Ber.*, 16, 2827 (1883).

silver chloride. This excess silver chloride is at once removed on the Büchner funnel. The filtrate is placed in a wide-mouthed flask equipped with a mechanical stirrer to prevent bumping, and is concentrated by boiling. This operation must not be interrupted while ammonia is still present, lest undesirable silver compounds be formed.

When the volume of the solution is reduced to about 200 cc., the silver-ammonia complex is completely decomposed and the rest of the silver chloride precipitated. More water is added and evaporated should there still be traces of silver in solution. The end-point is reached when a drop of aqueous hydrobromic acid, added to the clear supernatant liquid, no longer gives a localized turbidity. The silver chloride is collected on the funnel, and along with the original mass is placed in a 25% solution of technical sodium hydroxide for recovery later.

The glycine solution (vol., 190 cc.) is treated with 1 to 2 g. of Norit, filtered carefully by suction through retentive paper and treated with an equal volume of 95% ethyl alcohol. Pure-white glycine promptly crystallizes but the mixture is allowed to stand for an hour or more on ice. After filtration, washing with alcohol and drying in a desiccator, 43 g. of crystals are obtained. Another like volume of alcohol precipitates an additional 4 g., not quite so pure. It is isolated in like manner after an hour's cooling. Taken as a whole, the glycine contains nearly 0.1 mole per cent. of ammonium salts, judged by Nessler colorimetry.

The total yield of 47 g. is 63% of theoretical, or 0.63 mole. Primary amine left in the mother liquor in one run was 0.09 mole (by de-amination analysis). Total glycine thus accounted for, 0.72 mole. Total glycine originally estimated in solution, 0.86 mole, loss in manipulation, 0.14 mole.

If an ammonia-free product is desired, the glycine is dissolved in 200 cc. of water and shaken for a few minutes with 10 g. of granular permutite (after Folin). The mixture is filtered and 250 cc. of 95% ethyl alcohol slowly stirred into the filtrate. The precipitated glycine, a voluminous crystalline mass of snow-white appearance, is washed on the Buchner funnel with 95% alcohol and dried in a desiccator; yield, 37.5 g., or 50% of the theoretical for the whole process.

PURITY TESTS.—When heated to 230° (corr.) the final product starts to turn brown; it becomes almost black by 238°. In 0.1 *M* solution it shows no appreciable ammonia by Nessler colorimetry. In *M* solution a barely detectable coloration lies between that shown by 10⁻⁵ *M* ammonium chloride and that of the distilled water blank; chloride test, negative.

When permutite was omitted, but no other change made in the procedure, a *M* solution of the product gave Nessler coloration nearly as great as that of 10⁻⁴ *M* ammonium chloride. All tests were made in alkaline solution with allowance for acidity of the glycine. Observations were made immediately on mixing, as glycine soon reacts with Nessler's reagent to vitiate results.

Recovery of Silver.—The following modification of a well-known method⁶ is convenient here.

The moist silver chloride (1 mole) from the glycine process is suspended in about 400 cc. of boiling 25% sodium hydroxide solution contained in a liter beaker. An excess of corn sugar or glucose sirup is cautiously stirred in at a rate slow enough to avoid a sudden violent reaction causing overflow. After a few minutes of boiling the chloride is transformed entirely into a crumb-like mass of finely divided silver.

⁶ Gmelin-Kraut, "Handbuch anorganischen Chemie," Carl Winter's Universitätsbuchhandlung, Heidelberg, 1914, Band V, Abt. 2, p. 8.

By repeated decantations, rapidly made, and copious washing on the Büchner funnel with hot water, soluble matter is removed. A trace of chloride persists, however, but this need not be eliminated if the product is to be used again in the synthesis of glycine.

The silver, still wet, is treated in a liter Pyrex beaker with a slight excess of concd. nitric acid (sp. gr. 1.42). The silver, being very finely divided, is at once converted into silver nitrate, sufficiently pure for use again with glycine.

If the silver nitrate is desired as a laboratory reagent, the acid solution is simply heated until its temperature reaches about 240° , by which time the excess nitric acid is expelled. There is no trouble from bumping as the nitrate is extremely soluble at high temperatures.

The crude silver nitrate is then dissolved in cold water and diluted to 0.75 *M*, whereupon practically all dissolved silver chloride is precipitated. As would be expected, silver chloride is extremely insoluble in silver nitrate of concentrations below molal, but in nitrate solutions of more than molal concentration a considerable quantity of the halide either dissolves or is peptized.

The colloidal silver chloride, usually not in sufficient quantity to warrant salvage, is removed by filtration with the aid of decolorizing carbon. The resulting filtrate upon further dilution does not show the slightest turbidity and is perfectly serviceable as an ordinary reagent.

It is probably not worth while to attempt to make really pure silver nitrate from this recovered solution. It is possible, of course, to fuse the reduced silver and carry out the slow reaction of the compact ingot material with pure nitric acid and thus obtain a pure product.

Incidentally, the above process is very convenient for working up laboratory residues of silver chloride and thiocyanate. With iodide and bromide the process is also satisfactory, but more time should be taken to insure complete reduction with sugar.

Summary

An experimental study of the velocity and course of the reaction between aqueous chloro-acetic acid and ammonia shows that the product, glycine, goes astray seriously into by-products if its concentration is allowed to rise much over 1 mole per cent. of that of the ammonia present.

A method of preparation of glycine is given in which the ratio of ammonia to chloro-acetic acid is 60:1. Ammonium chloride is eliminated by means of silver oxide and a 50% yield of pure glycine obtained.

A simple method is given for recovery of silver oxide with the aid of glucose.

ESSENTIAL OILS IN DESERT PLANTS

I. PHYSICAL CONSTANTS

BY MAXWELL ADAMS AND RUTH BILLINGHURST

RECEIVED AUGUST 3, 1927

PUBLISHED NOVEMBER 5, 1927

In the semi-arid regions of western United States there is in most localities a stunted growth of plants referred to in general terms as sage-brush, but in reality composed of many widely differing species. The leaves and twigs of most of these plants when crushed have distinct and characteristic odors which indicate the presence of essential oils. Samples of a number of these plants have been collected and steam distilled for the purpose of detecting the presence of essential oils and determining their physical and chemical properties.

Specimens of these various desert plants collected at random, when steam distilled, usually yield from 0.05 to 0.5 of one per cent. of essential oil. The frequent occurrence of these oils has led one of us,¹ in a paper read before the American Association for the Advancement of Science, to suggest that, due to their diathermous properties, they serve, as experiments indicated, as a protection against rapid temperature changes for the plants and also suppress the rapid evaporation of water.

Tests made upon *Artemisia tridentata* prove that the oil exists only in the leaves and young shoots and that the percentage of oil shows a general increase from early spring until late summer. Leaves and twigs of *Chrysothamnus nauseosus* collected from parts of the same plants each month of the year show that the amount of oil varies from 0.04% during May and June to 0.23% in July, 0.39% in August and 0.83% in September. During the winter, when the leaves have fallen, the twigs contained 0.22%. A sample of *Graveolens nauseosus Mohavensis* grown in the botanical gardens at Berkeley, California,² yielded a smaller percentage of oil than the same variety growing in the more arid districts of Nevada.

The cause of these variations is undetermined; it may be due to the stage of development and maturity of the plants, or the increase of the oil during the driest season of the year may be a method of drought resistance developed by the plant.

Among the native plants of the semi-arid regions of the United States, essential oil has been observed in *Artemisia cana*,³ *Artemisia frigida*, *Artemisia Leudoviciana*, *Artemisia caudata*,⁴ and *Ramona stachyoides*.⁵

⁴ Frank Rabak, "On Several New Artemisia Oils," *Pharmaceutical Review*, 24, 324-325 (1906).

⁵ Frank Rabak, "Wild Volatile Oil Plants and Their Economic Importance,"

Volatile oil was found by us in the following plants: 1. *Artemisia tridentata typica*, leaves, flowers, and small twigs collected in various localities near Reno, Nevada, at various seasons of the year yielded when distilled from 0.3 to 0.92% of an oil, the first fraction colorless and the last distinctly green. It turns light yellow upon standing. The odor is that of the green plant, strong and very characteristic, and the taste is persistent and camphor-like. The vapors of the oil are tear-producing.

2. *Gutierrezia sarothrae*⁶ collected in September, 1922, near Wedekin Mine, Washoe County, Nevada. The oil from the entire top of the plant is light yellow in color and has a mild but somewhat unpleasant odor.

3. *Juniperus Utahensis*,⁷ leaves and small twigs collected in October, 1923, from trees growing eight miles north of Reno, Nevada, gave on distillation a mobile, colorless oil.

4. *Salvia lanceolata*,⁷ called "purple sage" because of its clusters of small, purple flowers. Leaves, flowers and small branches collected from the rock bluffs along the west shore of Pyramid Lake, Nevada, in June, 1920, and another sample from near Chloride Cliff on the eastern rim of Death Valley, California, May 14, 1926, yielded a clear, strongly fragrant oil.

5. *Thamnosma* (probably *Texanum*) collected from near the Lahontan Dam in Churchill County, Nevada, April, 1916. The shrub is almost leafless and the small thorny branches cut into short pieces and distilled yielded a colorless, fragrant oil.

6. *Tetrademia glabrata*, "spring rabbit brush,"⁸ collected in May, 1915, among the hills northeast of Reno gave on distillation of the flowers, leaves and small branches an ill-smelling oil which darkens readily and grows viscous when allowed to stand for a few days.

7. *Chrysothamnus graveolens*,⁹ tops of plants in flower collected in September, 1915, near the Station Farm, Reno, Nevada, yielded on distillation a colorless oil which soon changed to a light yellow color and when purified consists chiefly of dipentene. The yield varies from 0.04 to 0.85%, depending on the season of the year in which the plants are gathered.

8. *Chrysothamnus viscidiflorens elegans*⁸ collected on the flanks of Slide Mountain, near Franktown, Nevada, October, 1924. The tops when distilled yielded a colorless, ill-smelling oil.

9. *Chrysothamnus nauseosus graphalodes*¹⁰ yielded a light yellow, ill-smelling oil.

Bulletin No. 235, Bureau of Plant Industry, United States Department of Agriculture.

⁶ Identified by L. A. Waitzinger of the U. S. Bureau of Plant Industry.

⁷ Identified by P. A. Lehenbauer of the University of Nevada.

⁸ Identified by N. F. Peterson, Botanist, Nevada Agricultural Experiment Station.

⁹ Identified by S. B. Doten, Director, Nevada Agricultural Experiment Station.

¹⁰ Collected February, 1924, by L. A. Waitzinger at Benton, California, near the Nevada-California state line.

10. *Chrysothamnus nauseosus viridulens*.¹⁰ The smooth, green stems when distilled yielded a yellow oil which became viscous on standing.

11. *Chrysothamnus nauseosus hololeucus*.¹⁰ The white stems of this plant yielded a dark yellow, pleasant-smelling oil.

12. *Chrysothamnus nauseosus Mohavensis*, collected from the botanical gardens at Berkeley, California, March, 1924, yielded a clear, colorless oil with a disagreeable odor.

The distillations were carried out by placing the samples in a wire basket which fitted closely into a tin-lined copper still and passing in steam under a pressure of ten pounds. The distillation was continued for three to four hours. The light oil which floated on the surface was drawn off and purified in each case by a second steam distillation. No attempt was made to extract the oil which remained dissolved in the condensed water. In all cases, therefore, the per cent. of oil present in the specimen is somewhat greater than that recovered. When freshly distilled and dried in contact with potassium carbonate the various oils have the following physical constants.

TABLE I
PHYSICAL CONSTANTS OF THE OILS

These oils, being mixtures, do not have very definite boiling points. There was no pressure correction made; the temperature at which the liquid in a flask to which a reflux condenser was attached freely boiled at the local barometric pressure was recorded as the boiling point.

The specific rotation and refractive index of the freshly distilled oil are recorded. Our observations show that these constants are subject to change when the oils are kept for some time, especially when exposed to light and air.

PURIFICATION OF ABIETIC ACID FROM ROSIN AND PREPARATION OF SOME OF ITS DERIVATIVES¹

BY C. C. KESLER WITH A. LOWY AND W. F. FARAGHER

RECEIVED AUGUST 3, 1927

PUBLISHED NOVEMBER 5, 1927

Rosin has not received as much scientific study as its importance in the industrial arts warrants. The annual value of rosin produced, of which somewhat less than sixty per cent. is exported, is approximately forty million dollars.

Rosin consists principally of organic acids commonly called abietic acid of the empirical formula $C_{20}H_{30}O_2$, and of a small per cent. of neutral material termed "resene." The resene seems to exert a decided influence on the reactivity of abietic acid. This is evidenced in a number of ways, but it has been especially noted in the esterification of the acid. No reaction or only a very small yield is at times obtainable when rosin is employed, but a satisfactory yield results when pure abietic acid is used. One of the chief difficulties encountered in research on this material has been obtaining a pure abietic acid.

The sodium complex salt method^{2,3,4,5} was employed in securing abietic acid from which the other derivatives were prepared. It is of interest to note that abietic acid and the normal sodium salt are soluble in alcohol, whereas the sodium complex salt ($C_{19}H_{29}COONa \cdot 3C_{20}H_{30}O_2$) is insoluble. Advantage is taken of this fact to effect purification, the resene remaining in solution being thereby separated from the abietic acid. This method, it is believed, has decided advantages over methods previously used that involve long and tedious crystallizations. Yields of 80% may be secured and the time required for the purification is greatly shortened. It has been noted that when abietic acid or its salts are in contact with the resene, oxidation is greatly facilitated. This has been definitely shown by preparing rosin soaps and noting the resulting changes in the presence and absence of resene. Extended crystallizations, especially in the presence of resene, give ideal opportunity for such oxidation.

Isomerization of rosin is essential for the formation of the complex

¹ The research described in this paper was carried out while Dr. Kesler was the incumbent of the Rosin Fellowship sustained in Mellon Institute by the Pine Institute of America (1924-1926), to which organization the authors are grateful for this support and also for the release of the work for publication. The present contribution is an abstract of a thesis presented by Dr. Kesler to the Graduate School of the University of Pittsburgh in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

salts as commercial amorphous rosin gives no such precipitate. The isomerization can be followed by the change in optical rotation. The original acid rotates light to the right, while the isomerized products give a negative rotation. Mineral acids effect this change. Aqueous or gaseous hydrochloric acid proves to be an effective isomerizing agent. The same result may be accomplished by heating to 250°.

As only a few esters of abietic acid are noted in the literature,^{6,7,8,9,10} a number of esters were prepared in order that the properties of these interesting neutral derivatives of rosin might be investigated. The use of dry hydrogen chloride as a catalytic agent was unsuccessful, so more energetic methods were sought. A number of methods have been used, and in the case of phenols the very reactive material phosgene was employed. The type reaction is $\text{RCOONa} + \text{R'ONa} + \text{COCl}_2 \longrightarrow \text{RCOOR'} + 2\text{NaCl} + \text{CO}_2$.

Hahn¹¹ gives a method for preparing esters of benzenesulfonic and *p*-toluenesulfonic acids. Gilman and Beaber¹² have also prepared a number of esters of *p*-toluenesulfonic acid. The alkyl *p*-toluenesulfonates obtained by this method, when mixed and heated with equimolecular quantities of sodium abietate dissolved in water, give the desired esters of abietic acid and sodium *p*-toluenesulfonate, which is water-soluble and may be recovered. The reaction proceeds very smoothly and often gives 95% yields. The type reaction is

The cost of reagents is not at all prohibitive to commercial production. It is possible to prepare not only aliphatic esters by this method but certain terpene esters as well.

The lower aliphatic esters are heavy, viscous oils of increasing boiling points with increasing weights. The specific gravities decrease as the series is ascended. The refractive indices check quite closely with the specific gravities and indicate that two double bonds are present in the molecule. The esters of the normal alcohols have higher boiling points than the corresponding *iso* compounds. A similar relation is also true in the case of specific gravities. The esters were all distilled at reduced pressures without decomposition.

Esters prepared with phenols could not be secured by any of the usual

methods of esterification. As a result, a new method was developed which involves the action of phosgene upon dry sodium phenolates and sodium abietate with the formation of sodium chloride and carbon dioxide. It is quite essential that the materials be finely powdered, well mixed and thoroughly dried. Pressure increased the yields. The method works very well for all phenols employed and is believed to be a general reaction. Esters prepared with phenols are semi-solids at room temperature and are darker in color than the aliphatic esters. This method also gives fair results with certain of the terpene alcohols, such as are found in pine oil. Both rosin and pine oil are commercial products and their union gives esters which should be of considerable practical value. The pine oil alcohols are quite difficult to esterify as certain of them, such as terpineol, are tertiary alcohols. The esters are insoluble in water, but soluble in the usual organic solvents. However, they are only slightly soluble in cold alcohol but more so when heated. The insolubility in alcohol decreases as the series is ascended.

The plasticizers or softeners used in the manufacture of nitrocellulose lacquers are an important industrial commodity. The amount of plasticizer varies from 40 to 60% of the nitrocellulose employed. Its purpose is to remain in the film, keeping it soft and pliable without greatly diminishing its strength. The softener should be non-volatile and neutral in character; it should be miscible with lacquer solvents and a solvent for nitrocellulose; it should be stable on aging in lacquer films. Some of the esters of abietic acid appear to have application in this industry.

Experimental

One kilogram of "G" grade rosin containing 91% abietic acid was isomerized either by passing a current of dry hydrogen chloride gas through the melted rosin with constant stirring for twenty minutes, or by adding 1% of hydrogen chloride in the form of commercial aqueous hydrochloric acid to a hot 33% alcoholic solution of rosin. This was boiled for fifteen minutes. Aqueous or alcoholic sodium hydroxide was added to neutralize completely the hydrochloric acid and enough more to neutralize one-fourth of the acid content of the rosin. Stirring was discontinued and the mixture allowed to cool. Seeding facilitates crystallization of the sodium complex salt ($C_{19}H_{29}COONa \cdot 3C_{20}H_{30}O_2$). The entire solution sets into a white, solid, sponge-like mass composed of small, needle-like crystals which may be pressed or centrifuged to remove the mother liquor. Without washing, the salt contained less than $\frac{1}{2}$ of 1% of resene. A single alcoholic wash gives a pure sodium complex salt ($C_{19}H_{29}COONa \cdot 3C_{20}H_{30}O_2$), melting at 177° . Regeneration of abietic acid with subsequent precipitation does not raise the melting point.

Twenty grams of the complex sodium salt ($C_{19}H_{29}COONa \cdot 3C_{20}H_{30}O_2$) gave the following titration and gravimetric values.

Anal. Calcd. for 2.540 *N* alkali: 19.2 cc. Found: 19.1. Calcd.: Na, 0.3739 g. Found: 0.3734, 0.3729.

The calculated amount of mineral or acetic acid was added to the complex sodium salt in order to free the abietic acid. It melted when dry at 166° . Recrystallization does not raise the melting point.

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.47; H, 9.93. Found: C, 78.98; H, 10.33.

Sodium abietate was prepared by treating the pure complex sodium salt with sufficient alkali and slowly drying with constant stirring in an atmosphere of carbon dioxide. The small lumps were finely pulverized and dried in a vacuum oven at 100° for four hours. The acid formed by treating the dried sodium abietate with acetic acid has the properties of pure abietic acid. This method was employed for preparing sodium abietate in all subsequent experiments where it is used.

Ethyl Abietate ($C_{19}H_{29}COOC_2H_5$).—To one mole (324 g.) of dry sodium abietate, one mole (154 g.) of diethyl sulfate was gradually added and the reaction mixture slowly stirred on a steam-bath for two hours. It was cooled and extracted with benzene. Upon removal of the solvent, a viscous oil remained which is nearly odorless and possesses a light yellow color not removed by repeated distillation. The yield is 85% of the theoretical. Saponification number found: 170.1; calcd.: 169.6. The properties of the following esters are found in Table I.

Propyl Abietate ($C_{19}H_{29}COOC_3H_7$).—One mole of sodium abietate dissolved in 600 cc. of water was refluxed with one mole of *n*-propyl-*p*-toluenesulfonate with constant stirring for two hours. The reaction mixture was allowed to cool. The ester layer was washed with water and distilled. An 80% yield of light yellow, odorless oil was obtained. Saponification number found: 163.0; calcd.: 162.7.

Isopropyl Abietate ($C_{19}H_{29}COOC_3H_7$).—One mole of abietic acid was neutralized with 40 g. of sodium hydroxide in 600 cc. of water and heated until all the abietic acid was dissolved. Upon cooling, the soap set to a gel which was treated by the *p*-toluenesulfonate method as described above.

The following esters were also prepared by the *p*-toluenesulfonate method as described above.

n-Butyl abietate ($C_{19}H_{29}COOC_4H_9$); yield, 95%; saponification number found: 155.9; calcd.: 156.4.

*iso*Butyl abietate ($C_{19}H_{29}COOC_4H_9$); yield, 80%.

iso-Amyl abietate ($C_{19}H_{29}COOC_5H_{11}$); yield, 72%.

Allyl abietate ($C_{19}H_{29}COOC_3H_5$); yield, 45%.

Menthyl abietate ($C_{19}H_{29}COOC_{10}H_{19}$); yield, 65%.

Phenyl Abietate ($C_{19}H_{29}COOC_6H_5$).—One mole (116 g.) of carefully dried and powdered sodium phenolate was thoroughly mixed with one mole (324 g.) of well-dried and powdered sodium abietate. The mixture was placed in a glass tube in a well-ventilated hood and phosgene allowed to pass through the powder. No heat was applied but the heat of reaction was quite noticeable. A characteristic change to a resinous, viscous mass was noted and in one-half hour the reaction was complete. The reaction products were well washed with water and dilute alkali. The remaining semi-solid ester distilled at 330 – 333° at 4 mm., giving a dark-colored gum which did not become lighter in color by redistilling. The experiment was repeated in a bomb tube with liquid phosgene at room temperature and a yield of 87% was obtained. The specific gravity of the ester was 1.056 ($15^\circ/4^\circ$) and refractive index 1.5354. Upon saponification with 10% alkali and subsequent acidification, abietic acid crystals and phenol were again obtained.

The following esters were prepared by the phosgene method as described for phenyl abietate.

Hexalin abietate ($C_{19}H_{29}COOC_6H_{11}$); yield, 73%; saponification number found: 144.6; calcd.: 145.8.

m-Tolyl abietate ($C_{19}H_{29}COOC_7H_7$); yield, 78%.

α -Naphthyl abietate ($C_{19}H_{19}COOC_{10}H_7$); yield, 78%.

Terpineol abietate ($C_{19}H_{19}COOC_{10}H_{17}$).

Bornyl abietate ($C_{19}H_{19}COOC_{10}H_{17}$); yield, 75%.

Benzyl Abietate ($C_{19}H_{19}COOC_7H_7$).—One-fourth mole of abietic acid was dissolved in carbon tetrachloride with one-fourth mole of benzyl chloride. Twenty-five cc. of 40% sodium hydroxide was slowly added and then 25 cc. of water. The mixture was refluxed for three hours at which time the odor of benzyl chloride had disappeared. The ester was washed and the solvent removed by distillation. A yield of 85% was secured. Saponification number found: 141.7; calcd.: 142.8.

Cholesteryl Abietate ($C_{19}H_{19}COOC_{26}H_{49}$).—One-tenth mole of cholesterol was melted with one-tenth mole of abietic acid in the presence of zinc as a catalyst. After heating for two hours at 200°, a resin was obtained. The resin was dissolved in benzene and washed. The solvent was distilled off, leaving a resin which could not be distilled without decomposition. A yield of 94% was secured. Saponification number found: 83.6; calcd. 85.3. This ester was also obtained from cholesteryl chloride and sodium abietate. The cholesteryl chloride was made by treating cholesterol with sulfuryl chloride.

Cetyl Abietate ($C_{19}H_{19}COOC_{16}H_{33}$).—This ester was prepared by heating at 150° for six hours equal molecular quantities of cetyl iodide and sodium abietate. The reaction product was dissolved in benzene and washed. The recovered resin gives no test for halogen.

To determine the applicability of the esters of abietic acid as plasticizers, a number of films were prepared on a copper plate having a surface of mercury amalgam. A standard lacquer composition was prepared in which tricresol phosphate and dibutyl phthalate were used as the plasticizers. By substituting esters of abietic acid for the standard plasticizers, comparisons of the resulting films were made. A typical composition is as follows:

Substance	Per cent.	Substance	Per cent.
Nitrocellulose in ansol.	10	Butyl alcohol.	20
Ester gum.	5	Diethyl carbonate.	8
Esters of abietic acid.	5	Toluene.	32
Ansol.	20		

The solubility of the cellulose nitrate in the different esters, the flexibility and adhesion of the film and its strength and elasticity were especially noted. The results obtained indicate that abietic acid esters possess properties allowing their use wherever a neutral or softening effect is desired.

Summary

1. A method which is based on the formation of an acid salt of rosin has been employed for purifying rosin to obtain abietic acid in good yield. Some advantages of this method are indicated.

2. A number of new esters of abietic acid have been prepared and their properties determined (see Table I). Certain of these esters have commercial applications wherever a plasticizing or softening effect is desired.

3. A new method has been developed with phosgene for securing esters of phenols and esters with alcohols of the terpene family. It is believed to be a general reaction for such materials.

4. The value of esters of *p*-toluenesulfonic acid as esterifying reagents for preparing esters of abietic acid is shown.

ORGANOBERYLLIUM HALIDES

BY HENRY GILMAN AND F. SCHULZE

RECEIVED AUGUST 5, 1927

PUBLISHED NOVEMBER 5, 1927

Introduction

Durand¹ has recently described the preparation of methylberyllium iodide by the action of finely-divided beryllium upon methyl iodide in ether, using a trace of mercuric chloride as a catalyst. Gilman² had previously found it impossible to prepare organoberyllium halides directly. More recently, Gilman and Schulze³ have prepared these organometallic halides by indirect methods starting with beryllium dialkyls.

We have now attempted to prepare these substances following Durand's method, but without success. By the use of revised directions, in particular prolonged heating at elevated temperatures, we have succeeded in preparing organoberyllium halides directly. The methylberyllium iodide we obtained was, contrary to Durand's experiences, very soluble in ether. His method of purification, by ether washing, should, therefore, have completely removed the compound leaving no organoberyllium iodide for analysis. Finally we have shown that the gas Durand obtained by the hydrolysis of his reaction product was presumably hydrogen and not methane. Accordingly, our unavoidable conclusion is that Durand's product was not methylberyllium iodide.⁴

Experimental Part

When Durand's directions for the preparation of methylberyllium iodide were carried out in detail (using 0.091 g., 0.01 mole, of beryllium and corresponding amounts of methyl iodide, mercuric chloride and ether) a small amount of gray material remained suspended in the ether and most of the metal rested unchanged on the bottom of the flask. After removal of the ether by slow evaporation, the residue was washed twice with anhydrous ether leaving the grayish material and unused metal. The residue was analyzed after displacing all the air by carbon dioxide. Hydrolysis by dilute hydrochloric acid gave 216.5 cc. instead of the calculated 224 cc. of gas. Analysis by explosion with oxygen showed the gas to be pure hydrogen, and there was no trace of carbon dioxide. Qualitative analysis proved the absence of iodine in the "reaction product."

¹ Durand, *Compt. rend.*, **182**, 1162 (1926).

² Gilman, *THIS JOURNAL*, **45**, 2693 (1923). References to all earlier work are contained in this article.

³ Gilman and Schulze, *J. Chem. Soc.*, 1927.

⁴ His analogies with the related beryllium diethyl and magnesium diethyl are based in large part on Cahours' work with these compounds and we have shown much of Cahours' work to be incorrect (see ref. 3 and Gilman and Schulze, *THIS JOURNAL*, **49**, 2328 (1927) for an account of magnesium diethyl).

The local reaction reported by Durand is undoubtedly independent of the presence of methyl iodide or any other of the alkyl and aryl halides tried by us. This was shown by a wide variety of experiments in which beryllium powder was treated with varying quantities of mercuric chloride in the presence of ether and with or without the addition of various RX compounds. A local reaction invariably took place between the metal and mercuric chloride and a light gray solid formed. Larger quantities of mercuric chloride gave increasing amounts of the gray solid and free mercury appeared to deposit on the beryllium, probably forming an amalgam. Undoubtedly, the only reaction that occurred was a simple displacement of the mercury by the beryllium, inasmuch as free mercury was formed and in several cases the liquid etherate of beryllium chloride was noted.

The small amount of mercuric chloride (0.1 g.) taken by Durand would use up an extremely small quantity of the beryllium (9.1 g. of beryllium being equivalent to 271.5 g. of mercuric chloride) so that his gas analysis would hardly be affected. It is obvious that treatment with dilute hydrochloric acid would liberate the same volume of gas, regardless of whether the metal was essentially unchanged or had formed a quantitative yield of methylberyllium iodide.

Temperature.—No methylberyllium iodide is formed when 0.091 g. (0.01 mole) of finely-divided beryllium,⁵ 1.4 g. (0.01 mole) of methyl iodide, 15 cc. of ether and a trace of mercuric chloride are shaken in a sealed test-tube at room temperature for one week.

Heating at 80–90° for fifteen hours was generally necessary to prepare appreciable quantities of the organoberyllium halide. The reaction product was a slightly turbid solution, resembling somewhat the solution of a Grignard reagent, although it was generally lighter in color than many RMgX solutions. The greater part of the metal invariably remained unattacked and rested on the bottom of the tube. In addition to the metal, there was usually present a small quantity of black material in the form of small scales or definite particles. This material was somewhat lighter than the metal, settling less rapidly when the tubes were agitated.

In many experiments the reagents were heated at 80–90° for periods in excess of fifteen hours and up to one week. Judging by the depth of the color test recommended by Gilman and Schulze⁶ for RMgX and some other organometallic compounds, there was no appreciable increase in yield with these extended periods of heating. Incidentally, these experiments served to show that prolonged heating did not destroy the organoberyllium compounds. Only a few experiments were carried out at higher temperatures and positive tests were obtained after heating to 150°.

Catalysts.—Mercuric chloride, used by Durand, gave the best results with all the alkyl and aryl halides that were investigated. The other mercuric halides may be used but they are not as satisfactory. Beryllium chloride is next to mercuric chloride in order of effectiveness. Mercury and iodine together, iodine and bromine are about

⁵ The beryllium used in this study was obtained from the Beryllium Corporation of America. Their analysis showed it to contain more than 99.5% of beryllium, with about 0.2% iron, 0.1% silicon and no aluminum.

⁶ Gilman and Schulze, *THIS JOURNAL*, **47**, 2002 (1925).

of equal value. It was disappointing to find that a finely-divided beryllium-copper alloy containing about 12% of copper and activated by heating with iodine in an evacuated, sealed tube gave but moderately successful results, inasmuch as Gilman, Schulze and Peterson⁷ found that a magnesium-copper alloy containing 12.75% of copper is superior to Baeyer's activated magnesium in the preparation of some Grignard reagents that are formed with difficulty.

Solvents.—Ethyl ether was the only solvent used and it was dried by a sodium-potassium alloy. When beryllium was heated with methyl iodide and mercuric chloride at 80–90° for one week with no ether present a light gray solid and clear liquid resulted. This reaction product gave a positive color test directly without the usual necessity of heating until fumes were evolved.^{8,9}

No reaction occurs when methyl and ethyl iodides are treated as above, but heated only for fifteen hours. Furthermore, beryllium with methyl or ethyl iodide, but no catalyst, showed no signs of having reacted after heating at 80–90° for several days. This is of interest in connection with Cahours' early work.^{4,9}

Preparation of Methyl- and Ethylberyllium Iodide.—In general, only small quantities of materials were prepared at one time because of the difficulty and danger involved in the heating of large volumes of ether in sealed tubes. Convenient reaction vessels may be prepared from the commercially available small, heavy sealed bottles used for the shipment of low-boiling liquids.

About 0.5 g. of powdered beryllium, 0.2–0.5 g. of mercuric chloride, 5 cc. of the organic halide and 25 cc. of ether are placed in the bottle. The neck of the bottle is drawn down to a fine capillary, small enough so that particles of beryllium cannot pass through, and the end of the capillary is sealed. The bottle is placed inside a can, which acts as a shield in case of explosion, and this is set on a steam hot-plate. After maintaining a temperature of 80–90° for at least fifteen hours, the bottle is cooled and its capillary end is first inserted in a 50cc. Erlenmeyer flask and then broken by pressing it against the walls of the flask. The high pressure in the bottle forces the liquid out and the unused metal is retained by the capillary. It is advisable to wrap the bottle in a towel in order to guard against the danger of an explosion. If the bottle has a sufficiently long neck, it may be used again by adding a fresh portion of alkyl halide, ether and mercuric chloride to the residual metal, then sealing and heating as before.

Preparation of Other Organoberyllium Halides.—Ethylberyllium bromide and *n*-butylberyllium iodide were prepared in the presence of ether, with mercuric chloride or beryllium chloride or free bromine as a catalyst. Here it was necessary to heat at 80–90° for fifteen hours.

Phenylberyllium iodide gave a positive test when prepared in the presence of mercuric chloride after heating at 80–90° for fifteen hours. This experiment was not duplicated in another run. However, the phenyl-

⁷ A preliminary account of this work was presented at the Philadelphia, 1926, meeting of the American Chemical Society. The alloy has been referred to in several later studies. (See Gilman and Harris, *THIS JOURNAL*, 49, 1827 (1927), ref. 10.)

⁸ Methylberyllium iodide gives a positive color test when the solution is allowed to stand for ten to fifteen minutes with Michler's ketone before hydrolysis and the addition of the iodine-glacial acetic acid solution.⁶ The beryllium dialkyls, formed by heating alkylberyllium halides, give a color test at once. The slower reaction of alkylberyllium halides is not unique, inasmuch as some tertiary alkylmagnesium halides also require up to five minutes' standing before a satisfactory color test is obtained. (See Gilman and Schulze, *Bull. soc. chim.*, 1927.)

⁹ Cahours, *Ann. chim. phys.*, [3] 58, 5 (1860).

beryllium iodide was readily prepared by heating at a more elevated temperature (150 or 175°) with either mercuric chloride or beryllium chloride as a catalyst.

Tert.-butyl chloride and bromide appeared to have reacted when heated at 80–90° for fifteen hours with mercuric chloride as a catalyst. However, the products in both cases gave negative tests.⁸ Under like conditions, benzyl bromide and *n*-butyl chloride showed no evidence of reaction.

Reactions of Alkylberyllium Halides.—All of these compounds are decomposed by water, with the formation of the corresponding hydrocarbon.

The ethereal solutions do not fume in the air. However, by driving off the ether a liquid residue results and this on further heating gives off dense white fumes, probably of beryllium oxide. This application of heat by a small luminous flame converts the alkylberyllium halide to a beryllium dialkyl. Beryllium dimethyl¹³ was definitely identified in this manner when methylberyllium iodide was heated. The following equilibrium is quite probable under certain conditions

inasmuch as alkylberyllium halides are formed when beryllium dialkyls are treated with a beryllium halide. Some experiments on the heating of RMgX compounds indicate that the same may be true with organomagnesium compounds.

When carbon dioxide was bubbled through an ethereal solution of methylberyllium iodide for three hours, the solution still gave a positive test and no acetic acid was found after hydrolysis.

The color test with Michler's ketone is developed only after ten to fifteen minutes' standing prior to hydrolysis.⁸ Beryllium dialkyls give the test at once.

Acetanilide is formed from methylberyllium iodide and phenyl isocyanate. This is a standard reaction for organomagnesium, calcium and barium halides as well as for beryllium and magnesium dialkyls.

In general, the alkylberyllium halides are less reactive than the beryllium dialkyls and the RMgX compounds.

Summary

Organoberyllium halides could not be obtained directly by procedure given in the literature but were produced in the presence of various catalysts by prolonged heating in sealed tubes at temperatures up to 150°.

The properties of the methylberyllium iodide were markedly different from those given by Durand, so that our conclusion is that his product was not this substance.

Methyl- and ethylberyllium iodides, ethylberyllium bromide, *n*-butyl-

beryllium iodide and phenylberyllium iodide have been prepared and their reactions investigated.

THE PREPARATION AND BASE STRENGTHS OF SOME AMINES

BY WALLACE H. CAROTHERS, C. F. BICKFORD AND G. J. HURWITZ

RECEIVED AUGUST 12, 1927

PUBLISHED NOVEMBER 5, 1927

The measurements here recorded were made for the purpose of supplementing existing data on the base strengths of amines. The data obtained are summarized in the following table.

TABLE I
DATA ON BASE STRENGTHS OF AMINES

Formula	Neutral. equiv., calcd.	Neutral. equiv. found	$K_{\text{hydr.}} \times 10^{10}$ $t = 25^\circ$	$K_B \times 10^5$
$(\text{C}_6\text{H}_5\text{NH}_2)$	$(2.17 \times 10^5)^1$	$(4.6 \times 10^{-5})^1$
$\text{C}_6\text{H}_5\text{CH}_2\text{NH}_2$	107.1	107.3	4.26	2.35
$\text{C}_6\text{H}_5(\text{CH}_2)_2\text{NH}_2$	121.1	...	1.48	6.78
$\text{C}_6\text{H}_5(\text{CH}_2)_3\text{NH}_2$	135.1	135.1	0.63	15.9
$\text{C}_6\text{H}_5(\text{CH}_2)_4\text{NH}_2$	149.2	149.4	.40	24.8
$\text{C}_6\text{H}_5(\text{CH}_2)_5\text{NH}_2$	163.2	163.1	.33	30.6
$o\text{-CH}_3\text{C}_6\text{H}_4\text{CH}_2\text{NH}_2$	121.1	121.5	5.89	1.70
$m\text{-CH}_3\text{C}_6\text{H}_4\text{CH}_2\text{NH}_2$	121.1	121.8	4.24	2.40
$p\text{-CH}_3\text{C}_6\text{H}_4\text{CH}_2\text{NH}_2$	121.1	121.1	3.98	2.55
$o\text{-CH}_3\text{OC}_6\text{H}_4\text{CH}_2\text{NH}_2$	137.1	137.9	1.81	5.56
$m\text{-CH}_3\text{OC}_6\text{H}_4\text{CH}_2\text{NH}_2$	137.1	137.5	6.46	1.56
$p\text{-CH}_3\text{OC}_6\text{H}_4\text{CH}_2\text{NH}_2$	137.1	137.2	3.10	3.22
$\text{C}_6\text{H}_5\text{CH}_2\text{NHCH}_3$	121.1	121.3	2.63	3.80
$\text{C}_6\text{H}_5\text{CH}_2\text{NHCH}_2\text{CH}_3$	135.1	134.8	2.10	4.75
$\text{C}_6\text{H}_5\text{CH}_2\text{NHCH}_2\text{CH}_2\text{CH}_3$	149.1	149.1	2.40	4.18
$\text{C}_6\text{H}_5\text{CH}_2\text{CH}_2\text{NHCH}_3$	135.1	135.6	0.75	13.9

The first five amines constitute a series of the type $\text{R}(\text{CH}_2)_x\text{NH}_2$ where R is the negative phenyl group. The data are of some interest in connection with the transmission of polar effects through a chain of atoms. Data are available on several similar series of acids and it is well known that the effect of the substituent R on the dissociation of the acid diminishes continuously with the increasing values of x . Where R is $-\text{CH}=\text{CH}$, however, the dissociation constants appear to alternate with increasing values of x . Data on the acids $\text{C}_6\text{H}_5(\text{CH}_2)_x\text{COOH}$ are not available, but since phenyl contains the group $\text{C}=\text{C}-$, there was some possibility

that alternation might be observed in the series of amines here under discussion.

¹ Lunden, *Z. physik. Chem.*, **54**, 532 (1906).

The hydrolysis of an amine salt may be represented by the equation

and the hydrolytic constant is defined by the expression

$$\frac{[\text{RNH}_2][\text{H}^+]}{[\text{RNH}_3^+]} = K_{\text{hydr.}}^2$$

The hydrolytic constant of an amine then furnishes a measure of the tendency of a hydrogen ion to leave the nitrogen atom, and there should be a parallelism between the dissociation constants of acids and the hydrolytic constants of the corresponding bases.³ The amines, however, seem to present a simpler picture than the acids, for apart from the fact that there is in these a greater distance between R group and the proton which dissociates, the relatively greater complexity of the carboxyl group may permit a more complex behavior. Hantzsch⁴ has in fact advanced definite experimental evidence for concluding that two distinct types of carboxyl groups exist.

In regard to the amines $\text{C}_6\text{H}_5(\text{CH}_2)_x\text{NH}_2$, the data summarized above show that the values of $K_{\text{hydr.}}$ diminish continuously as the values of x increase. This decrease though continuous is not quite regular, and the data do not fit well the $1/3$ rule of Derick⁵ or an equation of the type suggested by Simms.⁶

It is interesting to compare the data on these amines with those on the reactivities of the corresponding chlorides as measured by Conant and Kirner.⁷ The effect of the phenyl group does not here diminish continuously as the distance from the halogen atom increases, but in the first members of the series there is evidence of alternation. It is evident

² It is of course implied in this that the conditions are such that the concentrations are equal to the activities.

As Brönsted has pointed out (Brönsted, *Rec. trav. chim.*, [4] **42**, 718 (1923)) the use of the equation $\text{NH}_4^+ + \text{HOH} \longrightarrow \text{NH}_4\text{OH} + \text{H}^+$ to represent the hydrolysis of an ammonium salt rests on an unnecessarily complicated conception. According to Brönsted's idea ammonium chloride reacts acid because the ammonium ion is an acid. The question of the extent to which the base strength of ammonia is determined by each of the reactions $\text{NH}_3 + \text{HOH} \rightleftharpoons \text{NH}_4\text{OH}$ and $\text{NH}_4\text{OH} \rightleftharpoons \text{NH}_4^+ + \text{OH}^-$ becomes immaterial when Brönsted's more general definition of a base is used. Incidentally the octet theory leads to a similar conclusion, since the most obvious manner of

representing ammonium hydroxide is $\text{H}:\ddot{\text{N}}:\text{H}$ $\begin{smallmatrix} \text{H} \\ \vdots \\ \text{O} \\ \vdots \\ \text{H} \end{smallmatrix}$ and the weakness of ammonia as a base is accounted for by supposing that the equilibrium lies in favor of $\text{NH}_3 + \text{H}_2\text{O}$, the formation of these involving merely the transfer of a hydrogen ion from the ammonium ion to the hydroxyl ion.

³ See in this connection Hixon and Johns, *THIS JOURNAL*, **49**, 1786 (1927).

⁴ Hantzsch, *Ber.*, **50**, 1422 (1917).

⁵ Derick, *THIS JOURNAL*, **33**, 1181 (1911).

⁶ Simms, *ibid.*, **48**, 1251 (1926).

⁷ Conant and Kirner, *ibid.*, **46**, 232 (1924).

that those qualities of structure which govern the base strength of amines are not the same as those which govern the tendencies of the chlorides to undergo metathesis. Of the two reactions the hydrolysis of the amine salt is evidently the simpler, since it involves merely the reversible separation of a proton. Concerning the mechanism of the reaction of an alkyl halide nothing whatever is known. If the term polarity is to be used, it seems much more appropriate to use it in connection with the hydrolysis of the amine salt, a reaction involving the loss of an elementary positive charge, than in connection with the reactions of an alkyl chloride which proceed in a fashion at present wholly obscure.

The reasons which Conant, Kirner and Hussey⁸ found for concluding that variations in the reactivities of chlorides could not be accounted for solely in terms of polarity find additional support in the above argument.

The data on the *o*-, *m*- and *p*-methyl- and methoxylbenzylamines indicate that the effects of these substituents are slight and vary in an irregular fashion with changes of position.

Of the secondary amines two have previously been measured by Bourgeaud and Dondelinger.⁹ For methylbenzylamine these writers give $K_B = 7.95 \times 10^{-8}$, and for ethylbenzylamine 5.04×10^{-8} . The values indicated in the above table are in one case 500 and in the other 1000 times as great as these. Although some difficulty was experienced in getting sharply consistent readings on these amines, the writers are inclined to suppose that the values given by Bourgeaud and Dondelinger must be seriously in error. These values are of an entirely different order of magnitude from those of the corresponding primary and the analogous tertiary amines, and imply an effect due to the introduction of a simple alkyl group quite unprecedented. The measurements of these investigators were evidently carried out with great care but their method appears to be fundamentally untrustworthy. They measured, with the aid of the hydrogen or quinhydrone electrode, the *P_H* of solutions of the pure hydrochlorides of the amines. Their solutions were therefore very inadequately buffered; and slight traces of impurities or quite possible variations in the compositions of the purified hydrochlorides would suffice to render their results meaningless.

As the table shows, the amines $C_6H_5CH_2NHR$ where R is methyl, ethyl and *n*-propyl are just about twice as strong bases as benzylamine, and a similar relationship holds between methylphenethyl- and phenethylamine.

Benzylamine has been measured by Bredig by the conductivity method¹⁰ and the value which he assigns to it ($K_B = 2.4 \times 10^{-5}$) agrees with that found in the present investigation.

¹⁰ Bredig, *Z. physik. Chem.*, 13, 191 (1894).

Method Used in Measuring the Base Strengths.—The method used was to determine the P_H of solutions of the base in water to which a definite fraction of an equivalent amount of hydrochloric acid had been added. This fraction was usually $\frac{1}{2}$ but sometimes $\frac{2}{3}$ or $\frac{3}{4}$. This method is satisfactory only if the amine is appreciably soluble in water and quite pure, and if the composition of the solution is definitely known. The purified amine was distilled in a vacuum in a small Claisen flask with a sealed-in thermometer, etc., and was collected with the aid of a bifurcated adaptor in two test-tubes. One of these contained a number of small bulbs weighed and marked standing on their capillary tips. The middle fraction of the amine was collected in this tube and when air was admitted to the receiver the bulbs were automatically filled. The amine was thus preserved from contact with moisture and carbon dioxide. The bulbs were immediately sealed off and weighed. To control the purity some of the tubes were broken under water and the solutions titrated using a suitable indicator (usually methyl red). To prepare a solution for measurement the bulb containing a known amount of the amine was placed in a glass-stoppered bottle, $\frac{1}{2}$ an equivalent of 0.01 N hydrochloric acid added and the stoppered flask shaken vigorously to break the thin bulb. This method of operation protected the amine against exposure to the air.

The electrodes were usually palladized platinum foils, though platinized platinum foils were also tried and in some cases wires were used. The hydrogen electrode was connected to 0.1 N and saturated calomel electrodes through a saturated potassium chloride salt bridge. Boundary potentials were disregarded. The two calomel electrodes were frequently compared with each other and with a hydrogen electrode in a standard 0.05 M potassium hydrogen phthalate buffer. The cells were immersed in a water-bath, the temperature of which was regulated by hand to $25 \pm 0.2^\circ$. For measurement of potentials a Leeds and Northrup Student Potentiometer was used. Measurements were made on three or more samples of each amine, with at least two fresh electrodes on each solution and usually at two different dilutions. In each case a series of readings was made against the 0.1 N calomel ($E = 0.3370$) and the saturated calomel ($E = 0.2458$) electrode. The agreement of the various series of readings was usually quite good, although some difficulty was experienced in getting sharply consistent results with the secondary amines. With a similar series of tertiary amines no consistent readings could be obtained.

Preparation of the Amines.—All of the amines measured in this work with the exception of one have been previously described. The following notes may, however, be of interest to those who have to prepare similar compounds.

The amines of the series $C_6H_5(CH_2)_nNH_2$ with the exception of benzylamine were prepared by the reduction of the corresponding nitriles. As von Braun has shown¹¹ this method, which gives poor yields in the preparation of phenethylamine, works very well for the higher members of the series. Commercial phenethyl alcohol was the starting point in the preparation of phenethyl cyanide. γ -Phenyl-*n*-propyl alcohol was prepared by the catalytic reduction of cinnamic aldehyde. This provided the starting point for the synthesis of phenylpropyl cyanide.

δ -Phenyl-*n*-butyl alcohol was prepared from β -phenethyl magnesium bromide by the action of ethylene oxide. This method has been used with satisfactory results in passing from RBr to RCH_2CH_2OH in a number of cases. In a small run this method gave a yield of 50% of the phenylbutyl alcohol, but in larger runs the yields were still poorer and the product required repeated careful fractionation. Although further study might increase the yields, this method cannot at present be recommended for obtaining compounds of the series $C_6H_5(CH_2)_n-$.

The substituted benzylamines were all prepared by the catalytic reduction of the appropriate nitriles or oximes, using acetic anhydride as the solvent. This method yields the acetyl derivative of the primary amine and avoids the formation of any secondary amine.¹² Hydrolysis of the amide then yields pure primary amine. The details of the preparation of *o*- and *p*-methylbenzylamines have already been described. The preparation of *m*-methylbenzylamine proceeds smoothly in the same fashion.

***p*-Anisylamine.**—The reduction of 0.1 mole of anisaldoxime in 40 cc. of acetic anhydride was complete in four hours using 0.1 g. of catalyst. The yield of the crude amide was quantitative. On crystallization from alcohol, it melted at 95.5–97°. The amide was hydrolyzed by boiling with 6 *N* hydrochloric acid for 24 hours. Some of the amide was transformed into a gum in this process and the yield of *p*-anisylamine (b. p. 132.8 to 134° at 33 mm.) was rather poor.

As has been previously pointed out the hydrolysis of benzylacetamide and substituted benzylacetamides is a slow process, although the reaction is much more rapid with hydrochloric acid than with alkalis. The presence of the methoxyl groups, however, complicates the hydrolysis by hydrochloric acid, and with the corresponding *o*- and *m*-compounds, methyl alcoholic sodium hydroxide at high temperature was used with much more satisfactory results.

Acetyl-*m*-methoxybenzylamine.—*m*-Anisic nitrile was prepared in good yield from *m*-anisidine by the Sandmeyer reaction; a colorless liquid, b. p. 111–112° at 12–13 mm. It readily crystallizes in an ice-bath to a mass of long needles. Reduction of the nitrile in acetic anhydride solution by the method already described yielded acetyl-*m*-methoxybenzylamine; b. p. 191–198° at 11 mm.; m. p. 58.5–59° (from ether and petroleum ether).

Anal. Calcd. for $C_{10}H_{13}O_2N$: N, 7.82. Found: 7.62

***m*-Methoxybenzylamine.**—The amide was hydrolyzed by heating for seven hours with methyl alcoholic sodium hydroxide in a sealed tube at 140–150°. The solution was steam distilled, the distillate neutralized with hydrochloric acid, evaporated to dryness, treated with sodium hydroxide, etc. The amine was obtained as a colorless liquid; b. p. 131° at 26 mm., 140° at 37 mm.

Neutral equivalent. Calcd. for $C_8H_{11}ON$: 137.1. Found: 137.5.

The hydrochloride of this amine has been described by Curtius.¹³

Acetyl-*o*-methoxybenzylamine.¹⁴—This was prepared in the same way as the *m*-

o-Methoxybenzylamine¹⁴ was prepared by hydrolysis of the amide; b. p. 127–28° at 30 mm.

Anal. Calcd. for $C_8H_{11}ON$: N, 10.22. Found: 10.07.

Neutral equivalent. Calcd.: 137.1. Found: 137.9.

The secondary amines were prepared from the corresponding primary amines by transformation into the *p*-toluenesulfonyl derivatives, alkylation and hydrolysis. Benzyl- and β -phenethylamines are much more readily acylated than aromatic amines. Hence, when the usual procedure of employing a 50% excess of the sulfonyl chloride is followed, considerable disulfonyl derivative is formed. The yields are therefore better if only 10–20% excess of the *p*-toluenesulfonyl chloride is used. The sulfonamides were prepared by adding a benzene solution of *p*-toluenesulfonyl chloride to an ice-cold solution of the amine in aqueous alkali. Afterward the mixture was heated on a steam-bath for two hours, the benzene distilled off and the residue acidified.

As the writer has previously stated, the benzenesulfonyl and *o*-toluenesulfonyl derivatives of benzylamine, β -phenethylamine, etc., are not soluble in aqueous alkali, statements in the literature to the contrary notwithstanding. It was found, however, that these amides are soluble in aqueous alcoholic sodium hydroxide (33% water, 66% alcohol). The use of this solvent made it possible to separate the *p*-toluenesulfonyl derivative from the di-*p*-toluenesulfonyl derivative and so to obtain the former in a state of purity.

This solvent was also found to be the best medium for the alkylation of the amines. Methyl iodide was found to be a much better methylating agent for these compounds than dimethyl sulfate, and ethyl bromide was better than diethyl sulfate. The alkylated *p*-toluenesulfonamides were freed from any unalkylated material by crystallizing them first from the alcoholic sodium hydroxide, in which the unalkylated material is soluble. This precaution was necessary because the alkylation was never quite complete and the separation of unalkylated material by the usual solvents required repeated crystallization. The alkylated amides were crystallized to constant melting point and then hydrolyzed in the usual fashion by heating in sealed tubes to 180° with concd. hydrochloric acid.

PUBLISHED NOVEMBER 5, 1927

Some time ago Schlenk and Racky² reported the preparation of tetraphenyldi-*tert*-butylethane and asserted that this product was a stable hydrocarbon which did not show any of the characteristics of the hexaarylethanes. The recent work of Conant and his students³ on derivatives of dixanthyl has shown that certain aliphatic groups substituted for the hydrogens of what might be considered the ethane carbons in dixanthyl have almost as great a tendency to cause dissociation into free radicals as do phenyl groups in these positions. It has been shown that di-*sec*-butyl-dixanthyl is dissociated to about the same degree as diphenyldixanthyl. One might expect from analogy then that a *tert*-butyl group would have a strong tendency to produce dissociation. It would appear that the compound described by Schlenk needs to be reinvestigated, especially since his conclusions rest on rather incomplete experimental results.

In reviewing the subject in the literature it was found that Schlenk prepared diphenyl-*tert*-butylmethyl chloride from diphenyl-*tert*-butyl carbinol and acetyl chloride and obtained a product which melted at

103–106°. About the same time Mme. Ramart-Lucas⁴ prepared this carbinol and obtained from it two isomeric chlorides, one melting at 71–72° and the other at 108–109°. The lower-melting chloride on hydrolysis gave the original carbinol and must have had the corresponding structure. It was further observed that the carbinol was easily dehydrated to give a hydrocarbon $C_{17}H_{18}$ which would add hydrogen chloride to give the higher-melting chloride mentioned above.

The structure of the hydrocarbon was studied by Mme. Ramart-Lucas.⁵ Several structures were suggested and disproved. Oxidation of the compound produced benzophenone, acetophenone and an acid which melted at 172–173° and to which from analyses the empirical formula $C_{17}H_{18}O_2$ was given. The structure which was favored seemed to be that of diphenyl-1,1-dimethyl-2,2-cyclopropane (I) which contained the cyclo-

propane ring. However, the above formula does not explain the formation of acetophenone as an oxidation product and it is difficult to conceive of its oxidation to an acid, $C_{17}H_{18}O_2$.

In order to draw any conclusions concerning the work of Schlenk, it seemed necessary first to establish the structure of this unsaturated hydrocarbon and of the higher-melting chloride which was used in his experiments. The structure for the hydrocarbon which seemed most probable in advance was that of diphenyl-2,3-methyl-2-butene-1 (II), which would be the dehydration product of the carbinol (III) that would be formed if the original carbinol, *tert.*-butyldiphenylcarbinol (IV), were to undergo a Wagner rearrangement.

In order to test this prediction, a sample of diphenyl-3,3-methyl-2-butene-1 was prepared by the following series of reactions

⁴ Ramart-Lucas, (a) *Compt. rend.*, 154, 1088 (1912); (b) *Ann. chim. phys.*, [8] 30, 367, 390 (1913).

⁵ Ref. 4 b, p. 406.

The diphenylmethylacetaldehyde was prepared from benzoin as described by Tiffeneau and Dorlencourt⁶ and was oxidized with alkaline permanganate solution to diphenylmethylacetic acid. The esterification of this acid and the reaction of the ester with the Grignard reagent were carried out in the usual manner. The carbinol was not isolated but was dehydrated directly.

The hydrocarbon obtained in this way agreed in all of its properties with the one obtained by the dehydration of *tert.*-butyldiphenylcarbinol. In order to complete the identification, dry hydrogen chloride was added to both samples and a chloride melting at 102–106° was obtained in each case. There can be no further question concerning the constitution of the hydrocarbon. The higher-melting chloride obviously has the formula

The structure thus established for the hydrocarbon explains how both acetophenone and benzophenone can be obtained on oxidation. However, this compound could not give a seventeen carbon atom acid on oxidation. It might be expected to give some diphenylmethylacetic acid. The acid obtained by Mme. Ramart-Lucas melted at 172–173°, which is the melting point of diphenylmethylacetic acid. Some difficulty was encountered in attempting to duplicate the chromic acid oxidation of the hydrocarbon. However, ozone easily oxidized it to the ketone, diphenylmethylacetone, which on oxidation with sodium hypobromite solution gave diphenylmethylacetic acid melting at 174°. This acid is identical with the sample prepared by the oxidation of diphenylmethylacetaldehyde. There seems to be very little question that the acid previously thought to have the formula $\text{C}_{17}\text{H}_{18}\text{O}_2$ in reality has the composition $\text{C}_{15}\text{H}_{14}\text{O}_2$.

Since in his work Schlenk² used the chloride melting at 106° in his Würtz reaction to prepare a hexa-substituted ethane, it is quite obvious that he did not obtain tetraphenyl-di-*tert.*-butylethane but probably a hydrocarbon of the structure.

⁶ Tiffeneau and Dorlencourt, *Ann. chim. phys.*, [8] 16, 254 (1909).

A few attempts to couple the lower-melting chloride to give an ethane produced only the unsaturated hydrocarbon described before.

Experimental Part

***Tert.*-Butyldiphenylcarbinol.**—The method of Schlenk⁷ was used for this preparation. From 325 g. of phenylmagnesium bromide in 1 liter of dry ether and 114 g. of ethyl trimethylacetate there was obtained 135 g. of carbinol; b. p. 148–150° at 2.5 mm.; n_D^{20} 1.5748. The constants given by Mmc. Ramart-Lucas⁸ are n_D^{26} 1.57306; b. p. 178–180° at 11 mm.

Dehydration of *Tert.*-Butyldiphenylcarbinol.—In attempting to prepare the bromide from the carbinol, 24 g. of the latter was dissolved in 160 cc. of dry benzene and treated with 24 cc. of acetyl bromide. The mixture was allowed to stand for about 24 hours. The benzene was removed under reduced pressure and the residue distilled at about 3–3.5 mm. At this pressure the product boiled at 125–128°; d_4^{20} 1.0007; n_D^{20} 1.5730; M_D 73.03. The physical constants reported previously⁹ are d_4^{26} 1.0031; N_D^{26} 1.57589; observed M_D 73.23.

A more convenient method of dehydration was found. Sixty g. of the carbinol and a few grams of *p*-toluenesulfonic acid were placed in a small flask and heated on a boiling water-bath for about two hours. The mixture was treated with ether and the *p*-toluenesulfonic acid was removed by washing with dilute sodium carbonate solution and water. The ether solution was dried over sodium sulfate, filtered and evaporated. The residue was distilled under reduced pressure. The yield was 45 g. (81% of the theoretical amount) of hydrocarbon boiling at 125–128° at 3–3.5 mm.

Diphenylmethylacetic Acid.—Diphenylmethylacetaldehyde was prepared according to the directions of Tiffeneau and Dorlencourt.⁶ Benzoin and methylmagnesium iodide gave methylidihydrobenzoin in about 75% yields. This compound on rearrangement by boiling with 20% sulfuric acid solution gave diphenylmethylacetaldehyde in 60–70% yields.

In a flask fitted with a reflux condenser and mechanical stirrer were placed 136 g. of the aldehyde and a solution of 220 g. of potassium permanganate and 90 g. of sodium carbonate in 800 cc. of water. The mixture was refluxed with stirring until the color of the permanganate solution had disappeared. The solution was filtered to remove the manganese dioxide, extracted with ether to remove indifferent substances and then acidified with sulfuric acid. On filtering and drying, 80 g. of the acid was obtained. This was purified by recrystallization from 95% alcohol. The acid thus obtained weighed 61.5 g., melted at 172–174° and gave a neutral equivalent of 227.4 as compared with the calculated value, 226.

Methyl Diphenylmethylacetate.—A mixture of 59 g. of diphenylmethylacetic acid and 41 g. of thionyl chloride was refluxed on a steam-bath until solution was complete and no more sulfur dioxide and hydrogen chloride were being evolved. The excess thionyl chloride was removed by heating the reaction mixture under reduced pressure on a water-bath. About 20 g. of absolute methyl alcohol was added to the residue and the solution was refluxed for about four hours. It was then dissolved in ether and the

⁷ Ref. 2, p. 211.

⁸ Ref. 4 b, p. 367.

⁹ Ref. 4 b, p. 391.

solution was washed with sodium carbonate solution and water. The ether solution was dried over sodium sulfate, filtered and evaporated. The residue was distilled under reduced pressure and the portion boiling at 149–152° at 3 mm. was collected. The yield of ester was 46.5 g. (70% of the theoretical amount). It was a viscous liquid; n_D^{20} 1.5691; d_4^{20} 1.1206; M_D , calcd., 70.43; obs., 70.13.

Anal. Subs., 0.2030: CO₂, 0.6018; H₂O, 0.1220. Calcd. for C₁₈H₁₈O₂: C, 80.0; H, 6.67. Found: C, 80.89; H, 6.72.

Diphenyl-3,3-methyl-2-butene-1.—To 15 g. of magnesium turnings and 400 cc. of dry ether was added 90 g. of methyl iodide. When the Grignard reagent was formed, 45 g. of methyl diphenylmethylacetate was added, the mixture was allowed to stand for several hours and then refluxed on a water-bath for about one hour. The solution was treated with ammonium chloride solution to decompose the excess Grignard reagent and to dissolve the basic magnesium salts. The ether layer was separated and the aqueous layer was extracted with two small portions of ether. The ether solutions were combined, the ether was evaporated and the residual oil treated with about 5 g. of *p*-toluenesulfonic acid and heated to 125° for about 10 to 15 minutes. It was then dissolved in ether and the acidic material removed by washing the solution with dilute sodium carbonate solution. The ether was evaporated and the residue was refluxed with alcoholic potassium hydroxide solution to hydrolyze any unreacted ester. This solution was evaporated until the alcohol was removed and then water was added. The insoluble oil was collected in ether, the ether solution dried over sodium sulfate, filtered and evaporated. The residue was fractionated under reduced pressure and the main fraction collected at 132–133° at 4.5 mm.

Anal. Subs., 0.2067: CO₂, 0.6903; H₂O, 0.1488. Calcd. for C₁₇H₁₈: C, 91.89; H, 8.11. Found: C, 91.09; H, 8.05.

The physical constants of this hydrocarbon and of the one obtained by the dehydration of *tert*.-butyldiphenylcarbinol are as follows.

TABLE I
PHYSICAL CONSTANTS

Compound	B. p., °C.	d_4^{20}	n_D^{20}	M_D	
				Calcd.	Obs.
Diphenyl-3,3-methyl-2-butene-1	132–133 at 4.5 mm.	1.0060	1.5757	73.05	73.03
C ₁₇ H ₁₈ from <i>tert</i> .-butyldiphenylcarbinol	125–128 at 3.5 mm.	1.0007	1.5730	...	73.08

A second fraction which boiled a little higher was collected. Its index of refraction was near that of the main fraction but analysis showed that it contained some oxygen.

The identification of the two hydrocarbons as samples of the same compound was completed by taking small samples of each in an absolute alcohol-ether solution and treating with dry hydrogen chloride. On standing the solid chloride separated and on recrystallization from alcohol and ether mixture it melted at 102–106° in each case. A mixed melting point showed no depression.

Ozonization of Diphenyl-3,3-methyl-2-butene-1.—A mixture of air and ozone was bubbled through a solution of 45 g. of the unsaturated hydrocarbon (obtained by the dehydration of diphenyl-*tert*.-butylcarbinol) in 200 cc. of glacial acetic acid for four

hours.¹⁰ More acetic acid was added from time to time to replace that lost by evaporation. The solution was then treated with water and the acetic acid neutralized with 20% sodium hydroxide solution. The ketone was collected in ether, the ether solution dried over sodium sulfate, filtered and evaporated. The ketone was distilled under reduced pressure. The yield was 32 g. of a yellow oil; b. p. 132–135° at 2 mm.; d_4^{20} 1.069; n_D^{20} 1.5748; M_D , calcd., 68.91; found, 69.21. This compound is described¹¹ as a solid melting at 41–41.5° and boiling at 310–311°. Our product did not solidify on standing for several days. It was analyzed as a check on its purity.

Anal. Subs., 0.2139: CO_2 , 0.6703; H_2O , 0.1382. Calcd. for $C_{16}H_{16}O$: C, 85.71; H, 7.14. Found: C, 85.51; H, 7.23.

Oxidation of Diphenyl-3,3-butanone-2 to Diphenylmethylacetic Acid.—In a 500 cc. round-bottomed flask, fitted with a mechanical stirrer, was placed a solution of 16.5 g. of sodium hydroxide in 140 cc. of water. The solution was cooled to 0° in an ice-salt bath and to the well-stirred solution was added 24 g. of bromine. The temperature was held at 0° during this addition. To the cold solution 11.4 g. of diphenyl-3,3-butanone-2 was added and the mixture was cooled and stirred for about three hours and then allowed to come to room temperature and stirred for another three hours. The flask was fitted with a condenser for distillation and the solution was distilled as long as bromoform came over with the water. It was necessary to add water to the reaction mixture from time to time. When the hydrolysis was complete, the alkaline reaction mixture was extracted with ether to remove unoxidized ketone and then acidified with dilute sulfuric acid. The acid which precipitated was filtered and recrystallized from 95% alcohol. It then melted at 173–174° and when mixed with a sample of diphenylmethylacetic acid prepared from diphenylmethylacetaldehyde showed no depression in the melting point.

Attempts to Prepare Di-*tert.*-butyltetraphenylethane. *Tert.*-butyldiphenylmethyl chloride was shaken with molecular silver in anhydrous toluene for long periods but the only product that could be isolated was the unsaturated hydrocarbon described above. It was also treated with magnesium in ether and then with cupric chloride. A brisk reaction occurred with magnesium but the unsaturated hydrocarbon was the only product that was isolated. The carbinol gave a deep red color with sulfuric acid but attempts to reduce the compound with vanadous chloride were unsuccessful.

Summary

1. The hydrocarbon $C_{17}H_{18}$ obtained by the dehydration of *tert.*-butyldiphenylcarbinol has been identified as diphenyl-3,3-methyl-2-butene-1.

THE APPLICATION OF THE OIL TURBINE TYPE OF ULTRACENTRIFUGE TO THE STUDY OF THE STABILITY REGION OF CARBON MONOXIDE-HEMOGLOBIN

BY THE SVEDBERG AND J. B. NICHOLS¹

RECEIVED AUGUST 20, 1927

PUBLISHED NOVEMBER 5, 1927

Depending on the experimental conditions, there are two principles by which molecular weights may be determined by means of the ultracentrifuge: the establishment of a sedimentation equilibrium between centrifuging and diffusion, and the measurement of the sedimentation velocity.² The first requires only a moderate centrifugal force of about 5000 times that of gravity but a relatively long time, generally two days. Unstable substances, for example, acid hemoglobin near the region of hematin formation, may be altered appreciably during this length of time. The second principle, on the other hand, requires for molecules of the order of magnitude of the proteins, centrifugal forces of at least 70,000 times that of gravity, introducing certain experimental difficulties, but enabling measurements to be made in as short a period as two hours of centrifuging, if necessary.

Although the sedimentation equilibrium method is sounder thermodynamically, the other method has certain advantages which justified the construction of an oil turbine type of ultracentrifuge capable of running at a speed of 42,000 r.p.m. and giving an effect 104,000 times that of gravity. In addition to the much smaller chance for decomposition of an unstable substance in the short time of centrifuging, it is possible to obtain more exact information when a mixture of molecules is present in a solution, whereas in the sedimentation equilibrium method only the resultant effect of centrifuging and diffusion is obtained; by using higher speed we determine the diffusion and the velocity of sedimentation separately. Under these conditions it is possible to detect anomalies in the diffusion produced by labile gel formation or hydration that might otherwise cancel out or be disguised.

Previous communications³ have given results obtained through the use of the sedimentation equilibrium method on hemoglobin and egg albumin. The present paper will give a short description of the high-speed oil turbine type of ultracentrifuge and determinations on the range of P_H over which hemoglobin can exist in its normal form.

Theory of the Sedimentation Velocity Method

After the very short initial period the centrifugal force per mole, $M(1-\rho V)\omega^2 x$, becomes equal but is of opposite sign to the frictional force, $f(dx/dt)$, where for dilute solutions $f = (RT/D)$. These quantities have their usual significance; M , the molecular weight; ρ , the density of the solution; V , the partial specific volume; ω , the angular velocity; x , the distance from the axis of rotation of the centrifuge; f , the frictional coefficient; t , the time; T , the absolute temperature; and D , the diffusion constant.

The expression for the molecular weight is, then, for small x -intervals,

$$M = \frac{RT}{D(1-V\rho)} \cdot \frac{dx}{\omega^2 x} = \frac{RTs}{D(1-V\rho)} \quad (1)$$

where $(1/\omega^2 x) \cdot (dx/dt) = s$ is the specific sedimentation velocity, a characteristic constant for every molecular species at a given temperature and for a given solvent. For large x -intervals it is necessary, of course, to use the integrated form of equation (1):

$$M = \frac{RT \ln \left(\frac{x_2}{x_1} \right)}{D(1-V\rho)\omega^2(h_2 - h_1)} \quad (2)$$

With a sufficiently strong centrifugal field of force it would be possible to measure directly the movement of the boundary of the dissolved substance with time, but generally sufficient diffusion occurs so that the boundary becomes too blurred to read off the x -values accurately. The boundary will become especially diffuse if there are several molecular species present of not very different weights. However, if sedimentation occurs rapidly enough so that pure solvent appears at the inner end of the solution column in a time short compared to the total time of centrifuging and if there is still a region of solution where there is no change of concentration with distance, then the true position of the boundary can easily be located. The theory of diffusion tells us that the place where the boundary would have been if there had been no diffusion is the surface where the concentration is half that of the original concentration of the solution. After a certain time of centrifuging, the constant part does not correspond to the original concentration in a sectorial cell, due partly to the fact that the molecules are thrown out radially and partly to the increased acceleration with distance. The gradual decrease in concentration with time can be calculated from the relation⁴

$$c_0 \left(\frac{x_0}{x_t} \right)^2, \quad (3)$$

c_0 being the original concentration and c_t the concentration at time t .

The diffusion constant can be determined independently of the centri-

⁴ Svedberg and Rinde, *THIS JOURNAL*, **46**, 2684 (1924).

fuging, if desired, but it is more reliable to calculate it under the same conditions from the same observations used to determine the sedimentation velocity. When pure solvent is obtained above the solution in a time short with respect to the total time, then the diffusion constant may be conveniently determined from the simple diffusion equations

$$c_s = \frac{c_0}{2} \left(1 - \frac{2}{\sqrt{\pi}} \int_0^y e^{-y^2} dy \right) \quad \left| \quad y = \frac{z}{\sqrt{4Dt}} \right. \quad (4)$$

in which c_s is the concentration at the distance z from the meniscus after the time t ; c_0 , the concentration of the unchanged part of the solution; and $\frac{2}{\sqrt{\pi}} \int_0^y e^{-y^2} dy$, the probability integral.

If a sufficiently high field of force is not available, then the more involved expression^b must be used

$$\frac{c_x}{c_0} = -\frac{B\sqrt{t}}{\sqrt{D\pi}} e^{-\frac{(Bt-x)^2}{4Dt}} + \frac{1}{2} \left[1 - \Theta \left(\frac{Bt-x}{\sqrt{4Dt}} \right) \right] + \frac{1}{2} e^{\frac{Bx}{D}} \left[1 + \frac{B}{D} (Bt+x) \right] \left[1 - \Theta \left(\frac{Bt+x}{\sqrt{4Dt}} \right) \right] \quad (5)$$

where B is the sedimentation velocity and $\Theta \left(\frac{Bt-x}{\sqrt{4Dt}} \right)$ and $\Theta \left(\frac{Bt+x}{\sqrt{4Dt}} \right)$ are probability integrals with the arguments indicated. Since this equation was derived for a gravitational field, it should be used only for very small x -intervals in a centrifugal field. Furthermore, there must be a region of constant concentration so that the liquid may be regarded as unlimited in the direction of the periphery.

With a centrifugal field 70,000 times that of gravity it is permissible to use the simple equations (4) after four hours of centrifuging for a substance of molecular weight 16,700 and after two hours for a weight of 33,400.

Apparatus and Method

The apparatus developed⁶ may be conveniently divided into the centrifuge proper,⁷ the oil circulation system, the vacuum and hydrogen system, the optical system and the stroboscopic tachometer.

The most important conditions which the centrifuge had to fulfil were: a centrifugal force in the cells of 80,000–100,000 times the force of gravity,

^b Mason and Weaver, *Phys. Rev.* [2] 23, 424 (1924).

⁶ For a complete description of the apparatus see Svedberg and Lysholm, *Nova Acta Reg. Soc. Scient. Upsaliensis*, Vol. ex. ord., ed. 1927.

⁷ The centrifuge proper was built in the workshops of Ljungström Steam Turbine Company through the courtesy of Mr. F. Ljungström, who suggested the use of high pressure oil turbines for driving the centrifuge. Most of the other parts of the apparatus were made in the workshops of this Laboratory. Mr. A. Lysholm, chief engineer, should be credited as the designer of the centrifuge.

temperature in the cells not higher than 35° , amplitude of vibration small enough so that sharp photographs could be taken during centrifuging at high speed, optical parts inside the centrifuge remaining free from oil dust. Fig. 1 shows the rotor, cylindrical in shape, 150 mm. in diameter, and 60

Fig. 1.

mm. thick. It is made of chrome nickel steel and has openings for four cells. It is driven by high pressure oil impinging against two eight-bladed oil turbines, one at each end of the shaft. The turbines receive 240

Fig. 2.

liters of oil per minute, and at the same time 7 liters of oil per minute lubricate and cool the bearings. The rotor revolves in hydrogen gas at a reduced pressure to avoid undesirable heat production in the rotor chamber.

The oil from the bearings is prevented from entering the rotor chamber by an elaborate system of oil rings and oil deflectors.

The centrifuge is shown diagrammatically in Fig. 2. To the left is an axial section, and to the right a section at right angles to the axis of rotation. The chief parts are the rotor, top and bottom casings, and the two end brackets. The top casing has the hydrogen inlet and carries the thermocouple for the measurement of the temperature of the

interior of the centrifuge. The end brackets contain the turbine chambers with inlets and outlets for the oil that has been pressed through the bearings. The main bearings and the plates for the pivot thrust bearings of the shaft are here also. Thermocouples are inserted into the bearings to ascertain their temperatures. An observation channel 34 mm. in diameter is bored through the end brackets and top casing and closed by round glass or quartz windows 10 mm. thick, protected from oil dust by special electromagnetically operated shutters.

The cells for the solution to be studied are made as follows. Two round glass or quartz plates 30 mm. in diameter and 10 mm. thick are cemented with a de Khotinsky cement having a high softening temperature to a third plate 30 mm. in diameter and 1.90 mm. thick. The latter has a sectorial aperture of 5°. The cell is cemented to a steel collar (a brass collar becomes deformed in time) having an opening coincident with the opening of the sectorial cell. This collar containing the cell

Fig. 4.

is then put into a steel shell (shown in Fig. 1) and supported at both ends by a system of sectorial disks and diaphragms (Fig. 3) so that actually a 3° sectorial cell is used. The steel shell bearing the cell is held in place in the rotor by means of a guard ring.

Fig. 4 shows the oil circulation system. The centrifugal pump B, driven by the

20 H. P. three-phase motor A, sucks the oil⁸ from the container C and forces it through the oil cooler D to the centrifuge E. From the turbine the oil passes through the pipes FF (only one is shown in the diagram) and back to the container. The oil pumped through the bearings drains down to the lower container H through the pipes GG. A small pump J then raises it again to the upper container C, forcing it through the filter K on its way. Before starting a run the whole oil flow is directed through the filter by means of the three-way valve N in order to remove suspended material which would wear away the bearings too rapidly. M is the vacuum pump, L the container for the oil employed for keeping the various joints vacuum-tight and O is a trap for oil droplets. Speed regulation of the centrifuge is obtained through changing the oil pressure by varying the speed of the main oil pump motor. In Fig. 5 is given the relation between oil pressure and speed of the centrifuge.

In hydrogen as well as in air at atmospheric pressure the rotor warmed up more than 10° above room temperature in a few minutes. Even a 0.5 mm. air vacuum obtained by the oil vacuum pump (M, Fig. 4) did not prevent injurious heating because the heat generated in the residual air cannot be conducted away rapidly enough. However, the heat conductivity of hydrogen is high and independent of pressure down to about 20 mm. of Hg, below which the conductivity decreases.⁹ But heat production decreases continuously with decreasing pressure and would become negligible at very small hydrogen pressures (as indicated by the dotted line, Fig. 6) if its dissipation were not radically hindered by the rapid decrease in heat conductivity of air below a pressure of 1 mm. of Hg and of hydrogen below 20 mm. of Hg. Therefore there must be an optimum pressure of hydrogen which will give the smallest temperature difference. The most favorable hydrogen pressure was found to be 12–15 mm. of Hg, as indicated by Fig. 6, where the ordinates give the temperature differences found to exist between the rotor and the casing of the centrifuge for different pressures of hydrogen. Therefore, hydrogen is let in from a container of compressed gas at a rate sufficient to maintain a pressure of 15 mm. of Hg while the vacuum pump keeps the system air-free during the centrifuging.

Resistance thermometers are used to ascertain the temperatures of the incoming and outgoing water of the oil cooler, the incoming and outgoing oil, the oil container and the cold junction of the thermocouples. Thermo-

Fig. 5.

⁸ Gargoyle Velocite Oil E is most suitable because of its low vapor pressure and low viscosity.

⁹ Soddy and Berry, *Proc. Roy. Soc. (London)*, **84A**, 582 (1911).

couples give the temperature of the main bearings and the top casing of the centrifuge. To determine the difference in temperature between the rotor and the top casing a substance or mixture of known melting point was put into the cell and subjected to the same experimental conditions as in the experiment. Azoxybenzol and piperonal mixtures give a temperature region in the vicinity of 30° . If a thin layer of substance is used the pressure effect on the melting point is negligible. The temperature difference was found to be 1.4° , ordinarily, with a hydrogen pressure of 12–15 mm. of Hg, so the temperature of the cell is then determined by adding this value to the reading of the top casing thermocouple.

Fig. 6.

The optical system is shown in Fig. 7. Parallel light is produced by focusing the image of the incandescent ball of the fixed-focus 100 c. p. "Pointolite" lamp B on the diaphragm D by means of a Dallmeyer lens C_1 of aperture $f:1.9$ and focal length 7.5 cm. The light from the diaphragm is then made parallel by means of a Zeiss-Tessar lens C_2 , of aperture $f:4.5$ and focal length 15 cm. E_1 and E_2 are a water filter and a light filter, respectively. For the visible and the long-waved ultraviolet region of the spectrum a special Zeiss anastigmatic lens H of aperture $f:12.5$ and focal length 99 cm. was used. G is the camera.

Since the rotor should run free of any gearing arrangement, the speed of the centrifuge is determined by a stroboscopic tachometer. At the back of the camera a motor J is mounted (Fig. 7) carrying a perforated disk K. The stroboscope motor is connected to a small generator M, which acts on a hot-wire ammeter calibrated to read revolutions per minute directly. To measure the speed, the rotating cell is observed through the holes of the revolving disk of the stroboscope and the speed of the motor adjusted by

means of the resistance L until the cell appears to come to a stop, at which time the speed is read off from N .

The rotor must be balanced to within a few centigrams, otherwise injurious vibration will occur. A balancing machine similar to the Lawaczeck-Heymann apparatus¹⁰ is quite suitable. The rotor is supported by two horizontal V-bearings lined with Babbitt metal. The bearings are fixed on top of two stiff vertical steel springs, one of which carries a small mirror for reflecting the image of a straight filament lamp onto a scale. By means of a small motor the rotor is given a speed corresponding to a vibration period above the resonance value of the springs. The rotor is then allowed to run free, and as its speed decreases through the resonance point the amplitude of vibration is read off on the scale. By systematic trial of small lead pieces put into the steel shells the unbalance can be reduced to a few milligrams.

Fig. 7.

The general procedure for carrying out an experiment is as follows. One cell is filled with the solution to be studied and another with a standard for comparison of light intensities (potassium chromate is satisfactory for the whole range blue-short ultraviolet of the spectrum). Then vacuum oil is added to form a layer 2 mm. thick on top of the solutions to prevent boiling caused by the hydrogen vacuum in the rotor chamber and to prevent the rise of convection currents. At a speed of 10,000 r.p.m. the 2 mm. of oil in the cells exerts a pressure of one atmosphere; therefore, since the vacuum pump is not started until an oil pressure of 3 kg./cm.² is reached, corresponding to a speed of 14,000 r.p.m., the solution is protected the whole time.

The cells in their steel shells are inserted into the rotor and the contact surfaces of the top casing are rubbed with wool fat to make the centrifuge vacuum-tight. Then the lid is put on and screwed tight and the windows with their electromagnetic shutters are put in place at the ends of the observation channel of the centrifuge.

¹⁰ Heymann, *Elektrotech. Z.*, 40, 235 (1919).

After removing air bubbles from the centrifugal oil pump the big motor is gradually set in motion and the vacuum pump started when a pressure of 3 kg./cm.² is reached. The pump for the lower oil container is also started at this time. As soon as an air vacuum of 5 mm. of Hg is reached, hydrogen is admitted to the rotor chamber and the flow regulated at 1.0–1.5 kg./cm.² pressure to give a total pressure of 15 mm. of Hg in the centrifuge. The oil pressure is now increased until the desired speed is attained, regulating at the same time the water to the oil cooler to keep the oil entering the turbines at a temperature of 25°.

During the centrifuging, photographs of double natural size are taken at 30-minute intervals. After three hours a substance of molecular weight approximately 68,000 has centrifuged so completely at a speed of 40,000 r.p.m. that there is no longer a region of constant concentration in a column of solution 1.2 cm. in length. After stopping the centrifuge, a series of different concentrations of the same solution are pipetted into the cell and photographed on the same plate, the centrifuge being run at a low speed for this purpose. The plate after development is microphotometered and treated as previously described in the sedimentation equilibrium determinations.

Temperature and the speed of the rotor are measured from time to time during centrifuging, partial specific volume is determined pycnometrically and the diffusion constant either independently or from the photographs of the solution during centrifuging. It is better, however, to determine the diffusion constant from the centrifuging because its value may be decreased by the pressure developed at the high centrifugal forces used (about 10 atmospheres per millimeter of solution at a speed of 42,000 r.p.m.).

Experimental Part

Adair¹¹ found by osmotic measurements that hemoglobin, over a considerable range of hydrogen-ion concentrations (P_H 6.8–8.3), gives a normal osmotic pressure corresponding to a molecular weight of about 68,000, after correcting for the pressure of diffusible ions. However, the ultracentrifuge offers a means of determining the molecular weight directly, eliminating any correction for the presence of diffusible ions, provided a sufficient concentration of electrolyte is present to repress the Donnan effect.¹² A series of determinations was therefore made to verify and extend Adair's results.

Carbon monoxide-hemoglobin was prepared in the following manner. Horse blood was defibrinated by shaking for fifteen minutes with Jena glass pearls, saturated with carbon monoxide, and cooled to 0°. The corpuscles were separated from the serum by centrifuging and then washed five times with 1% sodium chloride. The concentrated mass of corpuscles was then dialyzed at 0° to hemolyze and yield crystals and a

¹¹ Adair, *Skand. Arch. Physiol.*, **49**, 76 (1926).

¹² Tiselius, *Z. physik. Chem.*, **124**, 458 (1926).

saturated stock solution. Since the stroma cannot be centrifuged off from a concentrated solution of hemoglobin, they were removed by a method suggested by A. Tiselius of this Laboratory and based on an observation by Heidelberger.¹³ According to the latter, a toluene layer over a solution of hemoglobin containing stroma soon acquires some swelled stroma due to the action of the toluene on the cholesterol of the stroma. The contents of the bags were shaken with toluene in a shaking machine for one hour at 0° and then centrifuged, yielding a thick jelly of swelled stroma which could be skimmed off. Complete removal of the stroma was effected in two shakings with toluene. Then an equal quantity of 0.2 *M* disodium phosphate was added to complete the solution of the crystals and sufficient molar potassium dihydrogen phosphate added to bring the hemoglobin to its isoelectric point, *P_H* 6.7, following a procedure similar to that of E. J. Cohn.

The solution at this point still contains globulins, so further purification is necessary. Saturated ammonium sulfate solution was added slowly until crystals of hemoglobin just started to form, as indicated by the streaming effect of the small plate-like crystals in motion. This occurs when the solution becomes about 15% saturated with ammonium sulfate. Crystallization was allowed to continue for three days and then the crystals were centrifuged off and dialyzed to remove the ammonium sulfate, yielding an 11% solution of pure hemoglobin with a mass of crystals at the bottom of the bags. The solution was resaturated with carbon monoxide and used exclusively for the centrifuging. The crystallization from 15% saturated ammonium sulfate solution is not complete, so after the first crop of crystals is removed more ammonium sulfate may be added to the mother liquor to cause the remaining hemoglobin to crystallize. This crop may be somewhat contaminated, so it should be dissolved again and recrystallized.

The partial specific volume of the hemoglobin was determined at 30° over the range of hydrogen-ion concentrations studied and found to increase gradually from 0.7545 at a *P_H* of 6.0 to a low maximum, 0.759, in the neighborhood of a *P_H* of 9 for dilute solutions.

All of the centrifuging experiments were performed on carbon monoxide-hemoglobin solutions of 0.95–1.0 g. per 100 cc. Parallel light with a Lifa blue filter was employed throughout. The determinations therefore refer to the light absorption of the hemoglobin absorption band at 410 μ . The usual time of exposure for Hauff Ultra Rapid plates was 20–40 seconds, and the plates were ordinarily developed three minutes in Ilford metol developer or two minutes in Eclipse metol-hydroquinone developer.

Three different buffers were used: Walpole's acetic acid-sodium acetate for solutions more acid than a *P_H* of 5.5, Sørensen's primary-secondary phosphate mixtures for the range *P_H* 5.8–7.7, and Ringer's secondary sodium phosphate-sodium hydroxide mixtures for solutions more alkaline than *P_H* 7.7.

Table I is typical of the results obtained for the sedimentation velocity from centrifuging. It refers to a solution of carbon monoxide-hemoglobin at a *P_H* of 7.56 in primary-secondary phosphate buffer 0.0191 *M* with respect to phosphate. Fig. 8 gives a reproduction of the photographic record of the centrifuging, showing the conditions of the solution 0.5 hr., 1 hr., etc., up to 3 hrs. after the start of the run. Immediately above the sedimentation record is the potassium chromate standard for adjusting the light intensity to the same value throughout. The top row is the scale of concentrations.

From the variation of concentration with distance from the center of rotation after 1, 1.5, 2, 2.5 and 3 hours the diffusion constant was cal-

¹³ Heidelberger, *J. Biol. Chem.*, 53, 32 (1922).

Av. 5.46×10^{-13}

culated, giving a mean value of $0.0736 \text{ cm.}^2/\text{day}$ at 30° . Using equation (1), the above data then give a mean molecular weight of 66,800.

8/8 7/8 6/8 5/8 4/8 3/8 2/8 1/8 0/8

Concentration scale.

Fig. 8.

Fig. 9 gives the variation of concentration with distance after 0.5, 1.0, 1.5, 2.0, 2.5 and 3.0 hours of centrifuging of the same hemoglobin solution. These curves have been corrected by means of formula (3) for the gradual decrease in concentration of the solution with time due to the sector-shaped cell and the increase in acceleration with distance from the center of rotation. The dotted curves for 2 and 3 hours represent the theoretical diffusion curves of a substance of only one molecular species if subjected to the same experimental conditions. The agreement is evidently extremely

good, and since the small deviations at the ends of the curves cancel one another in the curves for 2 and 3 hours they are probably purely accidental.

Table II gives the results obtained over the P_H range 5.4 to 10.2. In many cases the values of the diffusion constant and sedimentation velocity were determined for each experiment from two plates taken with different times of exposure. The acetate buffer used for the P_H 5.4 was 0.091 M with respect to acetate. The double phosphate buffer for the two experiments at P_H 6.0 and for the two at P_H 7.56 was 0.0191 M , but for P_H

Fig. 9.

6.5 it was 0.06 M with respect to phosphate. The secondary sodium phosphate-sodium hydroxide buffer for the two experiments at P_H 9.05 was 0.0191 M , but for P_H 10.2 it was 0.091 M with respect to phosphate. The length of the column of solution was 11–12 mm. for all runs except No. 54 and D, for which it was 13.7 and 15.5 mm., respectively. Experiment D refers to a dialyzed solution, salt-free.

It will be seen from the table that carbon monoxide-hemoglobin exists as molecules of weight 68,000 over the whole range of P_H 6.0 to 9.05, but that below P_H 6.0 and above P_H 9.05 some change has occurred, as indicated by the low sedimentation velocity and high relative diffusion

TABLE II

INFLUENCE OF P_H ON THE DIFFUSION CONSTANT, SEDIMENTATION VELOCITY AND MOLECULAR WEIGHT OF CARBON MONOXIDE-HEMOGLOBIN

constant. The diffusion constant for P_H 10.2 has a fairly low absolute value on account of the hydration of the molecule which will be mentioned below. This change may be only apparent and in reality be caused by a small Donnan effect still unrepressed, or it may be due to a splitting up of the molecules. Sufficient data have not been accumulated as yet to decide between these possibilities because qualitatively these two phenomena act similarly on the diffusion constant and the sedimentation velocity of an ionized particle.

Experiments 61 and 68 very clearly show a hydration effect. For both runs a low sedimentation velocity and an equally low diffusion constant were obtained, giving an average of 0.91 of the normal values $D = 0.071$ cm.²/day and $s = 5.46 \times 10^{-13}$ cm./sec. Table III shows in more detail the effect of hydration on the centrifuging.

TABLE III

EXPERIMENT 61. CARBON MONOXIDE-HEMOGLOBIN AT P_H 9.05

Concentration, 0.99 g. per 100 cc.; secondary phosphate-sodium hydroxide buffer, 0.0191 M phosphate; $V = 0.759$ at 30° ; $\rho = 1.0007$; $T = 303.1^\circ$; length of column = 1.17 cm.; exposure time, 20 sec.; 3 min. development in half-strength Eclipse metol-hydroquinone developer.

					.0649	Av.	4.98×10^{-13}

The diffusion constant and the specific sedimentation velocity should be reduced in exactly the same ratio if hydration is present. This can easily be shown from the following considerations.

If we assume the water molecules attached to the hemoglobin to have their normal density, the centrifugal force on the hydrated particle will remain unchanged but the opposing viscous force will be increased. Calling the radius of the hemoglobin molecule r and that of the hydrated molecule R_1 , then

$$\frac{4}{3} \pi r^3 (\rho_{\text{Hb}} - \rho_d) \omega^2 x = 6\pi\eta R_1 \frac{dx}{dt}$$

where $(\rho_{\text{Hb}} - \rho_d)$ is the difference in density of the hemoglobin molecule from that of the dispersion medium. Rearranging

$$\frac{2}{9} \frac{(\rho_{\text{Hb}} - \rho_d)}{\eta} \cdot \frac{r^3}{R_1} = \frac{1}{\omega^2 x} \cdot \frac{dx}{dt} = S_{\text{obs.}}$$

$$S_{\text{obs.}} = \frac{r}{R_1} \cdot s$$

where $S_{\text{obs.}}$ and s are, respectively, the observed and the normal specific sedimentation velocities.

Likewise $D_{\text{obs.}} = (RT/6\pi\eta R_1) = (r/R_1) \cdot D$, where $D_{\text{obs.}}$ and D are the observed and the normal diffusion constants, respectively. Thus, both s and D should be reduced by the same ratio, (r/R_1) , if hydration has taken place; (r/R_1) was found to be 0.91 at a P_{H} of 9.05.

Now the number of water molecules held by a hemoglobin molecule can be calculated. Taking the density of a normal hemoglobin molecule as 1.33, the volume of a particle of molecular weight 66,800 is 82.9×10^{-21} cc. The volume of the hydrated particle is then 110.0×10^{-21} cc. and the volume of the water attached is 27.1×10^{-21} cc. The molecular volume of water at 30° is about 18.1 cc.; therefore the *free* volume of one molecule is 2.99×10^{-23} cc. The number of water molecules held by a hemoglobin molecule is then $27.1 \times 10^{-21} \div 2.99 \times 10^{-23} = 907$.

It is interesting to compare this value with the minimum number required to form a monomolecular layer on the hemoglobin molecule. The total surface of the Hb molecule considered as a sphere is 91.95×10^{-14} sq. cm. The cross section of a water molecule taken as a cube is 9.64×10^{-16} sq. cm. Therefore the minimum number that can be packed on the surface of a hemoglobin molecule is 954.

If the water molecules are considered as spheres the effective surface to be covered is that of a sphere of radius equal to the sum of the radii of the Hb and of the water molecules and is 105.7×10^{-14} . Assuming "cubical" packing the minimum possible number of water molecules is 713, but with hexagonal packing the number becomes 823. Hexagonal packing is the most probable mode of packing and since 823 is the *minimum* number possible, it is permissible to conclude that at a P_{H} of 9.05 there is a monomolecular layer of water surrounding the Hb molecules. A similar effect

of lesser magnitude was observed at a P_H of 7.73, using a low concentration of the secondary phosphate-sodium hydroxide buffer. But both solutions were poorly buffered, because the addition of the 1% protein changed the original P_H of the buffer by more than one P_H unit; therefore, since at P_H 7.56 a solution well buffered with primary-secondary buffer showed no hydration, this hydration effect is perhaps repressed if the solution is properly buffered. When more data have been collected this point can be decided.

The condition of the hemoglobin at the extremes of P_H and a fuller discussion of the phenomena occurring will be taken up in a later paper.

The rather high expenses connected with the construction of this centrifuge have been defrayed by grants from the foundation "Therese och Johan Anderssons Minne" and from the Nobel Fund for Chemistry.

Summary

1. An oil turbine type of ultracentrifuge has been described capable of running at a speed of 42,000 r.p.m. and yielding a centrifugal force 104,000 times that of gravity.

2. Determinations of the influence of P_H on the diffusion constant, molecular weight and specific sedimentation velocity of carbon monoxide-hemoglobin are reported over a P_H range 5.4–10.2. The diffusion constant and the specific sedimentation velocity are normal, respectively, 0.071 cm.²/day and 5.46×10^{-13} cm./sec. at 30° over the range of P_H 6.0–7.56, and the molecular weight is normal, 68,000, at least from a P_H of 6.0 to 9.05.

3. At a P_H of 9.05, in the neighborhood of a maximum in the partial specific volume curve, the Hb molecule appears to hold a monomolecular layer of water at its surface.

VARIOUS ω -CYCLOHEXYLALKYL ALKYL ACETIC ACIDS AND THEIR ACTION TOWARD *B. LEPRAE*. VIII¹

BY ROGER ADAMS, W. M. STANLEY, S. G. FORD AND W. R. PETERSON²

RECEIVED AUGUST 29, 1927

PUBLISHED NOVEMBER 5, 1927

In an earlier paper the ω -cyclohexyl derivatives of various normal aliphatic acids containing from one to thirteen carbon atoms in the side chain were described and their bactericidal character toward *B. Leprae*

¹ For previous articles in this field see (a) Shriner and Adams, *THIS JOURNAL*, **47**, 2727 (1925); (b) Noller with Adams, *ibid.*, **48**, 1074 (1926); (c) **48**, 1080 (1926); (d) Hiers with Adams, *ibid.*, **48**, 1089 (1926); (e) Van Dyke and Adams, *ibid.*, **48**, 2393 (1926); (f) Sacks with Adams, *ibid.*, **48**, 2395 (1926); (g) Hiers with Adams, *ibid.*, **48**, 2385 (1926).

² This communication is an abstract of the theses submitted by W. M. Stanley, S. G. Ford and W. R. Peterson in partial fulfilment of the requirements for the degree *maîtrise* at the University of Illinois.

and other acid-fast was bacteria tested. The acid with the three-carbon side chain showed a very slight action, but with increase in the length of the side chain the bactericidal character increased until a maximum was reached in the molecule with a nine-carbon side chain (I)

This investigation had as its object the synthesis of acids isomeric with those previously studied, containing the cyclohexane ring with side chains of varying length but with the carboxyl in positions other than at the end of the chain. From bactericidal tests it could then be determined whether the position of the carboxyl group at the end of the chain as in the natural acids is important, or whether the chief function of the carboxyl may possibly be the solubilizing of the molecule. Moreover, the new acids, if bactericidal, would lead to further conclusions in regard to the significance of molecular weight either of the whole molecule or of the side chain.

In this communication three series of acids have been described: β -cyclohexylethyl alkyl (II), γ -cyclohexylpropyl alkyl (III), δ -cyclohexylbutyl (IV) alkyl acetic acids, and the alkyl group has been varied in series (II) from ethyl to *n*-octyl, in series (III) from ethyl to *n*-heptyl and in series (IV) from ethyl to *n*-hexyl. Three isomers of each acid containing in the side chain from eight to twelve carbon atoms and holding the carboxyl group on the third, fourth and fifth carbon atoms from the ring, were thus made available in addition to a number of acids of lower molecular weight.

These acids were tested against the same strain of *B. Leprae* as that used in the earlier work (Table I). In series (II) the compounds with the R group as ethyl or propyl showed only a slight action, but with the *n*-butyl group they killed in a dilution of 1:40,000. The action rapidly increased with the size of the molecule until the *n*-heptyl and *n*-octyl showed a bactericidal action in dilutions of 1:220,000 and 1:320,000, respectively, far greater than the sodium salts of chaulmoogric or hydnocarpic acids or of the mixed acids from the saponified natural oils now used in the treatment of leprosy or of the ω -cyclohexyl aliphatic acids with the carboxyl at the end of the chain. The same results were obtained in series (III) and series (IV), the bactericidal action increasing very rapidly with the size of the molecule and the compounds isomeric with those in series (II) giving approximately the same bactericidal effect in the same dilutions. It is obvious that the position of the carboxyl group is probably of secondary importance. The value of this fact cannot be underestimated, because all of the most effective acids described in this paper are easily prepared as compared with the effective ones in which the carboxyl group is at the

end of the side chain. Moreover, investigation of the effect of other groups in the molecule such as various types of rings, amino groups, halogens, double bonds, etc., is rendered much easier in acids of this type.

^a Not tested in dilutions under 190,000.

A maximum bactericidal effect is not reached until a certain sized side chain is present, for example, one containing ten, eleven or twelve carbon atoms. It is probable, therefore, that in acids of this type molecular weight plays an important role, perhaps by producing the proper physical properties in the compounds tested. It still remains to determine whether the side chain must be straight or whether it may be forked.

The allyl derivatives in each series of acids studied appeared to have essentially the same effect as the propyl derivatives. Subcultures were made with many of the acids. Results showed that in all instances they were bactericidal and not merely inhibitive.

The three series of acids were prepared in one of two ways. The β -cyclohexylethyl bromide, γ -cyclohexylpropyl bromide and the δ -cyclohexylbutyl bromide were condensed with the sodium derivatives of diethyl alkyl malonates to give the corresponding diethyl- β -cyclohexylethyl, γ -cyclohexylpropyl or δ -cyclohexylbutyl alkyl malonates. The di-substituted malonic esters were saponified with alcoholic potassium hydroxide

and the dibasic acids decomposed in the usual way to give the monobasic acids. The second procedure merely consisted in introducing into the malonic ester the ω -cyclohexylalkyl group first and the alkyl group second. Apparently there is very little choice in the procedures.

Isomeric acids with the carboxyl on the first and second carbon atoms from the cyclohexane ring will soon be completed.

The bacteriological work was carried out by Gerald H. Coleman and W. M. Stanley.

Experimental

β -Cyclohexylethyl Bromide, γ -Cyclohexylpropyl Bromide and δ -Cyclohexylbutyl Bromide.—These alkyl halides were prepared according to the method described by Hiers with Adams.¹⁸

Alkyl Halides.—The alkyl halides were prepared from the corresponding alcohols. Of these alcohols, the *n*-amyl alcohol was produced from *n*-butyl magnesium bromide and formaldehyde,³ *n*-heptyl alcohol⁴ by the reduction of heptylic aldehyde with iron and acetic acid, *n*-octyl alcohol by the action of formaldehyde upon heptyl magnesium bromide,³ and *n*-nonyl alcohol⁴ either by the reduction of nonylic aldehyde with iron and acetic acid or by the condensation of *n*-heptyl magnesium bromide with ethylene oxide.¹⁸

Diethyl- ω -Cyclohexylalkyl Alkyl Malonates.—These were prepared by the condensation of ω -cyclohexylalkyl bromides with the sodium derivatives of diethyl alkyl malonates, using the usual procedure. The yields were quite satisfactory though they could be improved somewhat by distilling off the alcohol (in an oil-bath at 110–130°) from the sodium diethyl alkyl malonate before adding the ω -cyclohexylalkyl bromides and refluxing the mixture for several hours.

ω -Cyclohexylalkyl Alkyl Malonic Acids.—These acids were prepared by adding the diethyl- ω -cyclohexylalkyl alkyl malonates to an excess of hot, saturated alcoholic potassium hydroxide solution. The mixture was heated for an hour on a water-bath under reflux and then evaporated to dryness, taking particular care that all of the alcohol was removed. The solid potassium salt was dissolved in a little water and the dibasic acid precipitated with hydrochloric acid and extracted with ether. The malonic acids were purified by crystallization from benzene or acetone. If the former was used the product frequently contained benzene of crystallization. Where the dibasic acids were not

Summary

1. Three series of acids of the general formulas $C_6H_{11}(CH_2)_2CH(CO_2H)R$, $C_6H_{11}(CH_2)_3CH(CO_2H)R$ and $C_6H_{11}(CH_2)_4CH(CO_2H)R$ were prepared in which the R group was varied so that isomeric acids containing eight to twelve carbons, inclusive, in the side chain were produced. Some acids of lower molecular weight were also synthesized.

2. With increase in molecular weight the bactericidal effect toward acid-fast bacteria increased markedly until the higher molecular weight

compounds in the form of their sodium salts were much more effective than the sodium salts of pure chaulmoogric or hydnocarpic acids or the sodium salts of any of the mixed acids from natural oils containing chaulmoogric or hydnocarpic acids.

CERTAIN Δ^2 -CYCLOPENTENYL ALKYL ACETIC ACIDS AND THEIR ACTION TOWARD *B. LEPRAE*. IX¹

BY JAMES A. ARVIN² WITH ROGER ADAMS

RECEIVED AUGUST 29, 1927

PUBLISHED NOVEMBER 5, 1927

The effect of the size of the side chain on the bactericidal character of various acids containing the cyclohexyl group was shown in a research described in the preceding paper.¹ The number of carbon atoms present apparently played such an important role in these compounds that it seemed probable that it would play just as important a one certainly in other series of acids, and probably in other classes of compounds now being studied in this same field.

Perkins³ prepared Δ^2 -cyclopentenyl alkyl acetic acids in which the alkyl group was ethyl, *n*-propyl, *n*-butyl and allyl, and reported that some of these acids showed sufficient bactericidal action toward *B. Leprae* to warrant clinical testing. Judging from the results on cyclic acids in this Laboratory, by far the most effective compounds in this series should be those in which the alkyl group is octyl, or nonyl, or of even higher molecular weight. Since these substances have not previously been made, a series of Δ^2 -cyclopentenyl alkyl acetic acids has been produced and tested in which the alkyl group varies from *n*-amyl to *n*-nonyl (I).

CH CH

CH—CH(CO₂H)R

I₃

I

The results were exactly those predicted. The bactericidal action increased very rapidly from *n*-amyl to the *n*-nonyl, the *n*-hexyl killing in dilutions of 1:10,000, but the higher molecular weight compounds in very much greater dilutions, 1:150,000 in the *n*-nonyl (Table I).

The compounds were prepared by condensing the sodium derivative of diethyl- Δ^2 -cyclopentenyl malonate with various alkyl halides, preferably in the absence of the alcohol, so that a higher temperature might be reached

and a better yield of product formed. The di-substituted malonic esters were then saponified with alcoholic potash in the usual way and the dibasic acids converted to the monobasic acids merely by heating above the melting point.

The bacteriological work was carried out by Gerald H. Coleman and W. M. Stanley.

Experimental

Diethyl- Δ^2 -cyclopentenyl Malonate.—The procedure for obtaining this ester was a slight modification of that used by Noller and Adams.⁴ Instead of an excess of dry hydrogen chloride, the gas was passed into the redistilled cyclopentadiene until 1 molecular equivalent had been absorbed. The reaction mixture was allowed to stand for two hours at -5° to -10° , and then without distillation was added to 1.25 molecular equivalents of sodium malonic ester in absolute alcohol. The conditions of condensation were described in a previous paper.⁴ The ester was isolated in the usual way. The yield of the product boiling at $113-118^\circ$ under 5 mm. was 80–85% of the theoretical.

Diethyl- Δ^2 -cyclopentenyl Alkyl Malonate.—After preparing the sodium derivative of diethyl- Δ -cyclopentenyl malonate in the usual way from 5.8 g. of sodium, 175 cc. of absolute alcohol and 56.5 g. of diethyl- Δ^2 -cyclopentenyl malonate, 135 cc. of alcohol was distilled off from the mixture. The alkyl bromide (0.3 mole) was then added and refluxing was continued for forty-eight hours. The rest of the alcohol was then distilled and water added to dissolve the sodium bromide. The products were then isolated in the usual way. The yields of the di-substituted esters from *n*-amyl to *n*-nonyl inclusive were, respectively, 37, 39, 35, 34 and 42% of the calculated amount. There was always recovered from 45–50% of pure diethyl- Δ^2 -cyclopentenyl malonate unchanged.

Δ^2 -Cyclopentenyl Alkyl Acetic Acids.—A solution of 17 g. of potassium hydroxide in 75 cc. of alcohol was refluxed on a steam-bath with 0.1 mole of pure diethyl- Δ^2 -cyclopentenyl alkyl malonate for twenty-four hours. The reaction mixture was then

⁴ Noller with Adams, THIS JOURNAL, 48, 1080 (1926).

diluted with 60 cc. of water and distilled until the temperature of the mixture reached about 98°. The residue was refluxed for two hours. It was then cooled to 10° and acidified with concd. hydrochloric acid, using Congo Red paper as an indicator. The malonic acid was separated and the aqueous liquors were extracted with ether. The separated malonic acid was also dissolved in the ether, the ether solutions mixed and dried with calcium chloride and then the ether evaporated. The residue was heated in a round-bottomed flask with an air-cooled reflux condenser for two hours at 160–165°. The residue was distilled under diminished pressure and the yields of the five monobasic acids from *n*-amyl to *n*-nonyl were, respectively, 70, 51, 55, 61 and 72% of the calculated amount.

Summary

1. Δ²-Cyclopentenyl alkyl acetic acids where the alkyl varies from *n*-amyl to *n*-nonyl have been prepared.
2. The bactericidal action toward *B. Leprae* has been shown to increase rapidly with increase in molecular weight of the alkyl group.

STUDIES IN URETHANS. IV. ACYL DI-URETHANS AND THEIR REACTIONS WITH AMMONIA AND AMINES¹

BY S. BASTERFIELD, ESLI L. WOODS AND MYRON S. WHELEN

RECEIVED SEPTEMBER 13, 1927

PUBLISHED NOVEMBER 5, 1927

In a study of guanidine derivatives, Nencki² observed that dicarbethoxyguanidine was decomposed by alcoholic ammonia at 100° into monocarbethoxyguanidine and urethan. Malonyldi-urethan was found by Conrad and Schulze³ to be decomposed by the same reagent into malonamide, ammonium barbiturate and urethan. In neither of these reactions was a urethan grouping converted into a urea as might have been expected. The products obtained by Conrad and Schulze show that from some molecules of diurethan both urethan groups were removed, while from others only one was removed, and the carbethoxymalonamide so formed then condensed to barbituric acid.

The action of ammonia and amines on carbonyldi-urethan has been

¹ A preliminary version of this paper was received July 19, 1926.

² Nencki, *Ber.*, 7, 1588 (1874).

³ Conrad and Schulze, *Ber.*, 42, 729 (1909).

studied by Dains and his associates.⁴ They report that with aqueous ammonia both amide formation and loss of carbethoxy groups by hydrolysis take place, the main products being carbethoxy-biuret and allophanic ester. Some cyanuric acid and traces of biuret were also found, but apparently no urethan. With aqueous ethylamine, allophanic ester was obtained in 80% yield, and the reaction is interpreted as hydrolysis of a carbethoxy group. With aniline at temperatures from 110 to 170°, a great variety of compounds was obtained, indicating several possible modes of fission of the di-urethan molecule, as well as secondary reactions.

In the present study, oxalyl-, malonyl- and phthalyl-di-urethans have been found to have a strong tendency to lose urethan groups under the action of ammonia and amines, both in aqueous and non-aqueous media, and we regard the reaction as a general one of ammonolysis. Some experiments with carbonyldi-urethan and solutions of ammonia and ethylamine both in water and alcohol also indicate that the interpretation of Dains and his collaborators regarding the loss of carbethoxy groups by hydrolysis is not adequate. Doubtless there is some hydrolysis with aqueous reagents, but the presence of urethan and ethylurethan among the products of decomposition can only be explained by ammonolysis.

It is of interest to consider whether a urethan group is removed as a unit, fission taking place at *a* in the formula below, or whether a carbethoxy group is removed and converted into urethan by splitting of the molecule at *b*.

Reactions with ammonia cannot settle this point, since the results may be interpreted either way. Reactions with substituted ammonias, however, show that the first alternative represents the predominant mode of decomposition for oxalyl-, malonyl- and phthalyl-di-urethans. For example, with aqueous ethylamine at room temperature, both oxalyl- and malonyldi-urethans gave the di-ethylamides in large yield and urethan. If the carbethoxy groups had been removed by ammonolysis then the products should have been the unsubstituted amides and ethylurethan.

With aniline at the boiling point there was fairly complete decomposition into the anilides and urethan, the latter being converted by excess of aniline into diphenylurea. At lower temperatures intermediate products of the types

I

II

⁴ Dains, Greider and Kidwell, *THIS JOURNAL*, 41, 1004 (1919).

were obtained in varying quantities, depending on the time of heating and the concentrations of initial components of the reaction. These intermediate products yielded the anilides readily on further heating with aniline and their presence may be regarded as indicative of the course of the reactions.

Further evidence of the removal of urethan groups by ammonolysis was found in an experiment with malonyldibenzyl-di-urethan. This compound was decomposed by alcoholic ammonia at room temperature into malonamide and benzylurethan and by alcoholic ethylamine into diethylmalonamide and benzylurethan.

In none of these experiments with di-urethans was there found evidence of the formation of di-ureas.

The decomposition of carbonyl-di-urethan offers interesting points of contrast with the decomposition of the other di-urethans. Since with ethylamine this compound yields allophanic ester and ethylurethan, among other products, there must be a removal of carbethoxy groups by ammonolysis. The great variety of products obtained by Dains and his collaborators from the reactions of aniline with the di-urethan also indicates a more complex type of decomposition than is found with the di-urethans studied in this Laboratory.

In considering a possible explanation of these facts there are two points to be noted. In the first place, the non-formation of di-ureas and the ready formation of the amides of oxalic, malonic and phthalic acids are significant. With carbonyl-di-urethan and aniline, Dains and his co-workers⁴ observed the formation of carbonyldiphenyl-di-urea, but this is the only instance of di-urea formation. In the second place, the formation of the amides by the removal of urethan groups rather than of carbethoxy groups is especially interesting.

In carbonyl-di-urethan there is present only one kind of acyl radical, that of carbonic acid, while in the other three di-urethans are present, the radicals of much stronger acids in addition to that of carbonic acid. We know nothing of the free energies of formation of either the di-urethans or their products of decomposition but it seems evident that the presence of the radicals of the stronger acids has a very definite influence on the type of decomposition. There seems to be little chance of formation of carbamides except as secondary products when the radicals of stronger acids are present in competition. It may be well to note here that Dains and his collaborators found that methylenedi-urethan and similar compounds were not decomposed by amines even when heated.

Whether the influence of the acid radicals parallels the strength of the corresponding acids cannot be stated as yet. Rough observations on the rates of decomposition of the three di-urethans show that for a given base at a given temperature phthalyl-di-urethan is decomposed most rapidly, oxalyl-di-urethan next, and malonyl-di-urethan least rapidly.

The ionization constants for the four acids involved in the di-urethans considered here are as follows.

TABLE I
IONIZATION CONSTANTS*

	K (first hydrogen)	K (second hydrogen)
Carbonic acid	3.0×10^{-7}	3.0×10^{-11}
Oxalic acid	3.8×10^{-2}	4.9×10^{-3}
Malonic acid	1.6×10^{-3}	2.1×10^{-8}
Phthalic acid	1.2×10^{-3}	3.1×10^{-8}

* Landolt-Börnstein Tabellen.

Experimental Part

Oxalyldi-urethan, $(\text{CONHCOOC}_2\text{H}_5)_2$, was prepared by Hantzsch⁶ from oxalic ester and urethan in the presence of sodium ethoxide. It was obtained by Bornwater⁶ in small quantity in cold ether from oxalyl chloride and urethan. In boiling benzene, Bornwater found that carbonyldi-urethan was formed. In the present study the di-urethan was obtained in quantitative yield by mixing oxalyl chloride and urethan in the required proportions without a solvent. The mixture liquefied and hydrogen chloride was rapidly evolved. In the course of a few minutes the liquid became viscous and finally solidified. The solid crystallized from 95% alcohol in pearly plates; m. p. 172° .

Malonyldi-urethan, $\text{CH}_3(\text{CO.NHCOOC}_2\text{H}_5)_2$.—This was prepared by Conrad and Schulze⁷ by heating malonic acid and urethan in acetic anhydride. It was obtained by Backes, West and Whiteley⁷ by warming together malonic acid, urethan and phosphoryl chloride at 80° ; yield, 71%. In the present study it was readily obtained in 85% yield by refluxing malonyl chloride and urethan in required proportions in benzene until hydrogen chloride was no longer evolved; white, sandy crystals from alcohol; m. p. 124° .

Phthalyl-di-urethan, $\text{C}_6\text{H}_4(\text{CONHCOOC}_2\text{H}_5)_2$.—Phthalyl chloride and urethan in required proportions were heated together at 130° until evolution of hydrogen chloride had ceased. The mixture solidified on cooling and the solid was recrystallized from alcohol; yield, 60%; fine, crystalline powder of slight aromatic odor. The substance softens at 80° and gradually decomposes as the temperature is raised.

Refluxing the acid chloride and urethan in boiling benzene for many hours gave poor results.

Anal. Calcd. for $\text{C}_{14}\text{H}_{18}\text{N}_2\text{O}_6$: N, 9.09. Found: 9.28, 9.36.

Oxalyldi-urethan

1. ACTION OF AMMONIA.—Oxalyldi-urethan was treated with cold, concentrated, aqueous ammonia. An insoluble, white powder was rapidly formed which was identified as oxamide. The filtrate on evaporation yielded urethan and a little urea.

When dry ammonia gas was passed over the di-urethan heated to 90 – 100° in a water-jacketed tube, a sublimate of urethan was formed in the cooler part of the tube in the course of half an hour.

2. ACTION OF ETHYLAMINE.—The di-urethan was mixed with 33% aqueous ethylamine in the proportion of one to six molecular equivalents and the mixture allowed to stand in a corked flask for twenty-four hours. A precipitate of fine needles was then filtered off and the substance identified as di-ethyloxamide, m. p. 176° . The

⁶ Hantzsch, *Ber.*, 27, 1250 (1894).

⁶ Bornwater, *Rec. trav. chim.*, 31, 105 (1912).

⁷ Backes, West and Whiteley, *J. Chem. Soc.*, 119, 371 (1921).

amount was 70% of the theoretical. From the filtrate, after evaporation at 50–60°, was obtained urethan with a few drops of oil which was not identified.

3. ACTION OF ANILINE.—(a) At 190 and 150°. Mixtures of six molecular equivalents of aniline to one of di-urethan were heated for one and a half hours at the stated temperatures. The solid mass obtained after the reaction mixtures were allowed to cool was extracted with hot alcohol. The insoluble residue was oxanilide (m. p. 244–245°) in almost quantitative yield. The alcohol extract gave several crops of diphenylurea (m. p. 236°).

(b) At 100°. The solid product from a reaction at this temperature contained oxanilide in 60% yield. The alcohol extract gave a product which after many recrystallizations finally yielded a small fraction melting at 136–137°. A much larger amount of this substance was obtained by heating the reaction mixture for only half an hour. At the end of this time there was considerable unchanged di-urethan, but it was quite easy to separate the new product from it. The substance is apparently α -carbethoxy- β -phenyloxamide, $C_6H_5NHCOCONHCOOC_2H_5$. It is rapidly decomposed by aqueous ammonia at room temperature yielding phenyloxamide (m. p. 224°).

Anal. Calcd. for $C_{11}H_{13}N_3O_4$: N, 11.86. Found: 11.84, 11.86, 12.02.

There was no diphenylurea found in the reaction mixture at this temperature but monophenylurea and urethan were isolated. The last named was obtained by extracting the solid reaction product with water. The aqueous extract was evaporated and the brownish, crystalline residue recrystallized from ligroin. The purified substance melted at 48° and was identified as urethan.

Malonyldi-urethan

1. ACTION OF AMMONIA.—Malonyldi-urethan left in contact with concentrated aqueous ammonia at room temperature yielded malonamide, ammonium barbiturate and urethan. This result was similar to that of Conrad and Schulze³ who decomposed the di-urethan with hot alcoholic ammonia.

The di-urethan was not decomposed by dry ammonia at 100°, as was oxalyldi-urethan.

2. ACTION OF ETHYLAMINE.—The reaction was carried out as with oxalyldi-urethan except that the mixture was allowed to stand for one week. Evaporation of the mixture to small volume at 60° gave large, waxy crystals of di-ethylmalonamide in 92% of the theoretical yield. The substance was identified by a mixed-melting-point determination with a known sample of the amide.

3. ACTION OF ANILINE.—(a) At 190°. The reaction was carried out as with oxalyldi-urethan. The solid product was dissolved in hot alcohol. Several fractions of crystals melting at 201–202° were obtained. This material was finally separated by fractional crystallization into malonanilide, m. p. 223°, and diphenylurea, m. p. 236°. No other compound was present.

(b) At 150°. The solid product obtained after two hours' heating was extracted with hot alcohol and the mixture filtered. The filtrate contained malonanilide and diphenylurea. The relatively insoluble residue was finally dissolved in a large volume of boiling alcohol from which it separated on cooling in masses of silky needles, m. p. 234–235°. The substance was not decomposed in the cold by ammonia, but was transformed on being warmed with aniline for half an hour into malonanilide and diphenylurea. It was apparently α -phenyl- β -phenylcarbamyilmalonamide (phenylureido-malonylaniline), $C_6H_5NHCOCH_2CONHCONHC_6H_5$.

Anal. Calcd. for $C_{18}H_{15}N_3O_3$: N, 14.14. Found: 13.92, 14.09.

(c) At 120°. At this temperature a larger proportion of the above compound was obtained, with malonanilide and monophenylurea. There was no diphenylurea.

(d) At 100°. Very little change after several hours' heating. Malonyldi-urethan is evidently less sensitive to decomposition by aniline than is oxalyldi-urethan.

Phthalyl-di-urethan

1. ACTION OF AMMONIA.—The diurethan was treated with cold, concentrated, aqueous ammonia. A white, insoluble powder was rapidly precipitated. It was identified as phthalamide, $C_6H_4(CONH_2)_2$, m. p. 220°. Urethan was recovered from the filtrate. The decomposition was quantitative.

Anal. Calcd. for $C_8H_5O_2N_2$: N, 17.07. Found: 17.07.

2. ACTION OF ANILINE.—(a) At 190°. One molecular proportion of di-urethan and four of aniline were heated together for one hour. The solid mass obtained after cooling was extracted with cold alcohol. The extract yielded diphenylurea, m. p. 237°. The more insoluble residue melted at 203° and was identified as phthalanil,

Anal. Calcd. for $C_{14}H_9NO_2$: N, 6.27. Found: 6.08.

(b) At 100°. At this temperature, after the mixture had been heated for thirty minutes, phthalanil was obtained in large amounts and a small quantity of a substance consisting of fine, white needles, m. p. 225°. In order to obtain a larger quantity of this compound a mixture of di-urethan and aniline was heated for only eight minutes. As was expected a considerably greater quantity of the new substance was obtained and much less phthalanil. It was apparently α -phenyl- β -carbethoxyphthalamide, $C_6H_5-NHCOC_6H_4CONHCOOC_2H_5$.

Anal. Calcd. for $C_{16}H_{15}N_2O_4$: N, 8.98. Found: 8.83, 8.98.

The nitrogen content of diphenylphthalamide $C_6H_4(CONHC_6H_5)_2$ is 8.87%, but its melting point is 245°. To eliminate any doubt as to the identity of the new substance, diphenylphthalamide was prepared by the method of Rogow.⁸ The prepared sample melted at 245° and a mixture of it with the substance melting at 225° melted at 200°. It seems safe to conclude that the new substance is the product resulting from the removal of one urethan group by the action of aniline.

Carbonyldi-urethan

In view of the results obtained by the action of ammonia and ethylamine on oxalyldi- and malonyldi-urethans, and also because Dains and his associates make no mention of finding urethan in their study of the decomposition of carbonyldi-urethan, we made a few experiments with the latter substance to determine if urethan was a product of its decomposition by ammonia and ethylamine. (Cf. Decomposition of Dicarbethoxyguanidine.)⁹

1. ACTION OF AMMONIA.—Two and four-tenths grams of the di-urethan was mixed with concentrated aqueous ammonia and allowed to stand at room temperature for three days. One gram of allophanic ester (m. p. 192°) was separated by filtration and the filtrate evaporated on the steam-bath. From the solid residue 0.2 g. of pure urethan was isolated. The remainder was allophanic ester and urea and a small quantity of a substance which did not melt below 300°, and which was probably cyanuric acid. Traces of biuret were also found.

⁸ Rogow, *Ber.*, 30, 1442 (1897).

⁹ Basterfield and Paynter, *THIS JOURNAL*, 48, 2176 (1926).

Somewhat similar results were obtained by heating the di-urethan with alcoholic ammonia under pressure at 100°.

The quantity of urethan isolated was only 20% of the theoretical, but it probably indicates the main trend of the reaction, since urea, biuret and cyanuric acid may be formed through the medium of urethan.¹⁰

2. ACTION OF ETHYLAMINE.—The di-urethan in 33% aqueous ethylamine after standing for four hours at room temperature gave, contrary to expectations, allophanic ester in 75% yield. On longer standing the yield was diminished. In twenty-four hours only 30% of allophanic ester was obtained, and in seventy-two hours the ester had completely disappeared. The clear solution was evaporated in a vacuum, and a residue of oil and crystals was left. The oil was taken up in chloroform and, on being fractionated, yielded a portion boiling at 174–175° which was identified as ethylurethan, $C_2H_5NH-COOC_2H_5$. The crystalline material contained urea and a substance melting at 155° which was not identified.

Some experiments were made on the action of diethylamine on oxalyl- and malonyldi-urethans in alcoholic solution at 100°. After removal of the alcohol by evaporation oils were obtained which, on being fractionated, invariably gave urethan as one of the products. The other products have not yet been identified.

Summary

1. The decompositions of oxalyl-, malonyl and phthalyl-di-urethans by ammonia, ethylamine and aniline have been studied, and the strong tendency for urethan groups to be detached by ammonolysis noted.

2. A comparison with the decomposition of carbonyldi-urethan by the same reagents is made and the different results are indicated.

3. It is suggested that the mode of decomposition of acyldi-urethans is strongly influenced by the nature of the acyl radical. The tendency for urethan groups to be detached may be correlated with a tendency toward the formation of amides of the stronger acids in preference to formation of amides of carbonic acid.

SASKATOON, SASKATCHEWAN, CANADA

NEW BOOKS

General Chemistry. Theoretical and Descriptive. By THOMAS P. MCCUTCHEON, Ph.D., Professor of Inorganic Chemistry, University of Pennsylvania, and Harry Seltz, Ph.D., Assistant Professor of Physical Chemistry, Carnegie Institute of Technology. D. Van Nostrand Company, Inc., 8 Warren St., New York, 1927. x + 415 pp. 33 figs. 22.5 × 14 cm. Price \$3.50.

According to the authors the advantages of the division of general chemistry into two parts, theoretical and descriptive, are:

"Firstly, the student will have at hand a concise and orderly summary of chemical facts, emphasizing the natural groupings and relationships of the elements from the standpoint of the Periodic Law.

¹⁰ Werner, "The Chemistry of Urea," Longmans and Co., New York, 1923, Chaps. 3, 4 and 7.

"Secondly, the student will have available chapters on each of the essential topics of theoretical chemistry, each complete in itself, and free from diverting and irrelevant matter.

"Thirdly, the instructor will have a maximum opportunity to inspire and interest his students by injecting his own method and personality into the course."

A syllabus of lectures is given to suggest a way in which the theoretical and descriptive matter may be combined.

The first 162 pages include all the theoretical material generally included in a text of this kind, and the treatment is excellent. For the sake of brevity, the authors have included almost no historical matter and there are no lists of references in the text. Problems are given at the end of several of the chapters.

Descriptive chemistry, covered in part two, takes up first the more common non-metals, with chapters in order on acids, bases and salts; water, ozone and hydrogen peroxide; valence, equations, nomenclature; and preparation of metals and metallic compounds—classification of salts. The remainder of the elements are taken up in their periodic groupings with a brief discussion of family resemblances at the head of each chapter. It seems to the reviewer that the authors have here missed an opportunity to make their radical treatment really effective. Our modern ideas of atomic structure permit predictions of variations in properties of compounds of elements in the same family, as well as relations with compounds of other elements. It is suggested (p. 11) that, "Similarities in properties of certain groups of elements...are not fortuitous but are a result of a fundamental likeness in the structures of the atoms of these elements." This idea is not carried out to the extent of its possibilities in the discussion of the elements in their periodic groups. Without some such classification, a listing of the properties of elements and compounds seems to the student a hopeless collection of unrelated facts.

The discussions of industrial processes are excellent examples of concise treatment. More figures and illustrations would have added to the appearance of the book.

A. J. SCARLETT, JR.

Quantitative Analysis. By EDWARD G. MAHIN, Ph.D., Professor of Analytical Chemistry in Purdue University. International Chemical Series, H. P. Talbot, Ph.D., Sc.D., Consulting Editor. Third edition. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York; 6 and 8 Bouverie Street, F. C. 4, London; 1924. xvii + 595 pp. 120 figs. 21 × 14 cm. Price \$4.00.

It will always remain a matter of individual opinion how much should be included in a textbook of quantitative analysis. In this book the author

has devoted half the space to the usual simple gravimetric, volumetric and electrolytic determinations, after which he has described in a few chapters methods involving the use of special apparatus, such as the polariscope, calorimeter and refractometer. The rest of the book is devoted to the analysis of industrial products and raw materials, with a chapter on assaying. This part is not complete enough to take the place of more comprehensive reference books. One wonders just what determined the choice of materials so that, for example, paints and varnishes are not mentioned, although oil, fats and waxes are discussed. The reviewer feels that it is a mistake to attempt to write a book on quantitative analysis which is both a textbook and a compendium of industrial methods.

No mention is made of electrometric methods of titration, although it would seem that this subject more properly belongs here than does a chapter on the heat treatment of steel.

The physico-chemical principles involved in analytical processes are not elucidated as fully as might be desired.

Certain errors occur which may be eliminated in a future edition. A few may be mentioned. On p. 78 it is erroneously stated that if aluminum hydroxide is ignited in the presence of ammonium chloride, volatilization of aluminum chloride occurs. On p. 84, from a comparison between the perchlorate and chloroplatinate method for potassium, one would suppose that the former was less accurate and convenient, whereas such is not the case. The statement here and on p. 91 that the preparation of aqueous perchloric acid is dangerous is absurd. It is, however, quite unnecessary to prepare it because C. P. 60% acid has been on the market for years and is no more dangerous than other common acids. The use of 20% acid is a disadvantage not an advantage. On p. 91 it is stated that no definite data on the solubility of sodium perchlorate in alcohol are available. The method suggested for removing ammonium salts by evaporation with sulfuric acid is very undesirable, because it is then necessary to reconvert to chlorides with consequent loss by occlusion. The familiar method of evaporating with nitric and hydrochloric acids is much easier and more accurate. On p. 125 the e. m. f. of the Edison cell is given as 1.6 volts instead of 1.2. On p. 182 the curve for phosphoric acid indicates that this acid cannot be accurately titrated, and this statement is made on the following page, whereas it is a matter of common knowledge that such a titration is possible. In steel analysis no method for V is given, although it is included in the table of contents.

In spite of these criticisms the book contains a wealth of valuable information. It is well written and gives frequent reference to original papers. It contains many well selected problems. It can be recommended as a textbook for elementary and advanced classes.

H. H. WILLARD

Anleitung für das Praktikum in der Gewichtsanalyse. (Laboratory Manual of Gravimetric Analysis.) By DR. R. WEINLAND, o. Professor an der Universität Würzburg. Third enlarged and revised edition. Theodor Steinkopff, Dresden and Leipzig, 1925. viii + 132 pp. 3 figs. 23 × 15.5 cm. Price, unbound, M. 6.

This little book is rather unusual in that it contains nothing about the general operations of gravimetric analysis and only a few pages are devoted to a discussion of the ionization theory, the law of mass action and the method of calculating results. It consists of brief working directions for carrying out 20 simple determinations, 34 separation methods involving ores, alloys, etc., and 13 electrolytic methods. Questions are frequently introduced to call attention to important points and the reactions are well explained. There are abundant references to original papers. One noteworthy feature is the inclusion of many new methods not yet included in reference works on quantitative analysis, as well as some which have never been published elsewhere. Some excellent methods are not mentioned, for example, Starck's method for determining fluorine as PbFCl , and the phenylhydrazine method for aluminum which is widely used in this country. The pyrogallate method is given for bismuth but not for antimony.

Because of the large number of methods described, this book will be found very useful for reference, but as a laboratory text it would need to be supplemented by preliminary lectures or an elementary text.

H. H. WILLARD

Selenium. A List of References, 1817-1925. By MARION FOSTER DOTY. New York Public Library, New York City, 1927. 114 pp. 17.5 × 25.5 cm. Price \$0.65.

Although this book is only intended to contain the titles of works relating to selenium published between 1817 and 1925, and *owned* by the New York Public Library on June 1, 1926, it is apparently a complete index to selenium literature for the period mentioned.

The references in addition to being in chronological order are grouped under the following subjects:

Bibliography	Chemistry
General Works	General and Inorganic
Mineralogy and Crystallography	Organic
Physical and Chemical Constants	Analytical
Electrical and Optical Properties	Biochemistry
Cells and Their Uses	Colloidal Selenium
Other Industrial Applications	Patents

This division of material has given the list of references additional value since with the subject index, the author index and the patent index, the location of an individual article is made particularly easy.

Those who find it convenient to use the facilities of the Reference

Department of the New York Public Library will find the Library Catalog Reference Letters given with each item listed.

There is little doubt that this publication will prove to be a great help to those who are interested in selenium research.

V. W. MELOCHE

Indicators: Their Use in Quantitative Analysis and in the Colorimetric Determination of Hydrogen-Ion Concentration. By DR. I. M. KOLTHOFF, Conservator of the Pharmaceutical Laboratory of the State University, Utrecht. Translated by N. Howell Furman, Ph.D., Assistant Professor of Analytical Chemistry, Princeton University, Princeton, New Jersey. John Wiley and Sons, Inc., 440 Fourth Avenue, New York; Chapman and Hall, Limited, London; 1926. xii + 269 pp. 23 figs. 23.5 × 15 cm. Price \$3.50.

This book discusses fully the theory of neutralization, hydrolysis, buffer action, amphoteric compounds, determination of P_H , titrations and related phenomena. The mathematical treatment is ample. The use of indicators in determining the P_H of solutions and in titrations is described in detail both from a practical and theoretical standpoint; also the use of indicator papers. The theory of the color change of indicators and the effects of alcohol, neutral salts and proteins are fully discussed. There is an interesting chapter on the practical applications of indicator methods. Few errors appear. At the top of p. 142 the Sørensen buffer should be made up using 1/15 mole of Na_2HPO_4 instead of 1/10. On p. 130, line 19, "Exsiccator" should be replaced by "desiccator." The term "table salt" is used frequently instead of "sodium chloride."

This book is well written and should be available to all who have occasion to do any work in this field.

H. H. WILLARD

Abridged Scientific Publications from the Kodak Research Laboratories. Vol. X, 1926. The Eastman Kodak Company, Rochester, New York, 1926. 247 pp. Illustrated. 17 × 24 cm.

This valuable booklet contains the essential material of thirty-eight papers previously published in seventeen journals, scientific and industrial. It serves alike to propound major problems of present-day photography and to record the progress being made toward their solution. The critical discussion of reports from other laboratories contributes not a little to the picture.

While such titles as "Flocculation and Deflocculation of the Silver Halides" and "Simplified Deduction of the Doppler Effect for Elliptic Space" duly represent the theoretical aspects of the science, there is a preponderance of articles of lively interest and immediate value to practical photographers or even to unskilled amateurs. The problems of the

motion picture industry, also, receive considerable attention. Especially suggestive to moderately advanced workers are "Characteristics and Anomalies of Emulsions on Development," "Contrast of Photographic Printing Paper" and "On the Relation between Time and Intensity in Photographic Exposure, IV."

The Abridged Scientific Publications are worthy of wide distribution and careful study.

G. S. FORBES

Principles of Organic Chemistry. By DAVID E. WORRALL, Ph.D., Professor of Organic Chemistry in Tufts College. Longmans, Green and Company, 55 Fifth Avenue, New York City, 1927. xii + 312 pp. 20.5 × 14 cm. Price \$2.50.

We already have a number of excellent and highly satisfactory textbooks of organic chemistry, and they are being kept up to date. This good book is a further addition to the list.

It begins, we believe unfortunately, with a study of alcohols. On page one are given the two possible structural formulas of ethyl alcohol, followed immediately by the structures of higher alcohols. It seems to me that this is a very heavy dose for the beginner. Organic Chemistry is quite difficult for beginners during the early stages of its study and hard enough even when we begin with the simplest of hydrocarbons, methane. The statement is made that alcohols are the subject of the first chapter because "in actual (laboratory) practice one starts with an oxygen-containing compound." However, some of the best laboratory manuals begin with the preparation of methane. Theoretically and practically this leads on easily and logically to the halides and then to the alcohols; and I think we can also say that students are more familiar nowadays with "gas" than with alcohol. Neither do I like the order of the other subjects in the aliphatic series. Of the several arrangements used by writers, however, no one can be dogmatically called the best.

The statements throughout the book are very carefully made and the book is very readable.

Neue Methoden der Organisch-Chemischen Analyse. (New Methods of Organic Analysis.) By H. TER MEULEN, Professor at the Technical High School of Delft, and Dr. J. HESLINGA. Akademische Verlagsgesellschaft m. b. H., Leipzig, Germany, 1927. v + 49 pp. 22 figs. 15 × 21 cm.

This interesting booklet presents detailed directions for the quantitative estimation of carbon, hydrogen, oxygen, nitrogen, sulfur, the halogens, arsenic and mercury in organic compounds. Special attention has been given to the determination of nitrogen in coal and in coke, and to

methods for estimating the sulfur content of petroleum and petroleum products. While some modifications of the standard oxidation combustion methods are given, the novelty in most of the methods presented lies in the extensive use of catalytic hydrogenations. Approximately one-third of the pages are devoted to a direct method for the determination of oxygen, together with modifications of the procedure needed when nitrogen, sulfur, the halogens and other elements, interfering with the smooth running of the process, are present. By hydrogenation in the presence of nickel, the carbon is converted to methane, and the oxygen to water which is collected and weighed.

While, in all probability, few of these methods will supplant those now in general use, it is refreshing to find investigators attempting reasonable, if radical, advances in the field where the classic work of Liebig and Dumas was accomplished.

DECOMPOSITION OF DIACETONE ALCOHOL IN ALKALI HYDROXIDE SOLUTIONS

BY GÖSTA ÅKERLÖF

RECEIVED MAY 24, 1927

PUBLISHED DECEMBER 10, 1927

I. Introduction

Higher velocities of catalyzed reactions in solutions of electrolytes have seldom been measured on account of rapidly increasing experimental difficulties. Using titration methods in some cases it may be possible to obtain relatively accurate results for reaction velocities with a half period as low as 150 seconds. This was shown by the measurements of Harned and Seltz¹ for the conversion of acetylchloro-aminobenzene to *p*-chloro-acetanilide in solutions of hydrochloric acid. A purely physical method for velocity measurements has therefore far greater possibilities because it eliminates the taking of samples, which necessarily involves a large waste of time. In the following will be given the results of some measurements of the decomposition of diacetone alcohol in concentrated alkali hydroxide solutions. It was found possible to obtain reasonably accurate results up to reaction velocities with a half period of about 35 seconds. For still higher velocities the difference between the calculated values and those obtained with the apparatus used increased rapidly with increasing alkali hydroxide concentration. This was because the temperature changes caused by the reaction could not be counteracted rapidly enough.

With the method for measuring these higher velocities worked out in detail, it was possible to study various questions of great theoretical interest. Electromotive-force measurements of Harned² for mixtures

¹ Harned and Seltz, *THIS JOURNAL*, **44**, 1475 (1922).

² (a) Harned, *ibid.*, **48**, 326 (1926); compare further (b) Harned and Åkerlöf, *Physik. Z.*, **27**, 411 (1926).

of hydrochloric acid or the alkali hydroxides with the alkali chlorides at constant total molarity in aqueous solutions have shown that the logarithm of the activity coefficient of the acid or hydroxide varies directly as their respective concentrations. As Harned^{2b,3} has also shown that a number of the ions of these electrolytes show a distinct additive behavior, it would seem to be most probable that this relationship is also valid for the single ions of the acid or the alkali hydroxides. It was found by Åkerlöf⁴ that the decomposition velocity of diacetone alcohol in alkali hydroxide-alkali salt solutions is additive and always seemed to follow the activity of the hydroxyl ion as long as counteracting influences did not interfere. Therefore it was of considerable interest to measure the decomposition velocity in alkali hydroxide-salt solutions at constant total molarity over a wider concentration range. Just as for the electromotive-force measurements, here also a linear variation was found.

With varying constant total molarity a number of straight lines were obtained which seemed to be parallel within the experimental errors. The extension of these lines to zero salt concentration gave the logarithm for the pure hydroxide solution. Thus a method had been found of predicting experimentally with a certain degree of accuracy the decomposition velocity which would be expected for a pure hydroxide solution of a given concentration. It also was found that the thermodynamic activity of the alkali hydroxide present in the pure hydroxide solution was proportional to the reaction velocity. The values predicted from the activity function on the one hand and those from the constant molarity curves on the other agreed very well. Therefore it was possible to decide when the method used for the velocity measurements began to break down or at least when the accuracy of the results obtained might be suspected.

II. Experimental Methods

For reaction velocities up to $K = 0.1$ corresponding to a half period of three minutes, the experimental method used was in every detail the same as previously described. At higher velocities the trouble began. With increasing reaction velocities it was necessary to increase the amount of diacetone alcohol used in order to have enough left when the measurement could be started. However, at the same time it was found that the different values obtained for the velocity constant from a single run always showed a continuous decrease as the reaction proceeded toward its completion.

A detailed study of the heat of solution for the diacetone alcohol and the heat of reaction for its decomposition gave a clear conception of the difficulties encountered. When 5 cc. of diacetone alcohol at ordinary temperatures was dissolved in 100 g. of water, the temperature was found to increase 1.54 degrees. In an alkali hydroxide solution the heat of solution must be very nearly the same as in pure water and therefore in this case also an immediate increase was first observed. The temperature then began to drop, soon passed through the starting point and finally reached a value 0.19 degree lower. Table I gives a summary of some calorimetric measurements of the temperature changes using a Beckmann thermometer.

About 25 cc. of diacetone alcohol had been mixed with 520 g. of approximately 1 *N* sodium hydroxide in the silver foil solution vessel of the calorimeter. This was well heat-insulated and the temperature changes due to stirring amounted to about 0.005° in five or six minutes. Therefore only the end value has been given a slight correction. With increasing velocity the Beckmann thermometer is soon completely unable to follow the rapid temperature changes but it is possible that a method could be worked out with photographic registration of resistance changes for a thin wire or the electromotive-force changes for a set of thermocouples immersed in the solution.

With the apparatus available the following procedure was adopted for the measurement of higher reaction velocities. The reaction tube (Fig. 1) was evacuated for ten to fifteen minutes. In order to avoid temperature changes in the reaction tube at the start of the reaction due to temperature differences between the water pump belonging to the thermostat system and the water in the thermostat, this pump was started during the evacuation of the tube about five minutes before the diacetone alcohol was mixed with the solution to be used for the measurement. The running of the water pump usually caused a very slow temperature increase of 0.01 to 0.02° during the entire run of the measurement. The magnitude of the temperature change varied somewhat with the room temperature. The amount of water passed through the spiral in the reaction tube was approximately 1000 cc. a minute and the spiral had 30 complete windings on a total length of 15 inches.

The diacetone alcohol was carefully poured on top of the solution in the mixing vessel, then immediately mixed for a certain number of seconds with the alkali hydroxide solution with a very efficient high-speed stirrer. The filling of the reaction tube

Fig. 1.—Apparatus used for the determination of higher velocities for the decomposition of diacetone alcohol in alkali hydroxide solutions.

started the moment the stirrer stopped. After five seconds the tube was filled to eight or nine tenths. Then the filling was stopped in order to let some of the foam disappear. When a predetermined number of seconds had passed, the filling was completed, the stopcock to the vacuum line closed and a large drop of mercury drawn in from the supply tube at the top of the capillary. The entire length of the capillary was then kept filled with mercury (about 80 cm. pressure) for a few seconds in order to compress rapidly any tiny gas bubbles in the reaction tube. At last the mercury column was shortened to its usual length and the two stopcocks between reaction tube and mixing vessel were tightly closed. The measurement of the reaction velocity could be started a few seconds later.

After some training it was found that about five seconds were necessary for the setting of the cathetometer to any desired height with an error of less than 0.1 of one mm. The reader⁵ of the stop watch obtained an accuracy of plus or minus one-fifth of one second, but this accuracy was usually unnecessary, when other possible errors are considered. The complete mixing of the diacetone alcohol with the solution could easily be accomplished in ten seconds. For the complete filling of the reaction tube a time of not less than thirty seconds was found to be desirable.

It is easy to understand that this method of measuring high reaction velocities has its difficulties. The solutions foamed violently during the filling of the reaction tube on account of the high vapor pressure of the acetone formed. It was impossible to wait until the greater part of the foam had disappeared and, therefore, a chance had always to be taken that a rapid compression would dissolve the remaining gas bubbles within a few seconds. The spiral in the reaction tube had a relatively large surface. In one way this was a decided disadvantage because it gave such good resting places for gas bubbles. On the other hand, the surface had to be large in order to insure a sufficiently constant temperature.

^a Used as starting time for the calculation.

^b The large number of very rapid, consecutive time readings required the utmost attention. The author is highly indebted to Dr. C. C. French, who made all the time readings for more than 150 high-velocity measurements. The author wishes also in this place to express his most sincere thanks to Dr. French.

The constancy of temperature could not be directly determined but the temperature changes during the measurement itself must naturally have been very small, as only the very last part of the reaction was measured. It was, however, another possible chance that had to be taken. It might then appear that the only way to test the possible value of the method and the efficiency of the apparatus used was to see whether constant and reproducible results could be obtained. Table II gives the summary of a few measurements.

The measurements given in Table II may seem to indicate a fairly high accuracy for the results obtained. However, it was found that at velocities with half periods of less than thirty seconds the deviation between measured and calculated velocities increased rapidly, although the measurements showed a high degree of constancy and were easily reproducible. Table III gives a summary of some measurements with 3, 3.5 and 4 *N* sodium hydroxide solutions.

^a Used as starting time for the calculation.

The measurements given in Table III were obtained with a larger reaction tube having two spirals. The water velocity was very high. The infinity values always decreased slowly after they had reached their highest point. This maximum point was used as infinity value. The differences between observed and calculated values increase rapidly with increasing concentration of the alkali hydroxide. This apparently must be due to the inefficiency of the apparatus used. The temperature changes of the solution due to the reaction follow the same formula that was used for the calculation of the reaction velocity. The velocity with which the temperature of the solution in the reaction vessel comes back to the temperature of the water in the thermostat also follows this formula (Newton's cooling law). As long as the velocity for this heat exchange between

water and solution can follow the velocity for the temperature changes of the solution from the heat of reaction the observed expansion ought to give a true expression for the decomposition velocity of the diacetone alcohol. When this velocity increases beyond a certain limit, the velocity constants obtained must be too low, because the temperature decreased during the reaction.

III. Experimental Results with Aqueous Solutions of Potassium, Sodium and Lithium Hydroxide

A summary of the measurements with these solutions is given in Table IV. All concentrations are given in weight normality. For hydroxide concentrations of 0.8 and higher, the amount of diacetone alcohol used was about 5% of the total volume of the solution. The average error of the velocity constants is difficult to judge for the highest concentrations. Up to an hydroxide concentration of 1.6 *N* it may not exceed 2 or 3% unless there are unknown systematic errors. The velocity constants are given with the minute as the unit of time. In order to show how rapidly the experimental difficulties are increasing with increasing hydroxide concentration, the half period of reaction is given in seconds, *T*, for potassium hydroxide solutions.

* These values are recently redetermined.

A graphical representation of the reaction velocity as a function of the alkali hydroxide concentration is given in Fig. 2. The figure shows that in solutions up to 1 *N* the velocity is approximately proportional to the hydroxide concentration. Fig. 3 has a much greater interest. Here the ratio between velocity constant and hydroxide concentration is plotted as a function of this concentration.

This ratio shows for lithium hydroxide solutions an almost continuous

decrease, but for solutions of the other two hydroxides it passes through a minimum between 0.6 and 1 *N*, then increases, rapidly for potassium

Fig. 2—Curves for the decomposition velocity of diacetone alcohol in aqueous solutions of potassium, sodium and lithium hydroxide.

hydroxide but comparatively slowly for sodium hydroxide solutions. The comparison of the curves in Fig. 4 for the activity coefficients of the alkali

hydroxides as measured by Knobel,⁶ Harned^{7,8b} and Harned and Swindells,^{8,8b} with the curves for the ratio between decomposition velocity and hydroxide concentration shows they are very similar to each other. For the two sets of curves the minima appear at about the same place and their distribution relative to each other is in both cases approximately the same. The close relationship between activity of the alkali hydroxide present and the decomposition velocity is still more clearly shown in Table V where the ratio between the activity of the alkali hydroxide

Fig. 4.—Curves for the activity coefficients of the alkali hydroxides in pure aqueous solutions.

and the velocity constant is given. The activity coefficients of the alkali hydroxides were calculated from the following equation

$$\log \gamma_{\text{MOH}} = -\frac{0.354 \sqrt{2m}}{1 + H \sqrt{2m}} + B 2m - \log \left(1 + \frac{w \cdot 2m}{1000} \right)$$

where γ is the activity coefficient, A and B are empirical constants and w is the molecular weight of the solvent. The values of A and B are given in Table V. They were calculated by Harned and Åkerlöf.^{8b}

sodium hydroxide solutions is apparently a constant within the experimental errors. For lithium hydroxide solutions it varies slightly more and in a definite direction. However, the variations might easily be due to a combination of systematic errors in the velocity determinations and comparatively small errors of two or three millivolts in the electromotive-force measurements. Therefore it would seem to be proved with very little doubt that the decomposition velocity of diacetone alcohol in pure aqueous solutions of the alkali hydroxides is determined by the activity of the hydroxide present.

IV. Measurements at Constant Total Molarity with One Salt Present

The individual activity coefficients of the hydroxyl ion in pure alkali hydroxide solutions are unknown. It seems to be very probable that at a given concentration the activity coefficient of this ion is highest in potassium and lowest in lithium hydroxide solutions, which is the same order as for the ratio between activity of the hydroxide and the velocity constants. The activity coefficients of the cations of the alkali hydroxides change in the opposite order. Therefore it must be improbable that the activity of the hydroxyl ion is the only determining factor in the decomposition velocity of diacetone alcohol. This was also shown in the preceding paper. The compensating effect that must exist to keep the ratio between activity of the hydroxide and the decomposition velocity constant, may partly be caused by changes of the activity of the reacting substance due to the electrical field of the ions present. The presence of the hydroxyl ion is apparently necessary to get the reaction started. To account for the unknown effect it may therefore be assumed that after the start the cations participate to complete the process. In that

case their activity must enter into the velocity function. However, this assumption might bring in another difficulty. The individual activity coefficient of the hydroxyl ion decreases when an alkali halide is added. At moderate salt concentrations this decrease seems to be of the same relative magnitude as the decrease in reaction velocity, although the activity of the cation increases rapidly.

On account of this unknown effect a simple relation between the activity of the hydroxide and the velocity cannot be expected when a salt is added. Harned^{2a} and Harned and Åkerlöf^{2b} have shown that the logarithm of the activity coefficient of hydrochloric acid or the alkali hydroxides in alkali chloride solutions at constant total molarity varies linearly with their concentration. Therefore it seemed that this case would offer the best possibilities for a theoretical interpretation of velocity measurements in alkali hydroxide-alkali salt solutions. A summary of the measurements is given in Table VI.

^a Interpolated from results published in preceding paper.

A graphical representation of the values for log *K/N* given in Table VI is shown in Fig. 5 as a function of the alkali hydroxide concentration. In Fig. 6 are given the curves for the logarithm of the activity coefficients of the alkali hydroxides in solutions of the corresponding alkali chlorides at the constant total molarity of two. For the plotting of these last curves only two points could be obtained for each one of them but it has been shown by Harned and Åkerlöf that they must be straight lines.

As with the curves for the logarithm of the activity coefficients of the alkali hydroxides, those representing the velocity measurements are straight lines, but there is a great difference in the dispersion of the curves. In the former case they diverge at large angles but in the latter they seem to be very nearly parallel. This was partly to be expected. In Fig. 7 are given the electromotive-force changes for the hydroxyl ion in 0.1 *N* alkali hydroxide solutions at increasing concentrations of the corre-

sponding alkali chlorides according to the calculations of Harned.⁹ The electromotive force is proportional to the logarithm of the activity coef-

Fig. 5.—Curves for the logarithm of the ratio between decomposition velocity of diacetone alcohol and alkali hydroxide concentration in alkali hydroxide-alkali chloride solutions with the constant total molarity of 2.

ficient. Therefore the individual activity coefficients of the hydroxyl ion according to Fig. 7 must have quite different values for the three

Fig. 6.—Curves for the logarithm of the activity coefficients of the alkali hydroxides in alkali hydroxide-alkali chloride solutions with the constant total molarity of 2.

⁹ Harned, *J. Phys. Chem.*, 30, 433 (1926).

alkali hydroxides at small hydroxide and high salt concentrations. To the electromotive-force differences shown in Fig. 7 should also be added the differences in the pure 0.1 *N* hydroxide solutions since the curves are all referred to the same starting point. This would draw them still further apart. With the simple assumption that the decomposition velocity of diacetone alcohol is proportional to the activity of the catalyzing ion, the difference in distribution for the two sets of curves in Figs. 5 and 6 would be easier to understand.

Fig. 7.—Curves for the approximate electromotive-force changes of the hydroxyl ion in 0.1 *N* alkali hydroxide solutions at increasing concentrations of the corresponding alkali chlorides.

However, at present the most important result of the velocity measurements at constant total molarity is that $\log K/N$ varies linearly with the hydroxide concentration. The concentration of the cations of the electrolytes present in these solutions is constant. According to the additivity principle of MacInnes¹⁰ and Harned^{3a,b} for the activity coefficients of strong electrolytes it may then be considered as approximately valid that the activity of the cations is constant. If this approaches the true conditions, the logarithm for the individual activity coefficient of the hydroxyl ion must vary linearly with the concentration of this ion. Since it was found that in addition to the activity of the catalyzing ion there was another factor, as yet unknown, on which the decomposition velocity

¹⁰ MacInnes, *THIS JOURNAL*, **41**, 1086 (1919); **43**, 1217 (1921).

of the diacetone alcohol was dependent, the variations in this factor in solutions of strong electrolytes must follow the same general formulas previously found for the activity coefficient of an ion from electromotive force measurements.

V. Measurements at Varying Constant Total Molarity with One Salt Present

Harned and Åkerlöf have found that the curves for the logarithm of the activity coefficients of the alkali hydroxides in solutions of their corresponding chlorides at varying constant total molarity as a function of the hydroxide concentration are represented by a series of parallel,

Fig. 8.—Curves for the logarithm of the activity coefficients of potassium and sodium hydroxide in solutions of the corresponding alkali chlorides at varying constant total molarity.

straight lines. This is shown in Fig. 8 for potassium and sodium hydroxide solutions. A summary of the velocity measurements in sodium hydroxide-chloride solutions at varying constant total molarity is given in Table VII.

This table gives the values obtained for $\log K/N$ at the hydroxide concentrations 0.1, 1.0 and 2.0 *N*. A graphical representation of these measurements is shown in Fig. 9. The curves are drawn as straight lines, parallel to each other, except the line for the total molarity of one. The angle for this line with the others is, however, very slight. A comparison of these curves with those for sodium hydroxide-chloride solutions in Fig. 8 shows their relative distribution to be different, which was to be expected. The activity of the alkali hydroxide is determined by the product of the activities of cation and anion. As the function of the cation apparently

must be a little different from that of the hydroxyl ion, this must give a different distribution of the corresponding curves in the two cases.

Fig. 9.—Curves for the logarithm of the ratio between decomposition velocity of diacetone alcohol and alkali hydroxide concentration in sodium and lithium hydroxide-chloride solutions with varying constant total molarity.

In Fig. 9 all lines are extended to zero salt concentration. This gives graphically the logarithm for the reaction velocity in the pure hydroxide solutions at higher concentrations. In Table V was shown $\gamma N/K = R$, where R is a constant. It would then be interesting to compare the values for the reaction velocities in pure hydroxide solutions on one side as calculated from the given activity coefficients of the alkali hydroxides and on the other as derived from the measurements at varying constant total molarity. Table VIII gives a summary of the calculations for potassium and sodium hydroxide solutions. To illustrate in a simple way the increasing speed of the reaction with rapidly growing alkali hydroxide concentration the half periods are given in seconds (T).

TABLE VIII
DECOMPOSITION VELOCITY OF DIACETONE ALCOHOL IN SODIUM AND POTASSIUM
HYDROXIDE SOLUTIONS AT HIGH CONCENTRATIONS

6.0	1.387	2.30	-.418	2.29	7.9

^a These values derived from measurements on potassium bromide solutions.

The values obtained by the two different methods for the decomposition velocity of diacetone alcohol in a hydroxide solution of a given concentration agree very well. This seems to indicate that the measurements on which these calculations are based must be consistent and have a fairly high degree of accuracy. It does not, however, exclude the possibility of certain systematic errors due to the experimental method used. The values calculated for hydroxide solutions with a higher concentration than 4 N are entirely hypothetical. There are a number of indications that these values may be approximately valid. It cannot be decided from the results given here whether the decomposition velocity with increasing hydroxide concentration finally reaches an upper limit which it does not exceed. If this were to be the case it seems that it should have been noticed long before this limit had been reached. Rather the contrary is observed, the reaction velocity accelerating with increasing hydroxide concentration.

To determine the decomposition velocity for lithium hydroxide solutions of higher concentrations than two, measurements were carried out with lithium chloride in 0.1 *N* hydroxide solutions. The solubility of lithium hydroxide decreases very rapidly with increasing lithium chloride concentration. Therefore no other measurements were made for salt solutions with higher hydroxide concentration than those given in Table VI. A summary of measurements and calculations is given in Table IX.

TABLE IX

DECOMPOSITION VELOCITY OF DIACETONE ALCOHOL IN LITHIUM HYDROXIDE SOLUTIONS AT VERY HIGH CONCENTRATIONS

$\frac{K}{N}$	$\frac{K}{N}$	$K \times 10^4$	$\frac{K}{N}$	$K \times 10^4$	$\log K/N$	N	$\log K/N$	K

* Interpolated values for the 0.1 *N* hydroxide solutions.

The velocity constants for concentrated, pure lithium hydroxide solutions calculated from the activity coefficients measured by Harned and Swindells agree fairly well with the values in Table IX. The agreement is, however, not as good as shown for potassium and sodium hydroxide solutions.

In Fig. 5 were shown the curves for $\log K/N$ for the three alkali hydroxide-chloride solutions at the constant total molarity of two. The most striking feature of these lines is that they seem to be very nearly parallel. If, instead of the alkali chlorides, the nitrates, bromides, iodides or thiocyanates had been used, apparently the same result would have been obtained. This is evident from a comparison with the velocity measurements given in the preceding paper and shown graphically in Fig. 10. The curves for the logarithm of the ratio between decomposition velocity and hydroxide concentration are given at the constant total molarity of 2 for potassium and sodium hydroxide solutions with the salts mentioned present. The curves for solutions where the salt present has the same anion seem to be parallel within the experimental errors. This also gives the reason why the velocity curves in various salt solutions with constant hydroxide concentration never cross each other, a point formerly stressed as important. With the constant total molarity curves for all salt hydroxide solutions of the same kind still assumed as straight, parallel lines different values would have been obtained for the velocity constant in a hydroxide solution of a given concentration if these curves crossed. This must, therefore, be impossible.

The activities of the chloride, bromide and iodide ions at the same concentration are probably quite different and the same must be true for the potassium, sodium and lithium ions. Still it was found that the direction of the curves in Fig. 5 was approximately independent

Fig. 10.—Curves for the logarithm of the ratio between decomposition velocity of diacetone alcohol and alkali hydroxide concentration in alkali hydroxide-alkali salt solutions of constant total molarity with varying anion of the salt present.

of the nature of the cation and varied with the common anion of the salt present, which was shown in Fig. 10. Harned^{3a,b,2b} has given the following postulate for the activity coefficients of the ions of strong electrolytes. In solutions of strong electrolytes of the same valence type and with a common ion, at constant temperature and concentration, the activity

of this ion is a constant. In other words the logarithm of the activity coefficient of an ion is additive. At constant total molarity the concentration of the cation present is constant and thus its activity would be constant. This gives immediately the conclusion that the direction of the curves in Fig. 5 must be independent of the cation present, because when the activity of these ions is constant, then their influence on the reaction velocity may also be constant. The velocity changes would therefore be due solely to changes in the activity of the anions present. The halide ion may participate only indirectly in the reaction. The changes of the activity coefficient of the hydroxyl ion are then responsible for the variations of $\log K/N$ observed for potassium, sodium and lithium hydroxide-chloride solutions at constant total molarity.

VI. An Expression for the Reaction Velocity in Solutions with High Concentrations of the Electrolytes Present

Let us assume that we have an alkali hydroxide-alkali halide solution with only one salt present. The cation is common. At constant total molarity we have

$$\log \frac{K}{m_T - m_s} = B_s (m_T - m_s) + l \quad (1)$$

where m_T is the total concentration of the electrolytes present, m_s the salt concentration, B_s is a constant specific for the salt in the solution and l represents a function of the concentration. With decreasing salt concentration the following formulas are obtained for the pure hydroxide solution

$$\log \frac{K}{m_T} = B_s m_T + l \quad (2)$$

$$\frac{\gamma_{\text{MeOH}}(m_T) \cdot m_T}{K} = R \quad (3)$$

where R is a constant, which may be called the reduction factor between thermodynamic activity of the alkali hydroxide and reaction velocity. Substitution of l with Equations (2) and (3) gives for (1)

$$\log \frac{K}{m_T - m_s} = \log \gamma_{\text{MeOH}}(m_T) - \log R - B_s m_s \quad (4)$$

As mentioned before, $\log \gamma_{\text{MeOH}}$ may be expressed by the formula

$$\log \gamma_{\text{MeOH}} = - \frac{0.354 \sqrt{2m}}{1 + A \sqrt{2m}} + B 2m - \log (1 + 0.036 m) \quad (5)$$

where A and B are empirical constants. This gives finally

$$\log \frac{K \cdot R}{m_T - m_s} = - \frac{0.354 \sqrt{2m}}{1 + A \sqrt{2m}} + B 2m_T - \log (1 + 0.036 m_T) - \gamma m_s \quad (6)$$

It might be of some interest that Equation (6) is of the same type as the simplified form of the general equation deduced by Hückel¹¹ for the activity coefficient of a strong electrolyte. Harned and Åkerlöf have

¹¹ Hückel, *Physik. Z.*, **26**, 93 (1925).

shown that Hückel's general equation may be applied to the electromotive-force measurements for a large number of electrolytes in pure or mixed aqueous solutions. In Table X is given a comparison of observed reaction velocities and the values calculated from Equation (6). The observed values are interpolated from Table III in the preceding paper.

TABLE X

AGREEMENT BETWEEN OBSERVED REACTION VELOCITY AND THE VALUE CALCULATED FROM THE GENERAL EQUATION (6)

NaOH $A = 0.660$ $B = 0.050$		NaCl solutions $B_s = 0.117$ $(K \times 10^4)$		NaBr solutions $B_s = 0.139$ $(K \times 10^4)$		NaI solutions $B_s = 0.169$ $(K \times 10^4)$	
N	m_s	obs.	calcd.	obs.	calcd.	obs.	calcd.
0.1	0.9	152	146	146	139	134	131
.1	1.9	123	122	112	111	97	97
.1	2.9	102	106	93	92	74	75
.1	3.9	92	95	76	78	58	59
.1	4.9	84	86	63	67	46	48
.1	5.9	78	78	54	58	(39)	39

A better agreement between observed and calculated values could hardly be expected. It seems, however, as if the formula used might not be valid for solutions with small salt concentrations. It also cannot be used for hydroxide-salt solutions where the salt added increases the reaction velocity.

VII. Discussion

The measurements of relatively very high reaction velocities presented in this paper were not easy to carry out. The time required for every little detail had to be studied separately and shortened as far as possible or timed in such a way as to give the smallest possible error. The method is, therefore, not suitable for high precision measurements because it is too much hurried. It served to give fairly accurate and very important information in a so far completely unknown field. Its use might then be well justified. An attempt to work out an experimental method for measuring very high reaction velocities has been made by Hartridge and Roughton.¹² They give an excellent review of the theoretical possibilities and propose the use of rapidly flowing, continuously renewed solutions. For our purpose this would mean the use of very large quantities of highly concentrated alkali hydroxide solutions. A method using stationary solutions is, therefore, to be preferred if the desired sensitivity could be obtained.

In order to compare the results so far obtained from the study of the decomposition velocity of diacetone alcohol with results from investigations of other reactions, catalyzed by the same or other ions in solutions of strong electrolytes, we may first summarize the former.

¹² Hartridge and Roughton, *Proc. Roy. Soc. (London)*, **104A**, 376 (1923).

1. At constant alkali hydroxide and varying salt concentration all velocity curves had the same general form independent of the salt present. From the measurements at varying constant total molarity this was confirmed as a logical conclusion.

2. At constant total molarity $\log K/N$ varies linearly with the hydroxide concentration. At varying constant total molarity $\log K/N$ gives a number of parallel, straight lines.

3. The influence of the salt added is additive and thus also the slope of the constant total molarity curves is additive. With increasing activity of the salt the salt action in general increases.

4. In pure hydroxide solutions the velocity is proportional to the thermodynamic activity of the hydroxide present.

Fig. 11.—Curves for the velocity of hydrolysis of cyanamide in nitrate solutions of 0.25 *N* nitric acid.

Now we may compare these results with those for other reactions, and discuss what they have in common and where they differ. The first point seems to be valid for a large number of reactions. Harned¹³ and Åkerlöf¹⁴ have shown this for the hydrolysis of ethyl acetate, Grube and Schmid¹⁵ for the hydrolysis of cyanamide, Rivett¹⁶ for the conversion of acetylchloro-aminobenzene in acid-salt solutions. Harned¹³ found it to

¹³ Harned, *THIS JOURNAL*, **40**, 1461 (1918).

¹⁶ Rivett, *ibid.*, **82**, 201 (1913); **85**, 113 (1913).

be valid for the decomposition of hydrogen peroxide by the catalytic action of the iodine ion in salt solutions. A graphical demonstration may be obtained from Figs. 2, 3 and 4 in the preceding paper and Fig. 11 in this paper. We may, therefore, be justified in assuming this to approach the true conditions for all monomolecular reactions catalyzed by ions of strong electrolytes, as the halide acids, the alkali and alkali earth hydroxides and iodides. Exceptions to this rule are as yet unknown, but it might also be said that only a few cases have been studied.

Fig. 12.—Curves for the logarithm of the ratio between conversion velocity of acetylchloro-aminobenzene and acid concentration in hydrochloric acid-sodium chloride solutions of varying constant total molarity.

The second point is far more difficult to investigate. In the literature there are no velocity measurements to be found for solutions with constant total molarity of the electrolytes present. However, this would not be any hindrance because the curves for varying constant total molarity were parallel. Thus, to study this case, only two points were necessary for each curve, one for a salt-catalyst, the other for the pure catalyst solution of the same total concentration. Measurements over a wider concentration range with solutions of the pure catalyst have seldom been carried out. Therefore a definite relationship between the thermodynamic properties of the catalyzing electrolyte and the reaction velocity generally

cannot be proved. Nor is it possible to make an extrapolation of the reaction velocity for solutions of high concentrations. Often the probable experimental errors seem to be quite large. With a very limited concentration range it must then be rather difficult to arrive at a safe decision from some of the material available.

In the literature there is one case to be found where all the requirements necessary for a study of this point over a short concentration range are fulfilled. Harned and Seltz measured the conversion of acetylchloro-aminobenzene to *p*-chloro-acetanilide in solutions of hydrochloric acid

Fig. 13.—Curves for the logarithm of the activity coefficient of hydrochloric acid in potassium and sodium chloride solutions of varying constant total molarity.

up to a concentration of 1.0 *M*. They found a definite relation between activity of the acid and the reaction velocity

$$K = R\gamma_{\text{HCl}}^2 \cdot n_{\text{HCl}}^2 \quad (7)$$

where *R* is the reduction factor between reaction velocity and activity of the acid. The activity coefficient of hydrochloric acid may be given by an equation similar to (5).^{17,2a,b} In order to get the equation for the reaction velocity in acid-salt solutions, the measurements of Rivett for sodium chloride solutions in 0.25 *N* hydrochloric acid were interpolated. A few values of $\log K/N$ were plotted with these values for the pure

¹⁷ Scatchard, *THIS JOURNAL*, 47, 648 (1925).

acid solutions of the corresponding total concentrations. The curves obtained are given in Fig. 12. They must apparently be parallel, straight lines in analogy with the corresponding curves for the logarithm of the activity coefficient of hydrochloric acid in salt solutions at varying constant total molarity, which is shown graphically in Fig. 13 from the calculations of Harned and Åkerlöf. In regard to the calculations for the acetylchloro-aminobenzene reaction it may be noted that the concentration of the chlorine ion is constant at constant total molarity. Therefore $\log K$ is divided by the first power of the concentration of the acid, although the chlorine ion may participate in the catalysis.

In analogy with Equation (6) for the decomposition of diacetone alcohol, we, therefore, obtain the following formula for the conversion velocity in solutions with arbitrary acid-salt concentrations:

$$\log \frac{K \cdot R}{m_T - m_a} = -2 \left[\frac{0.354 \sqrt{2m_T}}{1 + A \sqrt{2m_T}} + B 2m_T + \log m_T - \log (1 + 0.036 m_T) \right] - B_s m_s \quad (8)$$

where B_s is a constant characteristic for the salt present in the solution. In Table XI is given a comparison of observed and calculated reaction velocities. The observed values are interpolated from the measurements of Rivett.

TABLE XI

AGREEMENT BETWEEN OBSERVED REACTION VELOCITIES AND THE VALUES CALCULATED FROM THE GENERAL EQUATION (8)

HCl $R = 13.8$ $A = 0.784$ $B = 0.0805$			KCl solutions $B_s = 0.181$ $K \times 10^4$		NaCl solutions $B_s = 0.162$ $K \times 10^4$		LiCl solutions $B_s = 0.107$ $K \times 10^4$	
m_T	$\gamma_{\text{HCl}}(m_T)$	m_s	obs.	calcd.	obs.	calcd.	obs.	calcd.
0.45	0.746	0.20	41.6	41.8	43.0	42.2	43.8	43.2
.65	.761	.40	58.2	57.8	60.7	59.0	63.1	62.0
.85	.786	.60	75.0	74.2	78.1	76.3	83.4	82.3
1.05	.818	.80	92.6	91.3	96.6	94.6	106	105
1.25	.855	1.00	111	110	116	114	129	130
1.45	.898	1.20	129	129	136	136	158	158
1.65	.944	1.40	148	149	157	159

The agreement between observed and calculated reaction velocity is very good. We have thus been able to show that also for the conversion of acetylchloro-aminobenzene the curves for $\log K/N$ at varying constant total molarity are represented by straight, parallel lines.

In the literature there are to be found measurements for two other reactions where this test could be applied as an indication that the reaction velocity is an activity function. These two reactions are the hydrolysis of ethyl acetate measured by Harned, Åkerlöf, Harned and Pfanstiel¹⁸ and others and the hydrolysis of cyanamide, measured by Grube and Schmid. For neither of these two reactions has been found a definite

¹⁸ Harned and Pfanstiel, *THIS JOURNAL*, **44**, 2193 (1922).

relationship between activity of the catalyst and reaction velocity. However, Harned and Pfanstiel have shown it to be very probable that the velocity of hydrolysis for ethyl acetate may be proportional to the activity

Fig. 14.—Curves for the logarithm of the ratio between velocity of hydrolysis for ethyl acetate and acid concentration in hydrochloric acid-sodium chloride solutions of varying constant total molarity.

of the hydrogen ion. The ratio between velocity and acid concentration shows a minimum at the same place as the individual activity coefficient of this ion. A graphical representation of the values for $\log K/N$ of

Fig. 15.—Curves for the logarithm of the velocity of hydrolysis for cyanide in nitric acid-lithium nitrate solutions of varying constant total molarity.

these two reactions in acid-salt solutions at varying constant total molarity is shown in Figs. 14 and 15. The data used for these figures, together with those for Fig. 12, are given in Table XII.

The curves in Fig. 14 for the hydrolysis of ethyl acetate in hydrochloric acid-sodium chloride solutions appear to be only roughly parallel, with deviations in slope of about 5%. Certain facts may seem to indicate that these deviations could be within the experimental errors. Therefore we cannot safely decide whether these curves should be regarded as parallel or not. The curves in Fig. 15 represent a wide concentration range and they seem to be parallel within the experimental errors. The velocity of hydrolysis of cyanamide must, therefore, be regarded as a function of the activity of the electrolytes present.

Among other reactions where the velocity seems to be a function of the activity of the catalyst may be mentioned the inversion of cane sugar, although the data available are insufficient for a complete test. This reaction has been the subject for a very large number of small investigations. Each time only a few measurements were carried out. The sugar concentration used was usually rather high and varied considerably from one case to another. Therefore the measurements from different investigations cannot easily be compared with each other. However, Hantzsch and Weissberger¹⁹ have shown that the ratio between inversion velocity and acid concentration is greatest for the acid with the highest activity coefficient.

¹⁹ Hantzsch and Weissberger, *Z. physik. Chem.*, **125**, 251 (1927).

For the decomposition of diacetone alcohol in alkali hydroxide-salt solutions the influence of the salt added upon the reaction velocity was found to be additive. In these solutions almost any kind of an alkali salt could be used for a study of this point. In acid solutions the number of suitable salts is quite limited. Salts of acids which must be regarded as weak electrolytes cannot be used for this purpose and the same is true for bi- and polyvalent acids. It seems as though in this case the differences between reaction velocities in alkali and alkali earth chloride and bromide solutions of their respective acids should be the simplest and easiest to measure. There are, however, no measurements to be found in the literature for a study of a possible additivity of the salt action on other reactions. It seems to be very probable that this might be the case, because the salt action is in general proportional to the activity of the salt added.

In our discussion a first attempt has been made to trace a general formula that may be used to express the velocity changes of simple reactions in catalyst-salt solutions as a function of the thermodynamic activities of the electrolytes present. It may perhaps be possible to use such an equation for a discussion of the intrinsic mechanism of these reactions. A large literature has grown up on this subject but positive, general results have seldom been attained. We were able to show that there seem to be other factors as yet unknown, but which must be known before we can arrive at a clear understanding of these processes.

VIII. Summary

In this paper are described measurements of reaction velocities with half periods down to thirty seconds. Attempts to measure still higher velocities were made and were partly successful. The values obtained were probably too low due to increasing, unpreventable, systematic errors.

With the method given, the decomposition velocity of diacetone alcohol has been measured in pure aqueous solutions of potassium, sodium and lithium hydroxide up to a concentration of 2.2 *N*. The velocity was found to be proportional to the activity of the hydroxide present.

Velocity measurements were then carried out for alkali chloride-hydroxide solutions with constant total molarity of 2. Log K/N varied linearly as a function of the hydroxide concentration, which is analogous to the behavior of the logarithm for the activity coefficient of the hydroxide.

Measurements at varying constant total molarity gave a number of parallel lines, just as the curves for the logarithm of the activity coefficient of the hydroxides in the same solution are straight, parallel lines. These lines extended to zero salt concentration gave the velocity in hydroxide solutions at high concentrations. Values obtained from the activity function agreed very well.

At all concentrations, even in very dilute solutions, it seems to be valid that the decomposition velocity of diacetone alcohol is a function of the thermodynamic activities of the electrolytes present. A short discussion of the measurements for other reactions as compared with those presented in this paper is given.

THE ACIDITY OF THE WATERS OF SOME PUGET SOUND BOGS¹

BY THOMAS G. THOMPSON, JAMES R. LORAH AND GEORGE B. RIGG

RECEIVED JUNE 11, 1927

PUBLISHED DECEMBER 10, 1927

Introduction

This investigation was undertaken in order to ascertain the degree of acidity of certain bog waters and to study the relation of such acidity to the carbon dioxide content of the water, the color of the water and the stage of plant succession. It was thought that such data would be useful for interpreting the physiology of plants characteristic of bogs and also for explaining the rather marked corrosive action of such waters upon concrete and cement products.

Experimental

The waters studied were collected from four typical Puget Sound bogs. Two of the bogs, Esperance and Sunnydale, were characterized by the presence of methane dissolved in the waters and by the occurrence of a small pond which each bog surrounded. Bogs of this type have been designated as "wet bogs." The other two bogs, Ronald and White Center, experience a very great lowering of the water table in the summer months, evolve no methane and do not surround open bodies of water. Such bogs have been termed "dry bogs." A more detailed description of these bogs, their flora and the nature of the dissolved gases has been previously published.²

Effect of Dissolved Carbon Dioxide Upon Acidity

Samples of water were collected from at least two different points in each bog and the amounts of dissolved carbon dioxide carefully determined. This was accomplished by the complete removal of the dissolved gases by boiling the samples under diminished pressure for an hour.² Analyses of the liberated gases followed. Owing to the high dilution it was assumed that all of the carbon dioxide was present in the waters as carbonic acid,

¹ Read before the Chemical Section of the Pacific Division of the American Association for the Advancement of Science, June, 1927.

and from the primary ionization constant of the acid the hydrogen-ion concentration as P_H was calculated from the following

$$\frac{(H^+) \cdot (HCO_3^-)}{(H_2CO_3)} = K = 3 \times 10^{-7}$$

$$P_H = \log 1/(H^+)$$

In Table I are given the parts per million of dissolved carbon dioxide in the different waters, the molality of such solutions and the calculated P_H . The calculations are given in the fourth column of the table and represent the maximum possible acidity due to the presence of carbonic acid.

Several investigators³ have explained the acidity of bog or moor water as due to carbonic acid. The data presented in Table I, in some cases, check remarkably with those reported by Endell and thus tend to support this view. However, some preliminary experiments, the results of which are given in Table II, show that the acidity of bog waters is also due to an acid or acids other than carbonic acid. In these experiments a sample of water was collected from Esperance Bog, one was taken from the pond in the bog and another was a sample secured a year previous from Ronald Bog, which had been allowed to stand in a tightly stoppered bottle in the laboratory during this period. The acidity, using two different indicators for each sample, was determined with a double wedge comparator. The P_H was then determined electrometrically but, by the time

³ (a) Endell, *J. prakt. Chem.*, **82**, 414-422 (1910); (b) Stremme, *Z. prakt. Geol.*, **16**, 122-128 (1908); (c) Cowles and Schwitalla, *Ecology*, **4**, 402-416 (1923).

equilibrium was reached with this method, all of the carbon dioxide had been driven from the solution by the passage of the hydrogen gas. From the data given in Table II it will be noted that in one instance the removal of carbon dioxide decreased the acidity, while in the others the acidity was slightly increased. Varying results were obtained with the different indicators and these results may be explained by differences in sensitivity, effect of the characteristic yellow color of all of the waters and possibly by a difference in the adsorption of the indicator by the colloidal material.

Fig. 1.—The relation between the acidity and the organic matter in bog waters.

A sample of water taken from a lake containing a small quantity of free carbonic acid showed a P_H of 6.3 with chlorophenol red, while the electrometric method gave a P_H of 7.95. The water of this lake had the characteristic yellow color of bog water and contained considerable quantities of colloidal matter. The carbon dioxide, in this particular case, produced the acidity and its removal caused a decrease past the neutral point. The colloidal material apparently had no effect upon the acidity. Much the same result was obtained with the water from Esperance Pond, except that the removal of the carbon dioxide did not produce an alkaline water. Comparing these data with those given for the bog waters, it is evident that the acidity of such bog waters is primarily due to an acid or acids in addition to the carbonic acid. The acid or acids are apparently stronger than the carbonic acid and the presence of the latter produces a buffering effect.

These observations are in accordance with those of Smorodinzew and

Adowa⁴ who noted a difference in the colorimetric and electrometric methods for the determination of the P_H of bog waters secured in the vicinity of Moscow. On thirty different samples their maximum plus variation was 0.71 with an average of 0.17. The maximum minus variation was 1.21 with an average of 0.46. The P_H of undiluted water from sphagnum measured electrometrically varied from 3.88 to 4.62, which is in accord with the measurements made on waters from bogs in the Puget Sound region as reported below.

To demonstrate still further that the acidity was due to acids other than carbonic acid, the experiments outlined in Table III were performed. In series No. 1 the sample of water was taken from the Sunnydale Bog, that in Series No. 2 represents the water from the pond in this bog, while those in Series 3 and 4 were taken from Esperance Bog, the sample used in Series No. 4 being secured from a hole dug very close to the pond.

All P_H determinations with the exception of some of those given in Table II were made by the ordinary method given by Clark⁵ with the use of a Leeds and Northrup potentiometer. The hydrogen electrodes were prepared from platinum foil and their accuracy was checked by buffer solutions. Because of the high resistance of some of the samples of water, the most sensitive type of wall galvanometer was utilized. Normal calomel electrodes, prepared from redistilled mercury, were employed and these were repeatedly checked against each other and also against electrodes used in other research work. The hydrogen was always passed through the water being tested and over the electrode for at least half an hour before readings were made.

TABLE II
COMPARISON OF COLORIMETRIC AND ELECTROMETRIC METHODS FOR THE DETERMINATION OF THE ACIDITY OF BOG WATERS

Source of sample	Electrometric P_H	Colorimetric P_H	Indicator
Esperance Bog	4.60	5.1	Chlorophenol red
		4.7	Bromocresol green
Ronald Bog	3.81	4.3	Bromophenol blue
		3.9	Bromocresol green
Esperance Pond	6.50	6.3	Chlorophenol red
		6.1	Bromothymol blue

Endell^{2a} in a study of the bogs of the Rhone region found that the colloidal material when separated by dialysis showed no acid reaction. If this is the case the acid substance is in true solution. Baumann and Gully,⁶ however, believe that the acid properties are due to colloidal properties, surface tension and adsorption by the cell membrane.

TABLE III

SERIES OF EXPERIMENTS WITH DIFFERENT WATERS DEVISED TO ILLUSTRATE THAT ACIDITY IS PRODUCED BY ACIDS OTHER THAN CARBONIC ACID

Series No. 1, P_H	Series No. 2, P_H	Manner of treatment of samples
4.02	5.92	Original samples of bog water.
4.03	5.88	After boiling for 5 minutes, cooling to original temperature and replacing the evaporated water with freshly boiled distilled water.
4.63	6.08	Dilution to twice the original volume with freshly boiled distilled water.
3.86	5.49	Concentration to 0.5 of original volume and cooling to original temperature.
3.56		Concentration to 0.2 of original volume and cooling to original temperature.
Series No. 3, P_H	Series No. 4, P_H	
4.30	4.92	Original samples of bog water.
4.29	4.83	After evaporating a definite volume to dryness at 90°, redissolving in freshly boiled distilled water and making up to original volume.

From the data presented in Table III the following facts are evident.

- (1) The P_H is the same after the sample has been boiled as it was before. The passage of hydrogen through the samples of the water lowered the partial pressure of the carbon dioxide to such an extent that it was completely expelled from solution and heating of the sample produced no further changes in acidity.
- (2) The acid substance is not appreciably volatile and is not affected by temperature changes.
- (3) The acid either forms a true solution in water and is very soluble or else it is a reversible colloid.
- (4) The change in acidity upon dilution and concentration is very similar to that which occurs with an acid buffered by a small amount of one of its salts.

Relation of Color to Acidity

The water of all four bogs studied, together with that of Lake Esperance, varied in color from a light yellow to a deep yellow. The intensity of the color was measured with a Lovibond tintometer, using yellow glass standards. The results are shown in Table IV. The samples were collected from two different places in four different bogs on February 27, 1926.

There appears to be rather an indefinite relation between color and acidity. The intensity of the color seems to increase with acidity. The later the stage of plant succession, the greater will be the color.

Acidity of Bog Waters

In Table V, is given the acidity of waters, collected over a period of fifteen months, from four different bogs. These samples were taken a month or so after the rainy season had started and in February, at the

^aAt the time these samples were taken the bog was flooded and much water drained from the bog into the lake and water from surrounding country drained into the bog.

height of the season. It was practically impossible to secure samples during the dry season owing to the marked lowering of the water table in

TABLE V
THE ACIDITY OF DIFFERENT BOG WATERS UNDER VARIOUS CONDITIONS

Sample no.	Date collected	Name of bog	Acidity, P_H	Description of conditions
1	11-28-24	Ronald	3.85	Minute particles of sphagnum suspended in sample. Determination run immediately after collection.
2	11-28-24	Ronald	3.85	Same as No. 1 but with all particles of sphagnum removed by filtration.
3	11-28-24	Ronald	4.11	A 2.5 liter bottle was filled with water used in No. 1. Thoroughly washed air was rapidly bubbled through the sample for forty-eight hours.
4	11-28-24	Ronald	3.83	2.5 liters of the water used in No. 1 was sealed in a bottle and kept for one year.
5	2-27-26	Ronald	3.83	Water from holes in two different portions of the bog taken at the height of the rainy season.
6	2-27-26	Ronald	3.89	
7	12-2-25	Sunnydale	4.40	35 feet from the pond in the bog.
8	2-27-26	Sunnydale	4.23	100 feet from the pond in the bog.
9	2-27-26	Sunnydale	4.04	150 feet from the pond where the conditions were much drier and the bog in a late stage of succession.
10	11-25-25	White Center	4.16	60 feet from marginal ditch.
11	12- 2-25	White Center	4.02	Center of bog.
12	2-27-26	White Center	4.09	200 feet from marginal ditch.
13	2-27-26	White Center	4.17	Center of bog.
14	11-25-26	Esperance	4.60	20 feet from the pond.
15	2-27-26	Esperance	4.93	30 feet from the pond. The entire bog was flooded.
16	10-31-25	Esperance	6.50	Water taken from pond.
17	2-27-26	Esperance	4.95	Water taken from pond. The entire bog was flooded.

the bog. The time at which the samples were collected appears to be of no consequence. The dominating factor influencing the degree of acidity is evidently the stage of succession of the bog, the acidity being directly proportional to the stage of succession.

It is a well known fact that aeration practically eliminates the toxicity of bogs to plant life. This is apparently due to two factors: (1) the removal of carbonic acid and the introduction of dissolved oxygen; (2) the partial oxidation of the organic material either chemically or by means of bacteria.

Sample 3 in Table V originally had a P_H of 3.85, but after thoroughly washed air had been passed through it continuously for forty-eight hours its acidity was decreased. The air was washed by first bubbling it through several bottles containing the bog water. This decrease in acidity indicates a partial oxidation of the acid-producing substance.

The acidities of the waters shown in Table V were all determined electrometrically and were not due to the presence of carbonic acid. In Table I is given the maximum acidity that might be expected from the presence of carbon dioxide.

The "dry" bogs, those containing no open water, have a greater acidity than the "wet" bogs. Furthermore, the acidity of the dry bogs is more constant than that of the wet bogs. The stage of succession and the drainage toward the pond, in the case of wet bogs, appear to be the dominating factors affecting the acidity.

In Table VI are given the results of the analyses of the different waters taken the same day from the four bogs. Two samples were taken at different places in each bog. In the third, fourth and fifth columns are given, as parts per million, the total solids, the ash and the organic matter. There appears to be a very definite relationship between the per cent. of organic matter and the acidity as expressed by

$$\% \text{ O. M. } \times P_H = K$$

This relationship is illustrated in Fig. 1.

TABLE VI
ANALYSES OF THE DIFFERENT BOG WATERS AND THE RELATION OF THE ORGANIC
MATTER TO P_H

Sample no.	Acidity, P_H	Total solids, p. p. m.	Ash, p. p. m.	Organic matter		$P_H \times$ per cent. O. M.
				p. p. m.	Per cent.	
5	3.83	88.6	14.6	74.0	83.52	3.20
6	3.89	89.1	13.1	76.0	85.30	3.32
8	4.23	77.2	18.8	58.4	75.65	3.20
9	4.04	82.7	15.2	67.5	81.62	3.30
12	4.09	45.2	10.4	34.8	76.99	3.15
13	4.17	83.9	21.8	62.1	74.01	3.09
15	4.93	54.7	12.9	41.8	76.41	3.77
17	4.95	75.8	26.2	49.6	65.43	3.24

Summary

1. While the acidity of bog waters of the Puget sound region may be due to carbonic acid, it is not the dominating cause of the acidity.
2. The maximum acidity that could be produced by carbonic acid is much less than that actually observed.
3. Colorimetric and electrometric methods for the measurement of acidity gave different results.
4. The acidity as measured electrometrically is not appreciably altered by evaporation of the waters and their dilution to the original volume.
5. There appears to be rather an indefinite relationship between color intensity and acidity.
6. The stage of succession of the bogs is directly proportional to the acidity.
7. "Dry" bogs show a greater acidity than "wet" bogs.
8. The per cent. of organic matter in the four bogs studied is a logarithmic function of the acidity. The amount of the organic matter present thus appears to be the controlling factor of acidity.

A MICRO METHOD FOR THE DETERMINATION OF SURFACE TENSION AND DENSITY

BY V. RICHARD DAMERELL

RECEIVED JUNE 13, 1927

PUBLISHED DECEMBER 10, 1927

Although several micro methods for the determination of surface tension¹ and density² are known, none of the apparatus employed in these is applicable to both determinations. The purpose of this article is the description of an exceedingly simple apparatus by which surface tension and density can be determined on amounts of liquid as low as one-tenth of a cubic centimeter, with a theoretical accuracy of from one part in 100 to one part in 300, depending on the liquid.

Apparatus.—A ten centimeter portion of 5 mm. soft glass tubing was heated to softness in a Bunsen burner with wing top attachment and quickly pulled to arm's length. By running a three centimeter column of water up and down the resulting capillary, an eight centimeter portion that had practically uniform bore was found, and a ten centimeter length was cut out so that the eight centimeter portion was on one end. This

end was filed flat and the other end notched, so the correct end could be used in all determinations. The radius was determined in the usual way with mercury and was found to be .01650 cm. A larger capillary was pulled, with a bore such that the small tube slipped in snugly, without sticking. This tube, used as a jacket, was made seven centimeters long and sealed at one end. A third tube, five centimeters long and sealed at one end was next made, being large enough to fit loosely over the jacket. This was the holding tube, used in the determination of density, to prevent the hands from touching the rest of the apparatus.

Determination of Surface Tension.—The jacket and holding tube were not used in the determination of surface tension. A small tube, with a capacity of about one-half of a cubic centimeter and 0.7 cm. in diameter, was used to hold the sample. This tube was put in a small thermostat and the liquid kept just at room temperature. The capillary tube (held close to the top by the fingers to prevent transfer of heat to the liquid) was lowered as nearly vertical as possible, so that the end just made contact with the liquid, in this way approaching the maximum rise from below. When the liquid had stopped rising, the capillary was pulled up, laid horizontally on a millimeter rule and measured by the eye to 0.1 mm. Now the end of the tube was dipped far into the liquid and after it had stopped rising was brought to the surface, thus approaching the maximum rise from above. To come from below again, a little of the liquid was shaken out of the tube and the first procedure repeated. Eight or ten readings were taken and the average recorded.

Determination of Density.—An assay balance weighing to 0.00001 g. was used. The weight of the capillary tube plus the jacket was first determined. Then the capillary tube was dipped in the liquid and the length of the column was determined as before, except that the capillary was held by forceps instead of the fingers. As soon as the length of the column was determined, a stop watch was started, the time of weighing being taken into account in order to correct for evaporation. The capillary was put into the jacket, great care being taken that none of the liquid ran out as it was being inserted, and the apparatus was weighed again. In all these operations the hands were kept off the apparatus, although a little practice was necessary to do this successfully. As soon as the second weighing was made, the time that the stop watch had been running was observed. The apparatus was left right on the balance, and at the end of another equal period of time a third weighing was made. The difference between the second and third weights was added to the first determined weight of the liquid, the assumption being made that the same weight of liquid would evaporate during each period of time. Since radius was known, as well as the length of the liquid column, the density was readily determined.

Experimental Results

TABLE I
SURFACE TENSION MEASUREMENTS

Subs.	Temp., °C.	Surface tension, dynes/cm.	Interpolated values of other observers for same temp.	Observer
H ₂ O	21	72.4	72.6	Accepted
C ₆ H ₆	18.5	29.5	29.2	Accepted
CCl ₄	23	25.7	25.3	Ramsay and Shields
			25.9	Jaeger
			26.4	Richards and Carver
(C ₂ H ₅) ₂ O	22	16.8	16.5	Jaeger
			16.6	Brunner
			16.8	Richards and Carver
C ₆ H ₅ CH ₃	23	28.4	27.6	Volkman
			28.4	Jaeger
			28.1	Richards and Carver
C ₆ H ₅ NO ₂	20	42.4	41.9	Ramsay and Shields
			43.2	Morgen (corrected)
			42.4	Jaeger
C ₆ H ₅ NH ₂	19	43.9	43.1	Jaeger
			43.6	Renard and Guye
			43.9	Volkman

TABLE II
DENSITY MEASUREMENTS ($R = 0.01650$ cm.)

Subs.	Temp., °C.	Observed density	Correct density
H ₂ O	22.5	1.002	0.998
C ₆ H ₅ N(CH ₃) ₂	23	0.950	.952
C ₆ H ₅ CH ₃	23	.857	.864
CCl ₄	25	1.592	1.584
C ₆ H ₅ NO ₂	26	1.188	1.198

Discussion of Results.—No correction for meniscus was applied, since due to the small bore of the capillary (.01650 cm.) the error introduced was negligible compared to the accuracy of the method as a whole.

Blowing into the tube, to force the liquid out in getting checks on the maximum rise, was found to introduce a large error. Results were also inconsistent when the tube was not wet with the liquid before determining maximum rise.

No readings were taken at other than room temperature, since with the present technique it is difficult to regulate the temperature of the liquid in the capillary.

In preparing the jacket for the capillary in determining density it was found essential to have one that fitted snugly. Otherwise, liquids like benzene and carbon tetrachloride were found to evaporate too rapidly to weigh accurately, in spite of the correction.

Liquids having a higher vapor pressure than 100 millimeters at 20°, such as ether and carbon disulfide, did not give satisfactory results in the determination of density.

Summary

A micro method for the determination of surface tension and density has been described which requires not over one-tenth of a cubic centimeter of sample for both determinations, which uses the same apparatus (with the addition of a jacket) for the determination of density as for the determination of surface tension and has an accuracy of from one part in 100 to one part in 300, depending on the liquid.

IMPROVED APPARATUS FOR THE REMOVAL OF DISSOLVED GASES FROM WATER¹

BY JAMES R. LORAH, K. T. WILLIAMS AND THOMAS G. THOMPSON

RECEIVED JUNE 22, 1927

PUBLISHED DECEMBER 10, 1927

Many different forms of apparatus for the removal of dissolved gases have been described in the literature. In general they consist of three types: those employing vacuum only,² which include numerous modifications of the Van Slyke apparatus,³ those employing heat only,⁴ and those employing both heat and vacuum.⁵

Those of the latter type will remove gases from water more completely than the first two, and so an apparatus was designed which combines the good features of the Van Slyke type with those of the apparatus described by Treadwell-Hall. This improved apparatus has been used by the authors with excellent success for the removal of gases dissolved in natural waters. It is adaptable to any size of system or amount of gas, provides means of making a sharp separation of water from gas, employs the minimum number of joints consistent with ease of manipulation and also provides a seal for each joint.

This apparatus consists of two separate pieces, a modified gas pipet and a special condenser. The latter consists of a $\frac{5}{16}$ " glass tube bent as shown in the diagram (Fig. 1) and surrounded by a water jacket, C. Adjoining this is a large bulb, B, to take care of the expansion of the water sample contained in the bottle when the latter is warmed. The tube, J, on the

Fig. 1.

bulb, B, is sealed at the end and provided with a hole, H, about half an inch from the end. The opposite end, E, of the condenser tube is made of capillary tubing and is joined to the straight capillary tube, A, of the gas pipet by means of a short piece of heavy-walled rubber tubing, R. To provide a seal for this connection a large glass tube, M, is filled with mercury or water.

The gas pipet, G, is provided above and below with well-fitting stopcocks, preferably of the vacuum type. The upper stopcock, S1, leads to the condenser by means of the tube, A, and to a gas buret or storage pipet by means of the capillary outlet, O. The lower stopcock, S2, leads to the side tube, T, and to a small pipet, W, used for temporary storage of water. Both T and W open into L, to which a leveling bulb filled with mercury is attached. The entire apparatus is best made of Pyrex glass. The approximate dimensions are shown on the diagram, the capacity of B being about 200 cc., G, 100 cc. and W, 20 cc.

Since speed is essential in making the connections, the gas pipet and sample bottle of water must be arranged so that the ends of the condenser will fit with a minimum of readjustment. The condenser is sloped slightly so that the condensed water will run back into the bulb, B. The gas pipet is completely filled with mercury, including capillary tubes O and A.

The manipulation is as follows. Bulb, B, is filled two-thirds full with freshly boiled, distilled water by applying suction to the opposite end of the condenser tube and then stopper, Z, is moved down until it just covers hole, H. The condenser is held so that the water runs into the tube, J, and displaces all the air from it. The original stopper is now removed from the sample bottle and the neck of the latter carefully filled with freshly boiled, distilled water. This sample bottle, of course, has previously been placed in its correct position in the water-bath. Then stopper, Z, is inserted by pushing down on the bulb, B, with one hand and very slowly turning the stopper with the other, thus allowing a little water to be forced out of the bottle as the tube, J, is forced in. The latter is forced down until the top of the hole, H, just barely comes below the bottom of the stopper. As soon as the connection is made the height of the water in the water-bath is increased so that it forms a seal for this joint.

To remove all air from the condenser tube, bulb, B, is heated by a flame until almost all of the water has steamed away. During this operation no water is in the jacket, C, and the entire condenser must be turned horizontally to such an angle that no steam strikes the gas pipet. Then, with one person holding the condenser in position and continuing the heating of the bulb, B, with the flame, another person pushes the end, E, into the wetted rubber connection, R, while steam is still issuing from the end of the condenser tube. The rubber connection is immediately wired and the glass cylinder, M, lowered from stopper, X, to stopper, Y, and filled with water or mercury. While making connections the gas pipet should be protected from steam by means of toweling. Care should be taken to have the lower stopcock open to allow for possible expansion of mercury due to heating.

The sample of water is warmed to any desired temperature. If it is heated by applying external heat to the bottom of the bath it is best to

place blocks of wood under the bottom of the bottle to prevent superheating. A stirring device on the bath is very desirable.

Some water will expand from the sample bottle into the bulb, B. Any desired amount of vacuum may be produced by lowering the leveling bulb containing mercury attached to the bottom of the pipet at L. If any water accidentally enters the gas pipet, G, the mercury may be lowered until the water is drawn into the reservoir, W. Stopcock, S2, is then turned so that the by-pass, T, is open and the gas forced through, O, into a storage pipet or buret. Then the mercury is lowered until it reaches stopcock, S2, again, which is then turned so that as the mercury is raised again the water from W floats on top. It is carefully raised until the bend, K, is reached where the water flows back into the condenser tube. Before attempting this operation the collected gas already extracted must be removed as described.

After all gases have been removed from the sample, the water in bulb, B, is boiled for a couple of minutes to remove any gases present and then the stopper, Z, is loosened. By lowering the leveling bulb, the gas in the condenser tube and bulb is drawn over into the pipet, water entering the system through hole H. The bend, K, and the joint between the condenser tube and the capillary tube, E, enables one to make a clean separation of the gas and water. It was found that if a simple bend was used some gas always remained at the top of the bend.

Summary

A modification of the usual apparatus for removing dissolved gases in water has been described.

A METHOD FOR DETERMINING THE TENSILE STRENGTH OF GELATIN JELLIES

BY A. ROSINGER AND J. J. VETTER

RECEIVED JULY 25, 1927

PUBLISHED DECEMBER 10, 1927

Up to the present time the only scientific method for determining jelly strength has been by the use of the Sheppard torsion dynamometer.¹ This apparatus is used for testing the jelly strength of glues and gelatins by the pure shear of moulded cylindrical test pieces.

The following method, first suggested by A. Rosinger in 1923, depends on the static loading of jelly membranes, and is based on the fact that a circular elastic membrane supported rigidly at its circumference and subjected to air pressure on one side assumes a spherical form.

¹ (a) Sheppard and Sweet, *THIS JOURNAL*, 43, 539 (1921); (b) Sheppard, Sweet and Scott, *J. Ind. Eng. Chem.*, 12, 1007 (1920).

When the wall thickness d' of a spherical surface is small compared to the radius r of the sphere, and the pressure within is p , the tensile stress (see any textbook on strength of material)

$$\sigma = \frac{pr}{2d'} \quad (1)$$

If we know the radius a of the frame holding the jelly membrane—a constant for the apparatus—and the height h of the spherical segment, the radius r of the sphere is

$$r = \frac{a^2\pi h^2}{2h} \quad (2)$$

There is no change in volume when a gel undergoes extension,² therefore by measuring the original thickness d of the jelly membrane the actual thickness d' for any radius up to the breaking point can be determined from the equation

$$d' = \frac{a^2\pi d}{\pi(a^2 + h^2)} = \frac{a^2d}{a^2 + h^2} \quad (3)$$

By substituting the values of r and d' from Equations 2 and 3 in Equation 1, we obtain

$$p \frac{1}{4 a^2 d} \cdot \frac{(a^2 + h^2)^2}{h} \quad (4)$$

and letting

$$\frac{1}{4 a^2 d} = c \text{ and } \frac{(a^2 + h^2)^2}{h} = x$$

the tensile stress becomes

$$\sigma = cpx \quad (5)$$

The experimental data necessary for the determination of the tensile strength are

original membrane thickness	d
volume of spherical segment	V
pressure on membrane	p

The surface elongation is

$$E = \frac{\pi(a^2 + h^2) - \pi a^2}{\pi a^2} = \frac{h^2}{a^2} \quad (6)$$

and the linear elongation is

$$\epsilon = \frac{l' - l}{l} = \frac{\sqrt{\pi(a^2 + h^2)} - \sqrt{\pi a^2}}{\sqrt{\pi a^2}} \quad (7)$$

Fig. 1 shows V , ϵ and x as functions of h .

The value d may be conveniently measured with a microscope by attaching a scale to the adjusting screw and focusing on the upper and lower surfaces of the membrane, and the height h of the spherical segment may be obtained from the volume of the latter, instead of by direct measurement. See Fig. 1.

² Bogue, "Colloidal Behavior," McGraw-Hill Book Co., New York, 1924, Vol. 1, p. 412.

The apparatus, Fig. 2, consists of three parts: A, the bell for holding the membrane, fitted with a two-way stopcock; B, the buret with the manometer tube; and C, the reservoir for adjusting the total amount of air in the system to a definite volume.

Fig. 1.

Experimental Part

The bell A is placed on a mercury surface and the gelatin solution poured in through the neck. After standing a definite time to set, the stopcock tube is attached to the bell and the latter shut off from the outside

air while being attached to the apparatus. The water level in C is adjusted to give a definite volume of air in the apparatus (1 liter) and water is run into the buret from a bottle above the apparatus to the zero point. The two-way stopcock attached to the bell is next turned to connect the latter with the apparatus and seal off the outside air. Water is run into

Fig. 2.

Fig. 3.

the buret through the stopcock S in 5cc. or 10cc. portions at a time and buret and manometer readings are taken after each addition. In releasing the pressure on the membrane, water is run out of the buret from the stopcock at the bottom in small portions at a time and buret and manometer readings are again taken. If a test is to be run over a considerable period of time, a beaker containing a small amount of water may be placed under the bell A to check evaporation from the membrane surface.

All membranes in the following tests were made from gelatin solutions prepared by soaking dry gelatin in cold water for fifteen minutes, heating

to 60° for five minutes and filtering. They were tested at 22 to 24° after standing for twenty hours.

To determine experimentally the value of a the arrangement shown in Fig. 3 was set up, using a very fine glass filament resting in the center

Fig. 4.

of the membrane and measuring the distance between the original and final positions in the graduated tube to find h , from which the value of a was calculated (see Table I).

TABLE I
DETERMINATION OF THE VALUE a

Eastman gelatin, P 1099; 20% jelly; 24 hours' setting; room temperature; $d = 0.2$

b	h , cm.	p , g./cm. ²	V , cc.	
0.0	0.0	0.0	0.0	
10.0	6.3	0.65	1.3	2.9
15.0	9.7	0.85	2.2	3.05
20.0	13.4	1.05	3.4	3.11
30.0	21.0	1.45	6.0	3.13
35.0	24.85	1.60	7.35	3.19
40.0	28.65	1.75	8.65	3.22
45.0	32.35	2.05	10.1	3.12

Av. 3.16

b = buret reading; m = manometer reading; buret cross section, 2 cm.²; $p =$

$m - b/2$; $V = b - p$; from the equation V

average, $a = 3.16$; $a^2 = 10$.

To determine the influence of gravity on the results, tests were made with duplicate samples, running one with the bell vertically upward

$d = 0.2$ cm.; 20% jelly, $\nu = 1.055$.

Fig. 5.

and the other downward. The result is shown in Table II and Fig. 4. The error due to gravity was eliminated by taking the mean of the two

curves. Fig. 5 shows the corrections to be made when the bell is held in a downward position with a membrane thickness of 0.2 cm. and gelatin

^a P. Bary, "Les Colloides," Dunod, Paris, 1921, p. 42.

In calculating the tensile strength, the actual thickness of the membrane at the moment the readings are taken is used and not the original thickness, as in most previous work on this subject.

Fig. 9.

With the dimensions of the apparatus as given in Fig. 1, the volume of the inclosed air (one liter) can be considered to decrease 1 cc. for each cm. of pressure, p , within the pressure range used in the tests.

Fig. 9 shows the form taken by the membrane, when stretched, at the junction with the glass, and shows that the upper point to which h is measured or calculated from the inner surface of the membrane is not a fixed point but lowers slightly as h increases. When h is less than 3 cm. no correction need be made.

Summary

An apparatus and method for studying the elastic properties of gelatin jellies under static loading conditions are described.

The apparatus can be used to study the time of relaxation of stretched membranes.

The method is applicable to the study of any elastic medium that can be formed into a membrane.

The influence of chrome alum and formaldehyde on gelatin jellies is shown.

THE VAPOR PRESSURES OF POTASSIUM AMALGAMS

BY RUSSELL W. MILLAR

RECEIVED JULY 30, 1927

PUBLISHED DECEMBER 10, 1927

According to the freezing point-composition curves of the amalgams of the alkali and alkaline earth metals,¹ these solutions should possess properties far different from those of the ideal solution. This assumption is confirmed by the vapor-pressure and electromotive-force measurements of several investigators.²

On account of the ease of distillation and availability of metallic potassium, its amalgams were chosen for study as examples of extremely imperfect solutions.

The method was that of Ramsay, which has been used by practically all investigators in this field. A closed J-tube was filled with the amalgam and thoroughly boiled out *in vacuo*, so that the short, closed arm contained no gas. The amalgam was then brought to a constant temperature and the pressure of the mercury vapor in the closed arm was balanced by that of hydrogen in the long arm. The pressure of the hydrogen was measured by means of a manometer. The fine adjustment of the hydrogen pressure was accomplished by means of a narrow barometric column as used by Hildebrand in his measurements of the vapor pressures of zinc amalgams.³

Apparatus.—The J-tube was of heavy-walled Pyrex tubing of 0.70 cm. internal diameter. The short arm was 3–4 cm. in length. The temperature was maintained by means of a well-insulated air-bath in which the temperature was kept uniform by means of a fan. Windows permitted observation of the amalgam. The voltage of the lighting circuit by which the oven was heated varied considerably, but it was found that equilibrium was attained so rapidly that the readings obtained fell upon the same curve whether the temperature was rising or falling.

The temperature was measured by means of a nichrome-constantan thermocouple

which was chosen because its e.m.f. varies almost linearly with the temperature and the coefficient is high. The e.m.f. was measured with a Leeds and Northrup "Type K" potentiometer and an unsaturated Weston standard cell which was checked against one calibrated by the Bureau of Standards. The thermocouple was calibrated against the boiling points of water and of naphthalene and the melting point of a sample of zinc furnished for the purpose by the Bureau of Standards. The e.m.f.'s observed were found to be represented accurately by the equation used by Eastman and Rodebush⁴ for copper-constantan at low temperatures

$$E = E_0 + aT^n$$

where E = e.m.f., and in the present instance $E_0 = -6840$, $\log a = 0.05706$, $n = 1.5490$ and T = degrees Kelvin. From this formula a table was constructed and all readings were converted to temperatures by its aid. The temperature scale was checked against that used by Smith and Menzies⁵ in their determination of the vapor pressure of pure

mercury by a similar determination with the apparatus used for the amalgams. The results are shown in Table I, which gives the pressures found and those calculated from the formula of Smith and Menzies. The divergence indicates the order of the experimental error; for instance, the temperature was known only to about 0.5° .

The pressure of the hydrogen was measured with a closed mercury manometer of 1.5 cm. internal diameter which was placed before an accurate steel scale. Readings were taken through a telescope placed about 2 meters distant.

Materials.—The mercury was washed three times by spraying through a column of dilute nitric acid 150 cm. high and twice distilled in a current of air under reduced pressure.

The amalgam was then made in a Pyrex glass apparatus represented by Fig. 1, which is one-third actual size. Having been well cleaned, the apparatus was first evacuated through the stopcock S by means of a mercury diffusion pump and heated almost to the softening point of the glass for about fifteen minutes. Air was then admitted, the tips of E and C were broken off and the desired amount of mercury was introduced through C, which was then sealed. The potassium, which had been kept under ether and dried beforehand, was placed in E, which was then sealed. The apparatus was evacuated for about two hours and strong heating of the parts which did not contain potassium or mercury was repeated at intervals. The potassium was warmed, but not melted, and the mercury was boiled gently. Finally, after a 500 cc. McLeod gage connected to the line showed not more than 0.00005 mm. pressure of mercury when the apparatus was hot, the potassium was melted. It ran readily through the capillary F into the first bulb D, leaving the oxide shell in E, which was then sealed off at F and discarded.⁶ The potassium was then distilled from one bulb D to the next and the residue in each case was sealed off. From the last bulb the potassium was distilled

Fig. 1.

⁵ Smith and Menzies, *ibid.*, 32, 1434 (1910).

⁶ This method of cleaning the alkali metals was described by Lewis and Kraus, *THIS JOURNAL*, 32, 1459 (1910).

slowly into the mercury in B. The stopcock was then closed and the J-tube A with the stopcock and the attached tube B was broken off at H. The amalgam was then well mixed and the amount poured into A which was necessary to fill it from the point G slightly past the bend. The tube was then sealed to the vacuum line and B was sealed off at G. Hydrogen was next admitted. During all of these operations it was necessary to keep the tube and its contents warm in the cases of the more concentrated amalgams, for the frozen amalgams always broke the tube on melting. The three more dilute amalgams had the color of mercury, but the three more concentrated ones were gray to copper-colored. The remaining portions of the concentrated amalgams, which were examined in B, were fairly hard and of considerable mechanical strength. It is not thought that the color of the concentrated amalgams was due to impurity or to moisture in the glass, for it appeared as soon as the potassium and mercury came into contact and did not increase in the presence of hydrogen. Indeed, mercury vapor, which was always present near the top of B, turned the bright surface of the globules of potassium almost black.

The hydrogen was produced by the electrolysis of sodium hydroxide solution, passed over hot platinized asbestos and dried with phosphorus pentoxide. It had no visible effect upon the amalgams.

TABLE I
THE VAPOR PRESSURE OF MERCURY

T, °K.	$p_{\text{mm.}}$, obs.	Smith and Menzies
468.3	14.7	14.77
518.0	62.4	64.88
571.9	244.8	240.05
575.3	258.7	258.37
613.0	560.7	555.6
613.9	570.4	565.2

Analysis.—The tube containing the amalgam was sealed off, broken and dropped into an excess of 0.5000 *N* hydrochloric acid. A piece of platinum wire aided the solution of the metal, which was complete in about twelve hours. The excess of acid was then titrated and the mercury, after washing and drying at 40°, was weighed. Check results were obtained on the excess of amalgam remaining in B after the amount needed had been poured into A.

There were several sources of error on account of which the results can lay no claim to high accuracy. Even with pure mercury the error was about 2%, due largely to the leak of heat up the thermocouple leads. The use of a radiation shield around the thermocouple and the J-tube did not affect the readings except when it obscured the levels of the amalgam. The amalgams of low concentration did not affect the glass but those of the highest concentrations darkened it after a time and then showed a tendency to stick slightly.

Two serious sources of error were the evaporation of mercury into the open arm of the tube and the accumulation of hydrogen in the closed arm, the former causing low results, the latter high. The pressure of the hydro-

gen was removed frequently, so that the amalgam boiled into the open arm of the tube and at the same time the mercury which distilled and condensed on the upper part of the tube was shaken down by violent tapping. After this operation hydrogen could not be detected in the narrow tip at B where the tube had been sealed off and the mercury in the open arm was kept at a minimum. The tube, when taken for the analysis, was always drawn off at a point which had been inside of the furnace, so that mercury which had condensed in the open arm remained there. The errors in the steel scale and the reading of the manometer were less than those mentioned above.

The data are given in Table II. The first column gives the temperature in degrees Kelvin and the second the pressure in millimeters of mercury at 0° . The mole fractions of mercury and of potassium are represented by N_1 and N_2 , respectively.

These data, together with Smith and Menzies' data for pure mercury, are plotted in Fig. 2, and the equations for the straight lines which best fit the points for pure mercury and for each amalgam follow.

No.	N_1	Equation	
0	0	$\log p_1 = 7.841 - (3125/T)$	(1a)
1	0.0492	$\log p_1 = 7.799 - (3125/T)$	(1b)
2	0.0552	$\log p_1 = 7.779 - (3125/T)$	(1c)
3	0.0877	$\log p_1 = 7.717 - (3125/T)$	(1d)
4	0.180	$\log p_1 = 7.569 - (3212/T)$	(1e)
5	0.321	$\log p_1 = 7.968 - (3950/T)$	(1f)

These equations represent the individual pressures within 1-5%, usually 2-3%.

Fig. 2.—The vapor pressures of potassium amalgams.

In Table III are given the values of N_1 and of the activity, $a_1 = p_1/p_1^0$, of the mercury for each amalgam at 200, 250, 310 and 390°. The values of p_1 and p_1^0 were calculated from the equations for the vapor pressures of the amalgams and pure mercury.

* Supercooled solution.

The equation of van Laar, which is discussed by Hildebrand,⁷ was used to express the relation at each temperature between a_1/N_1 and the composition expressed as $r_1 = N_1/N_2$. The constants of the following equations were calculated from the data of Table III.

$$200^\circ \quad \log a_1/N_1 = -64.71/(1 + 2.689r_1)^2 \quad (2a)$$

$$250^\circ \quad \log a_1/N_1 = -28.94/(1 + 1.774r_1)^2 \quad (2b)$$

$$310^\circ \quad \log a_1/N_1 = -14.16/(1 + 1.209r_1)^2 \quad (2c)$$

$$390^\circ \quad \log a_1/N_1 = -7.041/(1 + 0.816r_1)^2 \quad (2d)$$

TABLE IV
COMPARISON OF PRESSURES CALCULATED FROM EQUATIONS 1 AND 2

Amal. no.	Eq. no.	Temperature, °C.			
		200	250	310	390
1	1b	15.56	66.70	275.0	1218
	2a-d	15.47	66.24	272.8	1206
2	1c	14.85	63.70	262.5	1164
	2a-d	15.16	64.92	267.3	1182
3	1d	12.88	53.95	227.6	1085
	2a-d	13.10	56.24	231.7	1025
4	1e	5.98	26.74	114.6	530.0
	2a-d	5.98	26.76	114.8	530.1
5	1g	0.41	2.61	15.57	102.4
	2a-d	0.41	2.60	15.60	102.6
Pure Hg	1a	17.15	73.52	303.0	1343
	Smith and Menzies	17.20	74.20	305.0	1336

Table IV gives the value of the vapor pressures calculated from the van Laar equation for each temperature and those calculated from the vapor pressure equations 1a-f. It will be noted that the agreement is about that of the agreement of equations 1a-f with the experimental data.

From the relation

$$\log \frac{a_2}{N_2} = \frac{\alpha_1 \beta_1}{(\beta_1 + r_2)^2} \quad (3)$$

where a_2 is the activity of potassium and $r_2 = N_2/N_1$, which Hildebrand⁷ has derived from the van Laar equation, the activities of the potassium can be calculated and an idea of the magnitude of the Henry's Law constant can be obtained by setting $r_2 = 0$, although the extrapolation is hardly to be recommended.

Fig. 3 is the plot of a_1 against N_1 for each of the four temperatures, the largest deviation from Raoult's law at each of the two highest concentrations being that corresponding to the lowest temperature.

Hildebrand has shown that $\log a_1/N_1$, for many systems, varies approximately linearly with N_2^2 . In Fig. 4 these quantities are plotted for each temperature and the best curves, which are more nearly straight lines for the highest temperatures than for the lowest, are drawn.

⁷ (a) van Laar, *Z. physik. Chem.*, **72**, 723 (1910); (b) **83**, 599 (1913). (c) Hildebrand, "Solubility," The Chemical Catalog Co., New York, 1923, p. 45.

In order to calculate the e.m.f. of the potassium electrode we should have to calculate from Equation 3 the activity of potassium in a dilute

Fig. 3.—The activity of mercury in potassium amalgams.

amalgam at each temperature for which the constants are given in Equations 2a-d, find the activity of potassium in that amalgam at 25° by extra-

Fig. 4.—The variation of $\log a_1/N_1$ with N_1^2 .

polation and then measure the potential of the amalgam against some standard electrode. The last step has already been performed for a 0.2216%

potassium amalgam by Lewis and Keyes,⁸ but due to the fact that a_2 changes rapidly with the temperature, which a_1 does not, the extrapolation of the calculated values to 25° does not appear feasible.

It is of interest to note that, within the accuracy of these data, the heat of vaporization of mercury from the amalgams in which the concentration of potassium is as high as 8 mole per cent. is equal to that of pure mercury. This may be explained if we assume that a mercuride exists in solution, and that, with respect to pure mercury as the solvent, it is a perfect solute. Such may easily be the fact if a large number of atoms of mercury are chemically combined with or attached to each atom of potassium. This average number, calculated from the vapor pressure lowering and the concentration of the solution, is 9.44 for No. 1, 10.6 for No. 2 and 7.36 for No. 3. Evidently the analysis for No. 2 is low, a fact which accounts for the position for this amalgam on Fig. 3.

At higher concentrations than 8 mole per cent. the partial molal heat content of the mercury becomes negative, as is to be expected in solutions in which the deviations from Raoult's Law are so greatly negative, and the more so the higher the concentration of potassium.

Summary

The vapor pressures of mercury in equilibrium with five potassium amalgams have been measured. The concentrations ranged from 5 to 32 mole per cent. of potassium and the temperatures from 184 to 445°.

The equation of van Laar, which expresses the vapor pressure as a function of the concentration, temperature being constant, has been found to agree with the experimental data within the limits of accuracy of the latter.

The relative partial molal heat content of solvent mercury in the amalgams not exceeding 8 mole per cent. of potassium was found to be zero.

The deviations from Raoult's Law are among the greatest yet noted in any solutions and, as is to be expected, they decrease with rising temperature.

THE VAPOR PRESSURE OF SODIUM AND CESIUM AMALGAMS

BY HENRY E. BENT AND JOEL H. HILDEBRAND

RECEIVED JULY 30, 1927

PUBLISHED DECEMBER 10, 1927

The following investigation was undertaken as an extension of the work carried out by the senior author and his collaborators on the vapor pressures of amalgams in relation to the theory of metallic solutions.¹ It was hoped also that data might be secured which would permit the indirect determination of the e.m.f. of the cesium electrode.

The standard electrode potential of the alkali metals cannot be determined directly on account of the reaction between the metal and water. Lewis and Kraus² first showed that the electrode potential could be obtained by interposing a dilute amalgam of the alkali metal. The amalgam was used in aqueous solution with but little reaction with water. A second cell composed of an electrolyte other than water then gave the free energy change in going from the pure metal to the amalgam. The sum of the electromotive forces of the two cells gave the standard electrode potential.

This method was found successful with all the alkali metals except cesium. No solvent could be found for a salt of cesium which would not dissolve the metal. Consequently the method had to be abandoned. There seems to be no doubt that the e.m.f. of a dilute cesium amalgam could be measured against a hydrogen electrode using an aqueous electrolyte, so that the problem could be solved by an indirect determination of the e.m.f. between metallic cesium and the dilute amalgam. This could be accomplished by applying the Duhem equation to accurate data on the vapor pressure of cesium amalgams and so obtaining the relation between the activity of cesium and the composition of the amalgam. Some preliminary calculations showed that the results of the application of the Duhem equation would be sufficiently accurate to obtain satisfactory values for the activity of the cesium at the temperatures used in the investigation, although leaving somewhat doubtful the possibility of getting a sufficiently accurate temperature coefficient to make possible the extrapolation to 25°. An inspection of the freezing-point diagrams for the alkali metals led us to hope the hydrargyrites of cesium to be more dissociated than those of sodium, although the measurements showed this not to be the case.

The Materials Used

The sodium used was a good grade of commercial metal. No trace of other alkali metals was detected spectroscopically, nor could potassium be detected qualitatively, though one-tenth of one per cent. could have been observed.

¹ Hildebrand, "Solubility," A. C. S. Monograph, Chemical Catalog Co., New York, 1924, Chapter 16.

² Lewis and Kraus, *THIS JOURNAL*, 32, 1459 (1910).

The mercury was washed and distilled.

Kahlbaum's cesium bromide was tested spectroscopically for impurities without any positive test for metals other than cesium. The metal was prepared by mixing the dry salt with fresh calcium shavings in an iron tube. The tube was then placed in a glass tube, evacuated and heated to six or seven hundred degrees, which furnished a constant stream of cesium vapor. The metal was three times redistilled, leaving no residue the last time, and was found to melt above 25° in every case. The melting point of pure cesium is 26° .

The hydrogen was prepared by electrolysis of sodium hydroxide solution, dried by passing through concentrated sulfuric acid, phosphorus pentoxide and finally over an amalgam containing about eighty-five mole per cent. of sodium, which is liquid at room temperature. The hydrogen was then of sufficient purity to give no trace of oxide on the surface of the cesium in the upper part of the apparatus or in the tube containing the amalgam.

Experimental Method

The measurement of the vapor pressures was carried out essentially as in the previous work on vapor pressures of amalgams.³ The apparatus with which the cesium was to come in contact was thoroughly evacuated by a mercury vapor pump and well baked out. The cesium was contained in a small glass tube, as shown in Fig. 1, drawn out to a fine tip. After the glass had been out-gassed, the tip was broken by means of a weight controlled magnetically and the cesium allowed to run into the tube in which the pressure was to be measured. The mercury was then distilled into the cesium until the proper concentration had been attained.

Fig. 1.—Apparatus for preparing amalgams and measuring vapor pressures.

The furnace was raised to the proper position, heated to the temperature of the run and the fused salt bath poured in. It was found convenient to filter the fused eutectic of sodium and potassium nitrate frequently through glass wool. After each run the salt was siphoned out of the furnace. The amalgam was allowed to heat for about an hour in order to eliminate part of the gas which might still be held by the glass. This was then boiled out and the amalgam allowed to stand for a time sufficient to allow the temperature to become constant and also to insure the amount of permanent gas above the amalgam being nearly constant during the run. Usually but four measurements of the pressure were taken on the amalgam and an equal number on the tube of pure mercury. This was sufficient to insure an accuracy due to chance errors of ob-

³ (a) Hildebrand, *Trans. Am. Electrochem. Soc.*, **22**, 319 (1913); (b) Hildebrand and Eastman, *This Journal*, **36**, 2020 (1914); (c) *ibid.*, **37**, 2452 (1915); (d) Hildebrand, Foster and Beebe, *ibid.*, **42**, 545 (1920).

servation and temperature fluctuations of the order of magnitude of 0.05%. Since other errors were larger than this it was not deemed advisable to take a greater number of measurements.

Inasmuch as a fluctuation of one degree in the temperature of the furnace changes the vapor pressure of the mercury by 3%, the furnace was designed with the intention of obtaining as constant a temperature as possible. Thus the bath which was the basis of the furnace was surrounded by three glass shields with horizontal layers of asbestos to prevent circulation of air. Two shields of asbestos paper outside the glass shields served to circulate the gases from the Fisher burner around the outside of the glass shields and to prevent radiation to the manometers. A gas pressure regulator maintained the gas pressure for the burner constant to within one-tenth of a millimeter. As a result the temperature remained constant during a run to within a few hundredths of a degree. The heating liquids were diphenylsulfone, anthraquinone, phenanthrene, diphenylamine and phthalic anhydride.

The analysis of the amalgam was carried out in such a way as to furnish with one sample two independent determinations of the mole fraction. The tube containing the amalgam was, therefore, first weighed and at the conclusion of the analysis the glass tube was weighed empty, thus giving the total weight of the amalgam. The amalgam was then treated with water until most of the alkali metal had been extracted and the solution poured into a flask to be titrated. The last of the alkali metal was removed by digestion with acid. Hydrochloric acid was found to dissolve some mercury in the presence of air. However, half normal sulfuric acid was found to have no appreciable effect even when mercury was boiled in it for more than an hour. The mercury distills with the steam in appreciable quantities during digestion, necessitating the use of a long-necked flask with a condenser, water cooled, inside the flask. A small tube prevented excessive bumping. A platinum wire was placed in contact with the amalgam near the end of the extraction to decrease the overvoltage of the hydrogen.

The acid was standardized against Kahlbaum's sodium carbonate, against sodium carbonate prepared by recrystallizing as bicarbonate and by weighing as sulfate. These methods agreed to within one tenth of one per cent. At the conclusion of the experiments the acid was again standardized.

The mercury was transferred from the long-necked digestion flask to a small casserole by pouring under water to prevent spattering. It was then washed three times with filtered acetone, dried by filter paper and transferred to a ten cubic centimeter weighing bottle by means of a watch glass pulled out to a spout which would enter the weighing bottle. This method of handling the mercury was found to be thoroughly dependable. The mercury was heated to constant weight by placing in an oven at 115° for five-minute periods, cooling in a desiccator and weighing. Longer periods for heating were found to result in distillation of the mercury.

The check on the analysis was obtained by subtracting the weight of either metal from the total weight of the amalgam to obtain the weight of the other metal. In the analysis of the sodium amalgams a further check was obtained by evaporation of the solution after titration and weighing the sodium sulfate.

Errors and Corrections

The causes of error have been carefully evaluated and corrections applied where possible. A consideration of these errors indicated that the

probable error of the measurements should be about 0.3%. This is about the average deviation observed in the experimental points from the smoothed curve. The methods of correcting for some of these errors will be discussed briefly.

One of the chief sources of error in vapor pressure measurements lies in the difficulty of obtaining a pure vapor. Rather than attempt to eliminate all vapors other than mercury a correction was applied. A small tip was placed on the end of the closed arm of the pressure tube which functioned in principle as the capillary of a McLeod gage. At the conclusion of each run the fixed gas was compressed into this tube and its pressure measured. The pressure of the fixed gas in the closed tube is given by the equation

$$p = H - (P + S + h\rho)$$

in which H is the pressure in the open arm as measured by the manometer, P is the pressure of the mercury in the amalgam, S is the capillary depression of the amalgam, h is the difference in height of the amalgam in the two arms of the tube and ρ is the density of the amalgam referred to mercury at 25° as unity. This pressure p usually varied from a few millimeters of mercury to two or three centimeters. The pressure of the fixed gas in the closed arm during the run was then found by multiplying this pressure by the ratio of the volume of the capillary tip to the volume of the vapor in the closed arm during the run. This ratio was of the order of magnitude of 1/30. Similar corrections were applied to the mercury tube and the final activity corrected by these two factors.

The chief source of error in making the above correction arises from assuming a density for the amalgam. It was necessary, therefore, to make measurements on the density, the data being recorded in Table I. The values are but approximate, as accurate values were unnecessary in this work and could not be obtained by the method used. It is interesting to note that the apparent molal volume of mercury in cesium appears to be negative until the concentration of mercury is more than thirty mole per cent.

TABLE I
DENSITY AND PARTIAL MOLAL VOLUMES OF CESIUM AMALGAMS

N_1 , mole fraction of mercury	ρ , density referred to mercury	N_1	\bar{V}_1 , partial molal volume of mercury, cc.	\bar{V}_2 , partial molal volume of cesium, cc.
0.937	0.85	1.0	14.8	42
.914	.80	0.8	13.3	57
.909	.84	.6	9.0	65
.877	.75	.4		69
.868	.77	.0		71
.779	.58			

Perhaps the greatest source of error was caused by the difficulty in sighting on the meniscus of concentrated amalgams. The amalgam

presented a flat or concave surface on amalgams in which the concentration of cesium was more than about ten mole per cent. As the concentration increased the wetting of the glass increased until in about thirty mole per cent. amalgams the glass would be completely covered by a film of the amalgam which, of course, made readings impossible. This film could be readily removed by heating with a burner, but that necessitated removing the amalgam from the bath and destroying the temperature equilibrium. In a few cases it was possible to improve the conditions by treating the glass before the run with hydrofluoric acid. The commercial 50% acid was found most satisfactory for this purpose, a short treatment at the boiling point sufficing to give good results in amalgams of moderate concentration. However, even in these it was necessary to sight on the contact of amalgam with glass rather than on the center of the meniscus. This might account for several tenths of a millimeter error in the case of the more concentrated amalgams.

The tube leading to the furnace was made small to cut down diffusion of mercury vapor and heated to prevent condensation. In this manner the error due to distillation of mercury was cut down to less than 0.1%.

At the higher temperatures the more concentrated sodium amalgams attacked the glass, making it necessary to take observations in as short a time as possible while the glass was transparent. No such difficulty was encountered with the cesium amalgams.

Experimental Results

The data for sodium amalgams were obtained before those for cesium amalgams and consequently the latter are a little more accurate. Furthermore, the bearing of the cesium measurements on the value of the cesium electrode potential made it desirable to obtain more measurements on cesium amalgams. So many improvements were made after the first ten runs that these were not considered of sufficient value to tabulate. All of the experimental measurements from run eleven on are given in the tables. Table II gives the experimental data obtained for sodium amalgams and also values calculated by methods to be described.

The first column gives the average temperature of the runs. The temperature varied during a run by perhaps a tenth of a degree or less. The temperature varied from one run to another by half a degree. The first variation is of greater importance, due to the fact that the vapor pressure of mercury varies by about 3% per degree change in temperature, while the activity of mercury in an amalgam changes at the rate of about 0.05% per degree.

The second column of the table gives the mole fraction of mercury as obtained by the analysis. The two methods of obtaining the number of moles of mercury usually varied by about one part in ten thousand.

The two values obtained for the number of moles of sodium usually varied by about one part in a thousand. The third column gives the experimental values of p/p° .

The data from cesium amalgams given in Table III seem to be a little more accurate than those for sodium amalgams in the lower range of concentration, but inferior in the range of higher concentration. This was doubtless due to the greater tendency of the cesium amalgams to wet the glass. The temperature control was somewhat better than in the work on sodium. The variation of the temperature during a run was usually not more than one or two hundredths of a degree, while the variation of

the temperature from one run to another was less than three tenths of a degree. The values of N_2 are probably in error by 0.1% or less.

Interpretation of Results

The experimental data may be treated in a variety of ways. The most obvious way to show deviations from Raoult's law is to plot activity against mole fraction. This has been done in Fig. 2, in which the activity of mercury is plotted against its mole fraction. As is evident from the figure, this method of plotting does not permit extrapolation far beyond the region of experimental measurements.

A more useful method of plotting such data is to consider the deviations from perfect solution. For this purpose $\log a_1/N_1$ may be plotted against some function of N_1 . If Raoult's law is obeyed, the plot is a straight line, $\log a_1/N_1$ being zero. It is very convenient in many instances to plot $\log a_1/N_1$ against N_2^2 .⁴ Some of the data are so represented in Fig. 3, the points falling almost exactly on a straight line. The straight line is dotted in the figure, while the full curve is the best smooth curve which could be drawn through the experimental points.

The last columns of Tables II and III have been calculated from these curves. The fourth column of Table

II has been calculated by means of the equation $\log a_1/N_1 = \frac{1}{2}\beta N_2^2$. The value of the single constant $-\beta$,

obtained graphically, is 12.81 at 648.1°K. and 13.33 at 608.5°K. The values in the fourth column of Table III were obtained in the same manner, assigning values to $-\beta$ of 22.16, 24.74, 26.52 and 28.66 for the four temperatures, the smallest value being for the highest temperature.

The values in the last column of Table II were obtained by a more roundabout method, but one which furnishes information concerning the relative partial molal heat contents of the amalgams and also fits the

⁴ (a) Ref. 1, p. 48; (b) Hildebrand, *Proc. Nat. Acad. Sci.*, 13, 267 (1927).

experimental data better. The method consisted in first obtaining an equation which better fitted the experimental data for the temperature common to the greatest number of runs. Second, from this equation and the experimental values at other temperatures, the variation of the activity with the temperature was obtained. Third, from the change of activity with the temperature the relative partial molal heat content of mercury in the amalgams was obtained, which was then plotted against

Fig. 3.—The activity of mercury in sodium and cesium amalgams.

mole fraction and a smooth curve used to recalculate the activity at any temperature and concentration.

The empirical equation which best fitted the experimental data is $\log a_1/N_1 = 2.082 (\log N_2 + 0.418)$. The value of the coefficient of $\log N_2$ gives an idea of the difference to be expected between the values given in the last two columns of Table II. A similar plot for the cesium data indicated a similar value for the coefficient of $\log N_2$ in dilute amalgams, but one which approached 2 in the more concentrated amalgams. The

values at 608.5°K. in the sixth column of Table II were obtained from this equation.

From the above equation values of the activity were calculated at concentrations used in runs at other temperatures. The change in $\log a_1$ with respect to $1/T$ multiplied by 2.303/1.988 gives the relative partial molal heat content of mercury in the amalgam, referred to pure mercury as the standard state. These values vary with the concentration and may be represented by the equation $\bar{L}_1 = 4300 N_2^2$. Table IV gives the values obtained by the above method and those calculated from the equation, while Table V gives similar values for cesium. These values are subject to a rather large percentage error, inasmuch as the change of activity with the temperature is slight.

The values in the last column of Table II were calculated by this method and agree considerably better with the experimental points than those calculated by means of the more simple equation. The activity of mercury may now be calculated in an amalgam of any concentration and at any temperature, the accuracy depending on the range of extrapolation. If the range of extrapolation is great, doubtless the simpler equation would alone be justified.

In considering the data on cesium amalgams no simple empirical equation was found to represent the data accurately throughout the whole range studied. The curve was, therefore, treated in two portions, in the range from $N_1 = 1$ to $N_1 = 0.8$ being represented by the equation $\log a_1/N_1 = 8.954 N_2^2 + 42.40 N_2^3 - 110.3 N_2^4$ and in the range of more concentrated amalgams by the equation $\log a_1/N_1 = 7.793/(1 + 0.7267 r_1)$ in which r_1 is defined as N_1/N_2 . The curves representing these two equations differ but slightly, but since the change of activity with the temperature is but slight it is essential to fit the experimental points as well as possible. The accuracy obtained in determining the relative partial molal heat content is greater for sodium amalgams than for cesium amalgams. The

latter were found to be represented by the equation $\bar{L}_1 = AN_2^2$, in which the value for A was taken as 10,000, 6400 and 10,400 for the temperature intervals between the various runs, the first value being for the highest temperature. The values in the last column of Table V were calculated by means of these equations. Similar calculations were carried out by merely sliding a cut-out curve and gave values differing little from those calculated as above.

The Activity of the Alkali Metal

The calculation of the activity of the solute from the known activity of the solvent may be accomplished by either the graphical or analytical integration of the Duhem equation.⁵ The former is accomplished by plotting $\ln a_1/N_1$ against N_1/N_2 . The equation used is

$$\ln a_2/N_2 = - \int \frac{N_1}{N_2} d \ln a_1/N_1$$

The latter method consists in expressing $\ln a_1/N_1$ as a function of N_2 and integrating analytically. In these calculations a_2 , the activity of the alkali metal, will refer to the pure liquid metal as the standard state. On substituting the value of $\ln a_1/N_1$, namely $2.303\beta N_2^2/2$, and integrating we obtain the relation

$$\ln a_2/N_2 = 2.303[-\beta(N_2 - \frac{1}{2}N_2^2) + \frac{1}{2}\beta]$$

The right-hand member of this equation is identical with minus $\frac{1}{2}\beta N_1^2$.^{4a} The form of the equation first given has been used in the calculations since the term involving N_2^2 can be neglected for small values of N_2 . For a given value of N_2 the e.m.f. of a cell in which the reaction is the transfer of sodium to amalgam of this concentration is then given by the relation

$$E = \frac{RT \ln a_2}{23074}$$

If we take N_2 as 0.01772, we find the e.m.f. of such a cell to be 1.07 volts at 648.1° and 1.03 volts at 608.5°K. If we extrapolate such a value over the long range to 298° we obtain the value 0.72 volt. Such a cell has been measured by Lewis and Kraus and was found to have the e.m.f. of 0.85 volt. The assumption used in the above extrapolation is that dE/dT is constant over the range of extrapolation, which undoubtedly is incorrect. Lewis and Kraus determined dE/dT at 298°. If an average value of dE/dT is taken for the extrapolation, the e.m.f. is found to be 0.88 volt.

The foregoing calculations are of value in determining the reliability of similar calculations of the cesium cell. More data are available for the cesium calculations, but the difficulties of extrapolation are greater than for sodium due to the lower activity of the mercury in these amalgams.

⁵ (a) Hildebrand and Eastman, *THIS JOURNAL*, **37**, 2452 (1915); (b) Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Compounds," McGraw-Hill Book Co., New York, 1923.

Using the various empirical equations which expressed the experimental data, we find for the e.m.f. of the cell in which the reaction is a transfer of pure cesium into an amalgam whose concentration is 1.0 atom per cent. 1.43 to 1.47 volts at 609°K. Upon extrapolating to 25° we find a value of 1.71 volts, the agreement of the various methods of extrapolating being to the order of 0.05 volt. A further idea of the accuracy of such calculations may be obtained from Fig. 7.

The Deviation of Sodium, Potassium and Cesium Amalgams from Raoult's Law

It has been shown in Fig. 3 that the vapor pressure of mercury from sodium and cesium amalgams may be represented by the equation

$$\log a_1/N_1 = \frac{1}{2}\beta N_2^2 \quad (1)$$

in which β is a constant which varies with the temperature. The activity of the solute may be calculated from Equation (1) and the Duhem equation, giving

$$\log a_2/N_2 = -\beta(N_2 - \frac{1}{2}N_2^2) + \frac{1}{2}\beta \quad (2)$$

Equation (1) was derived from data extending over a concentration range of $N_1 = 1$ to $N_1 = 0.5$. We may test Equation (2) by means of the data obtained by Richards and Conant on sodium amalgams at 25°.⁶ They measured the e.m.f. of cells in which the reaction is a transfer of sodium from one amalgam to another of different concentration. These data give activities of sodium in amalgams referred to each other or, by extrapolation, referred to infinite dilution. For the test of Equation (2) it is necessary to have the activity referred to pure sodium as the standard state. This may be accomplished by combining the data of Richards and Conant with those of Lewis and Kraus.² The latter have measured the e.m.f. of a cell in which the reaction is the transfer of sodium into a dilute amalgam. Since $E/0.05915 - \log N_2$ differs from $\log a_2/N_2$ by a constant factor, the two sets of data may be combined by plotting $E/0.05915 - \log N_2$ as ordinate against N_2 as abscissa and shifting the curve along the ordinate until it coincides with the single measurement of Lewis and Kraus of $\log a_2/N_2$. The resulting curve is A in Fig. 4. The experimental points fall on a straight line almost within the limits of experimental accuracy. This has been observed for similar data on barium amalgams by Anderson.⁷

That these points should fall on a straight line for small values of N_2 is evident from Equation (2), for when N_2 is small the term N_2^2 may be neglected. The slope of the curve gives the value for the constant β and the departure of the intercept at $N_2 = 0$ from $\frac{1}{2}\beta$ indicates the departure to be expected from Equation (1) for large values of N_2 . The equation for the curve through the experimental points in Fig. 4 is log

⁶ Richards and Conant, *THIS JOURNAL*, 44, 601 (1922).

⁷ Anderson, *ibid.*, 48, 2285 (1926).

$a_2/N_2 = 20N_2 - 12.8935$. This value of β is in good accord with the values found at higher temperatures.

These data serve to emphasize again the importance of the constant β which expresses the deviation of both solvent and solute from Raoult's law.^{4b} The more exactly Equation (1) corresponds to vapor pressures throughout the whole range of concentration the more nearly will the intercept in Fig. 4 equal one-half the slope of the curve. The value of the intercept gives the log of the ratio of the activity of sodium in infinitely dilute amalgam to pure sodium.

Fig. 4.—Activity of sodium in sodium amalgam at 25°.

The value of β obtained from Fig. 4 makes possible the calculation of the vapor pressure of mercury from liquid sodium amalgams at 25°, using the equation $\log a_1/N_1 = -10N_2^2$. Poindexter⁸ has measured the vapor pressure of solid sodium amalgams, using the ionization gage. His data may be represented by an equation of the form of that above in which the constant at 298°K. is -22 ± 5 . As would be expected, the escaping tendency from a solid amalgam is much less than from a supercooled liquid amalgam. Poindexter found much higher vapor pressures in the case of the dilute liquid amalgams.

Table VI gives values of β for sodium and cesium amalgams obtained from the experimental work of this paper. The value for sodium at 298° is obtained from the data of Richards and Conant. The value for cesium at 298° is obtained by extrapolation. The values for potassium are obtained from the data of Millar.⁹ The value for barium is obtained from the data of Anderson.⁷ Barium and cesium amalgams seem to vary from perfect solution to about the same extent. There is quite a difference,

^{4b} Poindexter, *Phys. Rev.*, **28**, 208 (1926).

⁹ Millar, *THIS JOURNAL*, **49**, 3003 (1927).

TABLE VI

THE DEVIATION OF AMALGAMS FROM RAOULT'S LAW AS EXPRESSED BY β IN THE EQUATION $\log a_1/N_1 = \beta N_2^2$

Amalgam	Temp., °K.	$-\beta$
Sodium	648.1	12.82
	608.5	13.33
	298.1	20.0 ± 0.4
Potassium	663.1	19.0
	583.1	20.4
	523.1	21.8
	473.1	23.6
Cesium	651.4	22.16
	609.9	24.74
	573.9	26.52
	553.6	28.66
Barium	298.1	55.0 ± 1.0
	298.1	55.0

however, between cesium and sodium amalgams. The data of Table VI have been plotted in Fig. 5. It thus appears that the value for β is about the same for a sodium amalgam at 298°K., a potassium amalgam

Fig. 5.—The variation of $-\beta$ (in the equation $\log a_1/N_1 = \beta N_2^2$) with the temperature.

at 580° and a cesium amalgam at 770°. Doubtless the curves in Fig. 5 should not be straight lines, but since the data are not of sufficient accuracy to determine the curvature it has seemed better to draw them so. A straight line implies that the relative partial molal heat content of the

mercury is independent of the temperature. The equations for these curves are: $\beta_{\text{Cs}} = 15,620/T$, $\beta_{\text{K}} = 11,630/T$ and $\beta_{\text{Na}} = 3930/T + 6.84$. Combining these equations with Equations (1) and (2) (simplified) we obtain the expressions

$$\begin{aligned}\log a_1/N_{1\text{Cs}} &= -\frac{7810}{T} N_2^2 \\ \log a_1/N_{1\text{K}} &= -\frac{5815}{T} N_2^2 \\ \log a_1/N_{1\text{Na}} &= -(1965/T + 3.42) N_2^2 \\ \log a_2/N_{2\text{Cs}} &= -\frac{15,620}{T} N_2 + C \\ \log a_2/N_{2\text{K}} &= -\frac{11,630}{T} N_2 + C \\ \log a_2/N_{2\text{Na}} &= -(3930/T + 6.84) N_2 + C\end{aligned}$$

The expressions for the activity of the mercury a_1 are supported by experimental data up to a concentration of $N_2 = 0.5$. The expressions for the activity of the solute are of use in this simplified form to a concentration of $N_2 = 0.05$. Using the more exact expression of Equation (2), or its equivalent $\log a_2/N_2 = -1/2\beta N_1^2 + C'$, values for the activity of the solute may be obtained up to a concentration of $N_2 = 0.5$. The value of the constant C has been obtained only in the case of sodium amalgams at 25° , in which case it has been found to be 12.8935.

Compound Formation

Departure from perfect solution has frequently been explained by the assumption of compound formation.¹⁰ A large number of compounds have been shown to exist¹¹ in the solid phase for sodium amalgams, suggesting the calculation of the vapor pressure of amalgams from these data.

Fig. 6 gives three curves, A, B, C, calculated by assuming in each case the formation of one compound, namely, NaHg_2 , NaHg_4 and NaHg_{16} . The first two of these compounds are indicated by the cooling curve while the compound NaHg_{16} merely indicates an approximate formula which would be necessary to explain the behavior of dilute amalgams if only compound formation is considered. It will be observed that through a limited range each curve corresponds more or less closely with the smooth curve through the experimental points. In more dilute solutions the first two curves give too high an activity, and in more concentrated solution too low an activity. The second of these deviations may be accounted for to some extent by assuming dissociation of the compound. This has been done in Curve D, Fig. 6, by assuming the equilibrium constant $K = a_{\text{NaHg}_2}/a_{\text{Na}}a_{\text{Hg}}^2 = 1000$. By assuming similar dissociation for the other

¹⁰ Ref. 1, p. 72.

¹¹ Schüller, *Z. anorg. Chem.*, **40**, 385 (1904).

compounds it is possible to approach the experimental data through a narrow range of concentration, the agreement suggesting that compound formation is involved, but the results are far from satisfactory.

Doubtless the true state of affairs is to be represented by the existence of a large number of compounds simultaneously, each with its characteristic dissociation constant. The attempt has been made to see to what extent such an assumption accounts for the behavior of the amalgams.

The following solution of the problem has been suggested by Professor Scatchard and is based on the assumption of definite compounds, dissociating in accord with the mass law, each molecular species obeying Raoult's law.

"Given a system made up from 1 mole of sodium and n moles of mercury. The activity of the mercury is a ; the number of moles of mercury in the system is (Hg); the number of moles of sodium (0); the number of moles of NaHg_2 (2); of NaHg_4 (4); of NaHg_6 (6). We have the following equations

$$(2) = Ka^2(0) \quad (1)$$

$$(4) = K'a^4(0) \quad (2)$$

$$(6) = K''a^6(0) \quad (3)$$

$$n = (\text{Hg}) + 2(2) + 4(4) + 6(6) \quad (4)$$

$$1 = (0) + (2) + (4) + (6) \quad (5)$$

From (5)

$$\frac{\text{Hg}}{1 + (\text{Hg})} = \frac{a}{1 - a} \quad (6)$$

Substituting from Equations (1), (2) and (3) in (5) gives

$$1 = (1 + Ka^2 + K'a^4 + K''a^6) \cdot (0) \quad (7)$$

Substituting from (1), (2), (3), (6) and (7) in (4) gives

$$n = \frac{a}{1 - a} + \frac{2Ka^2 + 4K'a^4 + 6K''a^6}{1 + Ka^2 + K'a^4 + K''a^6} \quad (8)$$

Curves A, B and C are calculated by assuming complete formation of the compounds NaHg_2 , NaHg_4 and NaHg_6 , respectively, while D is calculated by assuming partial dissociation of NaHg_2 .

Fig. 6.—The activity of mercury calculated by assuming compound formation, compared with experimental values.

By means of Equation (8) very good agreement with the experimental data was obtained for a limited range of concentration by allowing K'' to equal zero and determining K and K' by successive approximations. The smooth curve through the experimental points in Fig. 6 is calculated

Curves A, B and C represent the mole fraction of NaHg_2 , NaHg_4 and NaHg_{16} , respectively.

Fig. 7.—The constituents of sodium amalgam calculated by assuming three compounds existing simultaneously.

suggests that n may be larger than 15.7. Millar has pointed out that n may be larger than 10 for potassium amalgams. It is interesting to note that if no change in atomic volume is experienced on the formation of such a compound, there is room on the surface of a sodium atom for 16 mercury atoms. A further test of the validity of the assumption of this compound is obtained

by assigning values to all three constants and agrees, within the limits of experimental error, with the experimental data from $a_1 = 0.1$ to $a_1 = 0.9$. The values chosen for the constants are as follows: $K = 500$; $K' = 2000$; and $K'' = 4000$.

The assumptions involved in the above calculations are that there are five molecular species present in a sodium amalgam and that these all obey Raoult's law. Doubtless other compounds are present and other factors would have to be considered for an exact treatment of the behavior of these amalgams. It is interesting, however, that such a simple picture should account so well for their behavior. A clearer idea of the constitution of the amalgams suggested by these calculations is obtained from Fig. 7. In Fig. 7 the activity (or mole fraction) of each constituent is plotted against the mole fraction of mercury in the amalgam.

The existence of such a compound as NaHg_{16} (C, Fig. 6) is also suggested by the work of Poindexter. This author suggests

by calculating the dissociation constant for the compound from the measurement of Lewis and Kraus and then calculating the data of Richards and Conant from this constant. Curve B, Fig. 4, has been calculated in this manner and agrees within the limits of experimental error to a concentration of $N_2 = 0.02$. The value found for the dissociation constant is 12.8579.

Summary

1. The vapor pressures of sodium and cesium amalgams have been measured at temperatures from 554 to 651°K. and at concentrations from $N_1 = 1$ to $N_1 = 0.5$. The data may be represented by the equation $\log a_1/N_1 = KN_2^2/T$.

2. The relative partial molal heat content of mercury in the amalgams has been calculated from the temperature coefficient of the activity, making possible the calculation of the free energy of transfer of mercury in amalgams at intermediate temperatures and over the range of concentration studied.

3. Approximate values have been obtained for the free energy of transfer of alkali metal to amalgam.

4. Values of the constant β , which expresses the deviation of both solvent and solute from Raoult's law, are compared for sodium, potassium, cesium and barium.

5. The whole of the deviation from perfect solution exhibited by sodium amalgams can be explained on the assumption of compound formation. The compounds NaHg_2 , NaHg_4 and NaHg_6 explain the vapor pressure of amalgams from an activity of 0.1 to 0.9, while in very dilute amalgams the compound NaHg_{16} explains both vapor pressure and e.m.f. data.

PUBLISHED DECEMBER 10, 1927

Arc Spectrographic Detection and Estimation of Germanium

The emission spectrum of germanium contains a number of persistent lines which, as is the case with all metals and with a few non-metals, lie in the optical spectral range. These lines serve admirably for the detection of small quantities of germanium, and in connection with some of the less persistent lines they can be used in the quantitative estimation of this element. A direct current arc of about half a kilowatt made between two electrodes of pure graphite was used for spectral excitation. The spectrograms were prepared with the aid of a quartz spectrograph of the Littrow auto-collimating type² using double-coated ortho photographic plates.³ 1.4408 g. of pure germanium dioxide was introduced into water, solution being effected with the aid of the least amount of potassium hydroxide, and the volume was made up to 100 cc., thus furnishing a solution containing an equivalent of one gram of germanium per 100 cc. From this stock solution, solutions containing 0.1, 0.01, 0.001, 0.0001 and 0.00001 g. of germanium per 100 cc. were prepared. The arc discharge was passed between the graphite electrodes for a few moments; it was then interrupted, to allow the electrodes to cool somewhat, and while the latter were still warm, a small, definite portion of each solution was placed on the lower electrode. These portions consisted of one-tenth cc. of solution and were delivered from a calibrated capillary pipet holding in all 0.12 cc. and divided into fiftieths of a cubic centimeter. Different electrodes and a separate plate were used for each concentration, one spectrogram of the blank arc and four of the arc charged with the germanium material being obtained on a single plate. The charges actually placed on the lower electrodes contained 1, 0.1, 0.01, 0.001 and

¹ The investigation upon which this article is based was supported by a grant from the Heckscher Foundation for the Advancement of Research, established by August Heckscher at Cornell University.

This article is respectfully dedicated by the authors to Professor L. M. Dennis, and will be reprinted as Article No. 6 in the Louis Munroe Dennis Quarter Century Volume to be published in 1928 in commemoration of the completion by Professor Dennis of twenty-five years of service as Head of the Department of Chemistry at Cornell University.

0.0001 mg. of germanium, respectively. The spectral lines observed at the different concentrations are given in Table I. In this table, as well as in those that follow, v signifies that the line in question is visible and f that it is faintly visible. The decrease of intensity has been brought about by the decrease of the quantity of material in the zone of excitation. The investigation was limited to the spectral range between λ 4682 and λ 2198 Å.

TABLE I
SPECTRAL LINES AT DIFFERENT CONCENTRATIONS

λ	1 mg.	0.1 mg.	0.01 mg.	0.001 mg.	0.0001 mg.	λ	1 mg.	0.1 mg.	0.01 mg.	0.001 mg.

2651.1 ^b	v	v	v	v	v	2314.2	v	f		
						2198.7	v	f		

^a Because of the low dispersion of a prism spectrograph in this range, λ 4226.6 of germanium is indistinguishable from λ 4226.7, a persistent line of calcium.

^b C. W. Gartlein of the Department of Physics, Cornell University, found that the wave length of this line is 2651.2 Å.

^c The wave length of this line was determined by C. W. Gartlein.

If germanium in any form in quantities larger than one milligram, be subjected to arc excitation, λ 2389.5, λ 2379.1, λ 2256.0 and λ 2246.4 will be visible in addition to the lines included in Table I. As seen from this table λ 3269.5, λ 2754.6, λ 2709.6 and λ 2417.4 are visible when 0.001 mg. of germanium is introduced into the arc, while λ 3039.1, λ 2651.6 and λ 2651.1 persist when one-tenth of this quantity is used. The *raies ultimes* of de Gramont⁴ are among these lines.

Occurrence of Germanium in Certain Tin Materials

Germanium-tin mixtures were prepared by mixing water solutions of germanium dioxide and stannous chloride in such proportions as to have 0.0001 mg. of germanium with tin varying in quantity from 0.01 mg. up to one milligram. Similar mixtures with higher germanium concentrations, using fixed alkali germanates, were also prepared. As ex-

⁴ De Gramont, *Compt. rend.*, 171, 1106 (1920). See also Foote and Mohler's "The Origin of Spectra," The Chemical Catalog Company, Inc., New York, 1922, p. 143.

pected, the presence of tin had no influence upon the spectral lines of germanium except in cases of lowest germanium concentration. When 0.0001 mg. of this element in a mixture with tin was subjected to spectral excitation, the persistent lines of germanium were much fainter than when germanium alone is used. Twelve tin minerals⁵ were subjected to arc spectrographic examination for the presence of germanium in the following manner. They were ground finely and definite quantities of each were introduced into the arc. These quantities varied from 6 to 10 mg. Several successive exposures were obtained from each mineral sample without replenishing the arc with fresh material; in this way it was observed that in the case of some of the minerals lines due to germanium were present in the first spectrogram only, while in the case of others they also appeared in those that followed. The results which were obtained from an examination of the spectral range between λ 3040 and λ 2590 are summarized in Table II.

TABLE II
GERMANIUM LINES IN SPECTROGRAMS OF TIN MINERALS

Cassiterite, King Mountain, North Carolina	Absent

Eight of the twelve tin minerals subjected to spectrographic analysis were found to contain traces of germanium. The estimated percentage of germanium in these minerals, which is given in the last column of Table II, was obtained as follows. A record was made of the spectral lines of germanium as observed in connection with each mineral. It was then assumed that a definite weight of germanium, say in milligrams, capable of yielding these particular spectral lines was present in the zone of excita-

⁵ Kindly supplied by Dr. David White of the U. S. Geological Survey.

tion. Knowing the quantity of each mineral subjected to excitation it was a simple matter to estimate its germanium content. This method has been found in our Laboratory to give fairly satisfactory results in a good many cases where the element to be estimated quantitatively is present in traces. It is important that minimum quantities of the crude material or mixture containing the element in question be introduced into the arc.

" Because of the extremely high lead content of this ore, the lead line λ 2651.7 was so wide that it completely obstructed the two germanium lines $\lambda\lambda$ 2651.5 and 2651.1.

Enargite as a Possible Source of Germanium

Enargite is a fairly common copper-bearing mineral in which this element is combined with arsenic and sulfur and associated with traces of other elements. Specimens of this mineral from various localities were investigated spectrographically for the presence of germanium. The method followed was similar to the one used in connection with the tin minerals and the results are recorded in Table III.

Since some of these ore minerals were available in comparatively large quantities, work was undertaken to extract germanium from them. The ore was ground finely, placed in a Pyrex distilling flask and decomposed with nitric acid. The contents were heated to dryness over a steam-bath, sulfuric acid was added and heat was applied until the oxides of nitrogen were driven off. Hydrochloric acid was then added and the whole saturated with chlorine and distilled in a slow current of this gas. Samples of the residue were tested from time to time spectrographically for the presence of germanium and the distillation was discontinued when germanium was found to be totally absent or present in negligibly small traces. The distillate which contained germanium tetrachloride was collected in a cooled receiver and saturated with hydrogen sulfide. The germanium disulfide thus obtained was removed and converted to the dioxide.

The method developed by Dennis and Johnson⁶ was used to determine germanium quantitatively in some of the enargite ores. It was necessary, however, to modify this method slightly in its initial stage. The weighed sample of enargite was decomposed in the manner just described in connection with the extraction of germanium from this mineral. The residue, freed from the oxides of nitrogen, was subjected to the hydrochloric acid-chlorine distillation. Determinations made on two samples of enargite gave the following results:

	Enargite No. 1	Enargite No. 5
Weight of enargite	50 g.	100 g.
Weight of GeO_2 extracted	0.0238 g.	0.0192 g.
Percentage of germanium	0.033	0.013

The enargite minerals dealt with in the present investigation contained much less germanium than the rare minerals argyrodite, canfieldite and germanite. Nevertheless, enargite, because of its availability, can be used as a source of this element. In school laboratories where students do experimental work with the so-called rarer elements, enargite can be made to serve as the crude material from which to extract germanium. In view of the variation of the germanium content in the different samples of enargite, it is possible that some enargites not as yet investigated are considerably richer in germanium. Ordinary copper of commerce is

⁶ Dennis and Johnson, *THIS JOURNAL*, 47, 790 (1925).

known not to contain germanium, and since large quantities of copper are obtained from enargite, it is not impossible that at some stage of smelting or refining the germanium contained in the ore is concentrated in some waste product or by-product. We know that this happens in the case of certain zinc ores containing minute traces of germanium; these traces are increased to a very appreciable content in a by-product during the process of smelting.⁷ It is our intention to extend the present investigation to copper smelter materials in hope of finding germanium in a form more concentrated than in the original enargite.

Summary

The arc spectral lines of germanium and the concentrations at which they appear were given.

The presence of traces of germanium in certain tin ores was noticed. A method was given for the estimation of traces of germanium.

Germanium was found to be present in appreciable traces in certain varieties of enargite.

A method for the extraction of germanium from enargite was described.

THE INFLUENCE OF RADIATION ON THERMAL UNIMOLECULAR REACTIONS

By JOSEPH E. MAYER

RECEIVED AUGUST 12, 1927

PUBLISHED DECEMBER 10, 1927

Introduction¹

The concept of molecules of high energy content as the reacting molecules in chemical reactions was first introduced by Arrhenius² primarily to explain the high temperature coefficient of most reactions. Although this theory has been generally accepted, there has been considerable dispute as to whether the mechanism of activation is by collisions between molecules or by the absorption of radiation. The radiation hypothesis, first suggested in a rather vague form by Trautz³ and later elaborated by W. C. McC. Lewis⁴ and by Perrin⁵ appeared to be much strengthened by

investigations of Hirst and Rideal⁶ who showed that the specific rate of the unimolecular decomposition of nitrogen pentoxide was as high or higher at very low pressures than at normal concentrations.

Various investigators⁷ have pointed out that the observed reaction rate demands a higher rate of activation than seems likely to be afforded by radiation even under favorable circumstances. Lewis and Smith⁸ showed that in the case of nitrogen pentoxide a high coefficient of absorption for radiation over a considerable range of the spectrum would account for the observed rate if the absorption of radiant energy alone were responsible for activation.

Later, measurements of absorption coefficients for nitrogen pentoxide in the infra red to wave lengths of about 7μ were published by Daniels.⁹ These were much lower than the values found necessary by Lewis and Smith⁸ to account for the observed decomposition rate. However, the absorption showed a noticeable trend, increasing with the wave length in the range studied. In view of this, and the fact that the greater part of the energy in the spectrum at room temperature lies at longer wave lengths, it was considered advisable to make rough measurements on the absorption coefficients farther in the infra red. The experiments are described and the results given later in this paper.

Daniels¹⁰ also measured the decomposition rate of nitrogen pentoxide exposed to the radiation from a Nernst glower, and found no increase in rate other than that due to the rise in temperature of the gas. This would be expected on the modified form of the radiation hypothesis in which it is postulated that the energy of activation is acquired, not by the absorption of one high energy quantum by a molecule of average energy, but by the consecutive absorption of many quanta of low energy. At normal pressures, collisions of the second kind would distribute the energy of partially activated molecules between successive quantum absorptions according to the Maxwell distribution law, raising the temperature of the gas. The rate would then at all times be determined by the measured temperature of the mass of the gas. Experiments of this type are also open to the objection that the effective radiation may be wholly absorbed by a very thin layer of the gas at the high pressure employed and not reach the main body of the reacting material.

Professor G. N. Lewis suggested that it would be advisable, therefore, to study the influence of radiation on the rate of a unimolecular reaction in the absence of collisions, and at such low concentrations that the absorption would not materially affect the density of radiation of any fre-

quency throughout the reacting material. In order to do this a molecular stream was employed. Because of the necessity of maintaining the rectilinear nature of the stream it was considered inadvisable to employ nitrogen pentoxide or any molecule which breaks into two or more parts at the moment of reacting.

Pinene was therefore used, the racemization of which had been shown by Smith¹¹ to be one of the most satisfactory unimolecular reactions.

A similar experiment on the dissociation of iodine molecules in a molecular stream under the influence of radiation was performed by Kröger.¹² In this case, however, the order of the reaction at normal pressures has not been determined. Later work¹³ on the heat of activation of the reaction from considerations of band spectra data makes possible recalculation of Kröger's data. This has been done and the results are recorded later in this paper.

The Total Absorption Coefficient of Nitrogen Pentoxide for Infra Red Radiation

Apparatus.—The study of absorption spectra at long wave lengths is made difficult by the fact that all materials which may be used as windows and prisms at shorter wave lengths absorb too highly for applicability in the extreme infra red. A very simple apparatus without windows was suggested by Professor Lewis with which determinations could be made of the coefficient of total absorption over all the black body spectrum at low temperatures. The source consisted of a black body kept at constant temperature, and the receiver was a sensitive thermopile.

Owing to the absence of windows a vacuum thermopile could not be used. The thermopile employed consisted of eight "Ideal" to "Manganin" junctions. The thermopile was some three inches long and could be slipped down the neck of an ordinary 500cc. flask as shown in Fig. 1; it was rigidly attached to a glass stopper, a glass tube carrying the leads out of the apparatus. The flask in which the thermopile was enclosed was blackened on the inside with lampblack and was placed in a metal container so that it could be completely surrounded with ice and water. A short neck through which the thermopile could be illuminated, projected from the side of the flask through the walls of the container. A sensitive galvanometer was connected to the thermopile, the deflection of which was read directly and used as a measure of the radiation intensity.

The absorption cell consisted of another 500cc. flask with two short necks sealed at opposite sides and projecting through the ends of a trough which surrounded the cell. The ends of the two necks which were flush

¹² Kröger, *Z. physik. Chem.*, **117**, 387 (1925).

¹³ Franck, *Trans. Faraday Soc.*, **21**, 536 (1926).

with the ends of the trough, were closed by sliding shutters. The shutter at the end facing the thermopile could be filled with ice and water in order to maintain it at the same temperature as the rest of the wall surrounding the junctions.

The radiator was a glass flask, coated outside with lampblack, in which water or any other liquid could be boiled to maintain it at constant temperature.

Experiments.—By observing the galvanometer deflection at definite times after opening the shutter, the absorption coefficient was determined with pure dry air and with nitrogen pentoxide at known pressure in the absorption cell. After twenty seconds the galvanometer had prac-

Fig. 1.

tically come to equilibrium; the ratios of the two deflections, both at twenty seconds or both at thirty seconds, gave the same results within the limit of experimental error.

The partial pressure of nitrogen pentoxide was maintained by placing crystals of it with phosphorus pentoxide in the bottom of the cell, and in addition slowly introducing dry air which had been passed over crystals at the same temperature as the cell. The large volume of the cell compared with the small openings at the ends, some two square centimeters' cross section, together with the slow addition of gas, was considered sufficient to maintain a constant pressure over the short period of time the shutters were opened.

Boiling water and boiling acetophenone (202°) were used as temperature controls for the radiator.

Table I shows the recorded data for a typical experiment.

TABLE I
 DATA OF A TYPICAL EXPERIMENT

Time	Galvanometer scale readings in tenths of mm. for time in sec. from opening of shutters						Galvanometer deflections from zero time in tenths of mm.		Average deflections and fraction transmission

	12	178		203	208	214	191	202		

The absorption cell was 14.3 cm. long and the pressure of nitrogen pentoxide (26.8°) was 495 mm., the black body at 202°.

The ratios for the thirty-second and for the twenty-second deflections represent the fraction transmission of the gas. These agree with each other within the limits of experimental error, the values at thirty seconds being generally the more reliable. The average of these is taken as the result for this experiment.

 TABLE II
 SUMMARY OF EXPERIMENTAL RESULTS

13	.0	51	.786	202	9.20

Owing to the fact that the transmission was measured directly, the absorption, which is the logarithm of the reciprocal of the transmission, could not be obtained with any accuracy at low pressures. Even at 0° , at which temperature the pressure is 51 mm. and the absorption about 9.2%, the results were extremely erratic. Table II shows a summary of the experimental results.

In Table II, Col. 1 is the number of the experiment, Col. 2 the temperature of the absorption cell, which temperature controls the pressure of nitrogen pentoxide given in Col. 3. Col. 4 is the transmission, or fraction of the total energy incident on the thermopile after passing through the cell containing nitrogen pentoxide. Col. 5 is the temperature of the black body radiator. The value of the absorption coefficient ($\log 1/F)/c \times l$, in which c is the concentration in molecules per cc. and l is the length of the cell (14.3) in cm., is given in Col. 6.

Results.—The value of α obtained in Table II is found to be the same within the experimental error for the black body radiator at 100 and 202° . It is also found to be of the same order of magnitude as the absorption observed by Daniels⁹ for wave lengths shorter than 7μ .

The coefficient of absorption is the α of the equation

$$\frac{E_1}{E_2} = e^{\alpha \times l \times c} \quad (1)$$

in which E_1 is the energy incident upon, and E_2 the energy transmitted by, a cell of length l containing gas at a concentration c . This equation is strictly true only for energy of single frequencies. The α of Table II is the average of the α 's for all frequencies obtained, not by integrating the differential equation

$$\frac{\partial E_\nu}{E_\nu} = \alpha_\nu \times c \times dl \quad (2)$$

for all frequencies, but by determining the average α found in the integrated form. The α_0 or average of the α_ν in the differentiated form, which would experimentally be the α at zero values of concentration times length of cell, would be expected to be larger than the values found at high pressures. To estimate the value of α_0 , the logarithm of α has been plotted against the pressure in Fig. 2 and the curve obtained has been extrapolated to the axis of zero pressure. The antilogarithm of the intersection has been taken as the most probable value of $\alpha_0 = 3 \times 10^{-20}$.

Although the value of α_0 so obtained may be in error ten-fold, the observations are sufficiently accurate for the purpose of the experiment. In the units in which α_0 is expressed it represents the fraction of a beam of black body radiation one square centimeter in cross section which would be extinguished by a single molecule of nitrogen pentoxide. The maximum value of α_0 calculated by Lewis and Smith⁸ is the cross section of the quantum as derived from their equation

$$\alpha_0 = \sigma = \frac{\lambda^2}{8\pi} = \frac{c^2}{8\pi \nu^2} \quad (3)$$

Taking the wave length $\lambda = 9\mu$ as that corresponding to the greatest energy in the black body spectrum at 300°K. , we find that by equation (3) the cross section $\sigma = 3.2 \times 10^{-8} \text{ cm.}^2$ is found to be 10^{12} times the value of α_0 found in this experiment.

Using the maximum value of the absorption coefficient from their equation, Lewis and Smith⁸ calculated the reaction rate constant of nitrogen pentoxide to be $3 \times 10^2 \text{ sec.}^{-1}$ at 300°K. , which is 10^7 -fold greater than the experimental value of $4 \times 10^{-5} \text{ sec.}^{-1}$. The absorption coefficient determined experimentally should then be expected to give a rate of

about 10^5 -fold too little. Calculations have been made, assuming nitrogen pentoxide to be a molecule of 14 degrees of freedom, as do Lewis and Smith, integrating the number of molecules absorbing quanta of sufficient energy to activate them over the total number of molecules, and using the same absorption coefficient for all molecules and all wave lengths. The value of the rate constant $K = 1 \times 10^{-10} \text{ sec.}^{-1}$ so obtained is smaller than the experimental by a factor of 2.5×10^{-6} .

The Racemization of Pinene under the Influence of Radiation

Apparatus.—For the determination of the racemization of pinene under the influence of radiation in a molecular stream, a micro-polarimeter tube, the capacity of which was only one-tenth of a cubic centimeter, was used in the measurement of the optical rotation. It was necessary to collect about three-tenths of a cubic centimeter on the receiving surface to allow for the loss in transferring the liquid and in filling the tube. Stern¹⁴ showed that in a molecular stream determined by two slit orifices the

¹⁴ Stern, *Z. Physik*, 39, 751 (1926).

maximum concentration in the stream was independent of the width of the first orifice, hereafter called the nozzle to avoid confusion with the second, or defining, orifice. This is necessitated by the fact that the maximum pressure which may be permitted in the gas behind the nozzle is such that the mean free path of the molecules is of the order of magnitude of the width of the slit, in order to avoid collisions after emission into the first chamber. In the case of a nozzle of circular cross section, however, the maximum obtainable concentration in the stream will increase with the diameter of the nozzle, since the quantity of gas flowing through at any given pressure increases with the cross-sectional area, or square of the diameter of the nozzle; whereas the maximum permissible pressure decreases with the first power of the diameter. The stream will then be expected to remain perfectly defined by the geometrical design of the apparatus, and the

Fig. 3.

quantity of material incident on the receiving plate will increase directly with the pressure up to this threshold value. Above this pressure the stream loses its perfect definition and becomes fuzzy at the edges. It was found experimentally, however, that the amount of material collected on the receiver increased directly with the pressure far above this maximum pressure. At these higher pressures the radius from the nozzle, beyond which the concentration of the gas is so low that no collisions between molecules take place, can be calculated, and this radius, rather than the diameter of the nozzle, is the significant factor in determining the dimensions of the stream. Since perfect definition of the stream was not required in this experiment, but merely the inclusion of all but a small fraction of the pinene within certain limits, to avoid contact with the furnace, the experiments were performed with a greater pressure behind the nozzle than would be permissible for most molecular stream work.

The molecular stream apparatus was constructed of Pyrex glass, as shown in Fig. 3. A tube wrapped with nichrome wire and having a thermocouple inside of it projected downward into a chamber; the end of the tube, drawn to a nozzle, was 3 cm. above the center of a circular orifice 7 mm. in diameter which defined the stream. Below this orifice the stream passed into a glass tube about 6 cm. in diameter which carried the furnace and on the bottom of which the pinene impinged. The bottom of this tube was drawn to a fine teat for convenience in draining. The complete apparatus was immersed in liquid air during the experiments. The nozzle had a smallest diameter of one millimeter and flared outward slightly after the design of steam turbine nozzles. The first chamber was connected by means of short glass tubing over 2 cm. in diameter through a liquid-air trap to a mercury-vapor vacuum pump which pumped directly into a high vacuum line evacuated by a second such pump. A McLeod gage measured the pressure in this secondary vacuum line, the construction of the lines being such that the pressure in the apparatus was less than one quarter that measured in the gage.

To produce the radiation field a cylindrical quartz tube 33 mm. in diameter and 35 mm. high was nicked at the ends with a saw and wound longitudinally inside and out with platinum wire. About 390 cm. of wire 0.508 mm. in diameter, making 55 complete turns, was used. The furnace was supported in the chamber by its heavy copper leads

and by five tungsten wires, projecting radially inwards from short side tubes in the wall of the chamber. The inner walls of the chamber were silvered to reduce loss of radiation to the liquid air. A voltmeter connected to the leads into the furnace, together with an ammeter in series with the circuit, permitted measurements of the energy input.

Experiments.—The pinene used was distilled several times into liquid air under a high vacuum to remove residual gases. Immediately before the experiment sufficient material for the run was redistilled into a container connected to the nozzle. The apparatus was well baked out, surrounded with liquid air and the nozzle and furnace heated to the desired temperature. The pinene was then allowed to pass through the nozzle at 4mm. pressure by lowering a mercury trap.

During the course of the experiment frequent observations were made of the temperature of the nozzle, which was maintained within 3 of 93°, and of the amperes flowing through the furnace and the voltage at the leads. In the last experiment made at the highest temperature the ammeter reading was 6.1 amperes with a maximum variation of 0.1 ampere, and the voltmeter read 53.2 volts with a variation of 1 volt. The pressure was measured, by means of the McLeod gage, frequently during the experiment and was always observed to be less than 10^{-4} mm. after the experiment had been going on for a few minutes. As before mentioned, the pressure in the apparatus was probably less than one quarter of this value.

When all the pinene had passed into the apparatus the furnace current was stopped and air permitted to enter the chambers. The liquid air was removed and the pinene drawn out of the bottom of the furnace chamber by breaking the teat.

During all distillations of pinene, mercury from the traps collected on the liquid-air cooled surface with the pinene and formed a black, colloidal solution. After standing for an hour, the mercury settled to the bottom, leaving clear pinene. The liquid collected in the apparatus was similarly black at first but after standing became as clear as the original sample.

If pinene were allowed to strike the furnace at the temperature of the experiment sufficient decomposition resulted to create a marked increase in pressure. The fact that the pressure remained low during the course of the experiments was considered sufficient proof that no appreciable quantity of pinene touched the furnace. There was always observed a slight increase in pressure at the beginning of the experiment, probably due to traces of residual gases in the liquid.

About 4 cc. of pinene passed through the nozzle per hour, three hours being necessary to collect sufficient material at the receiving surface to insure ease of analysis.

After the experiments were completed a black thermocouple was sealed into the bottom of the furnace chamber. The temperature observed in the center of the furnace under conditions duplicating an experiment recorded the density of radiation through which the stream passed. During the course of the experiments, due largely to the distillation of platinum from the furnace and to several minor accidents of operation, the silvered walls of the furnace chamber had become blackened. Calculations at that time showed them to be less than 50% reflecting. Undoubtedly during the experiments, especially the earlier ones performed when the mirrored walls were in good condition, the density of radiation was much higher than that about to be calculated, making the results even more conclusively unfavorable to the radiation hypothesis than the succeeding calculations would indicate. The resistance of a piece of the same platinum wire that was used in the furnace was determined at 0°, at 100°, and at 444.6°. This calibration and the measured resistances of the furnace at 0° and during the experiments made possible fairly accurate estimates of the average temperature of the platinum wire when the furnace was in operation.

About six experiments in all were completed, the radiation density in the furnace chamber corresponding to temperatures of from 830°K. to 1053°K. In none of the

experiments was there a detectable racemization. The optical rotation could be measured in the micro-polarimeter tube which was used to an accuracy of about 3%.

Conclusions

The geometrical dimensions of the furnace were such that it subtended the 0.726 part of the complete solid angle about a point in the center. The platinum wire covered 0.270 of the total area of the inside surface of the quartz. From this, and from an equation given by Geiss¹⁵ for the emissivity of platinum at the temperature T ,

$$E = \gamma T^{\phi} \sigma T^4 \quad (4)$$

in which $\gamma = 6.22 \times 10^{-4}$, $\phi = 0.767$, and σ is the Stefan Boltzman radiation constant, it was calculated that the energy density of radiation emitted from the platinum wire should be, at a point in the center of the furnace,

$$U_{Pt} = 0.726 \times 0.270 \times \gamma \times T_{Pt}^{\phi} \times C \times T_{Pt}^4 \quad (5)$$

in which CT^4 is the density of radiation in a hohlraum completely surrounded by walls at the temperature T .

Assuming quartz to be 90% a black body, since the temperature was such that most of the emitted radiation was of longer wave length than the limit of transparency, the contribution of the quartz to the radiant energy at a point in the center was calculated to be

$$U_Q = 0.726 \times 0.730 \times 0.900 \times C \times T_Q^4 \quad (6)$$

The actual density of energy was known to be

$$U_T = C \times T_{th}^4 \quad (7)$$

from the measured temperature T_{th} of the thermocouple. Using the average temperature of the platinum wire determined from the resistance data for T_{Pt} , and equating the sum of equations (5) and (6) to equation (7), the temperature of the quartz, T_Q , was evaluated.

The density of energy of various frequencies in a hohlraum at the temperatures T_{Pt} and T_Q was calculated from the Planck equation, the densities for T_{Pt} were multiplied by the factor $(0.726 \times 0.270 \times \gamma \times T_{Pt}^{\phi})$, and those for T_Q by $(0.726 \times 0.730 \times 0.900)$; the two were then added. The results for the different experiments were represented by curves of densities plotted against frequencies.

To determine the lowest temperature at which pinene should show noticeable racemization in the time of the experiment, use was made of the experimental equation relating the specific reaction rate constant K to the absolute temperature T .

$$K = ke^{-h\nu/KT} \quad (8)$$

in which $\nu = 4.60 \times 10^{14} \text{ sec.}^{-1}$, the frequency corresponding to the energy of activation, 43,710 calories, found by Smith,⁸ and k is a constant having the value $2.6 \times 10^{14} \text{ sec.}^{-1}$.

¹⁵ Geiss, *Physica*, 5, 203 (1925).

From the velocity of the molecules leaving the nozzle and the length of the radiation field, the time during which the molecules were exposed to the radiant energy was calculated to be 1.2×10^{-4} sec. Using this time and assuming that the reaction could be detected if it progressed 6% (about twice the experimental error in reading the polariscope), the value which the reaction rate constant K would have in order that the pinene should be racemized was calculated to be 431 sec.^{-1} . This value was used in equation (8) and T_m , the minimum temperature at which pinene should show appreciable (6%) racemization in the time for which it was exposed to the radiation of the furnace, was determined to be 800°K .

Fig. 4.

In Fig. 4 the curve for the energy density of radiation plotted against the frequency as calculated from the Planck equation is given for $T = 800^\circ$. Curves 5 and 6 in the same figure are the curves for the distribution of radiation in the furnace chamber under the conditions of Experiments 5 and 6, the highest temperatures at which observations were made. In these experiments the average temperatures of the platinum wire were 1700°K . and 1790°K ., respectively, the temperature of a black body in equilibrium with the radiation in the center of the chamber 1004°K . and 1053°K ., and the calculated temperature of the quartz 1065°K . and 1123°K ., respectively.

The curves show that for Experiment 5 above frequencies of 3×10^{18} [$\lambda = 10\mu$] and for Experiment 6 above frequencies of 2×10^{18} [$\lambda = 13\mu$]

the radiation in the furnace chamber is of greater density than in a hohlraum at 800°K. The curve for radiation in a hohlraum at 1000°K. is also shown in the figure. At this temperature only the 10^{-6} part of the pinene should have remained unracemized. The greater part of the curves of both experiments lies above the curve for 1000°K.

Kröger¹² has attempted to measure the dissociation of iodine in an apparatus similar to the one employed in this research, using a cylindrical platinum furnace. Calculations were made on the basis of these data, using a theoretical heat of activation not available to Kröger at the time of publication. Franck¹³ has shown that the energy to which an iodine molecule must be raised by the absorption of radiation in order to dissociate is greater than the heat of dissociation by 22,000 cal. Using the heat of activation thus calculated, 57,000 cal., we may estimate the rate of dissociation of iodine at any temperature by the use of the equation first proposed by Dushman¹⁴

$$K = \nu e^{-h\nu/KT} \quad (9)$$

which differs from Equation (8) only in the substitution of ν for the experimentally determined k . This equation has been found to agree closely with the experimental rate constants of all the unimolecular reactions so far investigated, and although all theoretical derivations so far advanced may be objectionable it appears to be empirically applicable to unimolecular rate constants.

Kröger states that in his experiments no dissociation was observed and that the accuracy of his measurements was of the order of 1%. Following the method employed with pinene and assuming the length of his radiation field to be 6 cm., and the velocity of the molecules to correspond to 29.3°, we find the T_m in this case to be 934°K. Kröger estimates the temperature of his furnace in the experiment at the highest temperature to be 1300°K. At this temperature the density of radiation of frequency 6×10^{14} , chosen as a convenient reference since it is the frequency corresponding to the heat of activation, is about 10^4 -fold the density of the same frequency at 934°K. The density in the furnace chamber of all frequencies must be smaller than that calculated for 1300°K. by some factor dependent on the shape of the furnace employed, and for sufficiently low frequencies this factor would decrease the density to a lower value than that corresponding to a hohlraum at 934°K. It, nevertheless, appears evident that the rate of dissociation of iodine by radiation alone is much slower than that calculated by Equation (9).

In the case of iodine the rate of dissociation, by radiation, using the calculated heat of activation, is lower than the rate of reaction normally found in thermal reactions of the same energy of activation, whereas the

¹⁴ Dushman, *THIS JOURNAL*, 43, 397 (1921).

experiment with pinene shows that using the known (extrapolated) rate, radiation alone does not cause reaction.

Theoretical Discussion

The results of these experiments appear definitely to show that in neither of the two reactions considered, the decomposition of nitrogen pentoxide or the racemization of pinene, can the activation by the absorption of radiant energy alone be of sufficient rapidity to play an important role in the reaction.

It should be pointed out, however, that in the calculations of the probable rate of activation by collisions as made by Rice and Ramsperger¹⁷ the chance that one molecule of energy ϵ will acquire an additional energy $\Delta\epsilon$ in one collision drops rapidly as the value of ϵ , the energy which the molecule already possesses, is increased. The chance that a molecule of energy ϵ will acquire the additional energy $\Delta\epsilon$ in a fixed period of time by the absorption of radiant energy depends only on the density of radiation of frequency $\nu = \Delta\epsilon/h$, and on the absorption coefficient of the molecule for radiation of this frequency. The smaller energy difference between quantum states at high energies and the greater *a priori* probability of the higher states indicate that the absorption coefficient for low-frequency radiation may increase rapidly with the energy ϵ of the molecule. This is in accord with the experimentally observed increase in the infra red absorption coefficients of many gases with rise in temperature.

It is probably true, therefore, that as we consider higher and higher steps of energy acquisition the relative importance of the absorption of radiation increases in comparison to the transfer of energy by collisions. However, calculations already made of the rate of activation by radiation, using the absorption coefficient of nitrogen pentoxide, expressly included the possibility of activation by the absorption of low energy radiation by molecules of high energy existing in equilibrium numbers. It would, therefore, be necessary, if this process is to play an important part in the normal mechanism of activation, that these molecules of abnormal energy (but unactivated) possess an enormously higher absorption coefficient than the normal molecule.

In this case the absorption of energy by collisions would be the mechanism of greatest rapidity up to a certain energy above which the activation due to radiation would become the predominant factor in the mechanism of producing activated molecules for the reaction. If such a mechanism were the true one the rate of the reaction could not be even approximately maintained in the absence either of collisions or of radiation. This possibility is in no way inconsistent with experimental facts presented here or elsewhere and should not be neglected in considerations

¹⁷ Rice and Ramsperger, *THIS JOURNAL*, 49, 1617 (1927).

of the possible mechanisms of chemical reaction. Such a mechanism would also show a lowering of the specific reaction rate at low pressures found for some typical unimolecular reactions by Hinshelwood and Thompson,¹⁸ Hinshelwood¹⁹ and Ramsperger,²⁰ and discussed by Rice and Ramsperger¹⁷ in connection with the mechanism of activation.

Acknowledgment should be made to Professor G. N. Lewis at whose suggestion this work was started and whose constant advice and aid made the research possible.

Summary

The absorption coefficient for black body radiation of low temperatures has been measured for nitrogen pentoxide. The values obtained were of sufficient accuracy to determine that the rate of activation of nitrogen pentoxide by radiation alone is of insufficient rapidity to account for the observed decomposition rate.

The racemization of pinene under the influence of radiation in a molecular stream was also studied. Under the conditions of the experiment there were no collisions and the concentration of gas was sufficiently low to avoid decreasing the radiation density by absorption in the outer layer. The concentration of radiation over the greater part of the frequency range was far above that in a hohlraum at a temperature sufficiently high to produce racemization in the time of exposure used in the experiment. No racemization was observed.

Attention was called to the fact that a theory involving both collisions and radiation as necessary for observed rates of activation was conceivable and not incompatible with experimental phenomena, although radiation *alone* could not be important in either of the two reactions studied.

A STUDY OF SUPERACID SOLUTIONS. I. THE USE OF THE CHLORANIL ELECTRODE IN GLACIAL ACETIC ACID AND THE STRENGTH OF CERTAIN WEAK BASES

BY NORRIS F. HALL AND JAMES B. CONANT

RECEIVED AUGUST 16, 1927

PUBLISHED DECEMBER 10, 1927

It is well known that many substances which show no basic properties in water will nevertheless form salts. Thus the salts of various amides, many oxonium salts and the halochromic salts of unsaturated ketones may be prepared from an equivalent quantity of perchloric or sulfuric acid provided certain non-aqueous media are used. In the presence of water, however, such salts are often completely hydrolyzed. In this and the following paper we investigate certain of the properties of these solutions in which salt formation is exceptionally complete, and we propose to call such solutions "superacid solutions." The work of Brönsted¹ has done much to clarify the problem of the interrelations of acids and bases in different solvents, a problem which forms the general subject of the present series of papers, while the behavior of acids in non-aqueous media has been the subject of investigation by Hantzsch,² who has brought to light many important relationships in this field.

We attempted to attack this problem in a quantitative way by investigating the hydrogen-ion activity of various non-aqueous solutions and selected the e.m.f. method as initially the most promising, provided a suitable electrode could be found. If "salt-errors" are to be avoided, an electrode must be used in which the activities of all reacting electrode materials with the exception of the hydrogen ion are the same for all the solvents studied. Such electrodes are the hydrogen electrode, the two *saturated* quinhydrone electrodes of Biilmann³ and the various saturated electrodes investigated by Conant and Fieser,⁴ who studied many substituted quinones. The usefulness of the hydrogen electrode and of certain of the others is limited by the chemical reactivity of their active materials or by the susceptibility of the electrode to the action of "poisons." As a first solvent for investigation we chose acetic acid, because this substance has been repeatedly shown to be suitable for the preparation of salts of very weak bases. In this solvent the most suitable electrode appeared to be that formed by the completely chlorinated quinone (chloranil, tetrachloroquinone) and its hydroquinone. This electrode had already

been tested in acetic acid solutions in this Laboratory⁵ and found to be satisfactory. Its advantages over other saturated electrodes are (1) chemical inertness and (2) low solubility of the electrode materials.

To illustrate the principle of our method, let us consider the following electrochemical cell

Both electrodes are strictly reversible. When the cell operates, solid chloranil ($\text{C}_6\text{Cl}_4\text{O}_2$) is converted into hydrochloranil at one electrode and the reverse process occurs to the same extent at the other electrode, according to the following equation

This is obviously independent of the nature of the solutions in the two halves of the cell. If the bridge adequately eliminates the liquid junction potential, the e.m.f. of the cell (E) is a measure of the free-energy change attending the passage of one mole of hydrogen ion from one solution to the other.

E is thus a measure of the difference in the partial molal free energy of the hydrogen ion in the two solutions or of the difference of the logarithms of the corresponding hydrogen-ion activities, thus

$$\frac{\bar{F}''}{F} = \frac{RT}{F} \ln \left(\frac{a' \text{H}^+}{a'' \text{H}^+} \right) \quad (2)$$

If such a cell is to be used to determine the hydrogen-ion activity of one of the solutions, that of the other must be fixed by reference to some standard state. There are a variety of possible ways of selecting the standard state. It has seemed most desirable to us to choose for each solvent a particular solution of which the electrically measured hydrogen-ion activity is set equal to unity. This we have done for acetic acid as later described (p. 3059). Essentially the same thing has been done for water by assigning the single potential $E = 0$ to the "normal" hydrogen electrode.

To increase the reproducibility of our measurements we found it desirable to compare different acetic acid solutions, not directly with each other, but each separately with a standard aqueous reference electrode. In other words, we measured the e.m.f. of cells of the following type

regarding their potentials as positive when the platinum electrode was positive to the mercury.

⁵ Conant, Small and Taylor, *THIS JOURNAL*, 47, 1959 (1925).

In our work, the siphons of the calomel half cells, which terminated in glass stoppers, usually dipped into a beaker of saturated potassium chloride solution, into which also dipped one end of the special bridge which is later discussed in detail. This was a glass-stoppered U-tube containing a concentrated acetic acid solution of lithium chloride and gelatin. The other end of the bridge dipped into another beaker which contained the solution under investigation (saturated with chloranil and hydrochloranil), the platinum electrodes and an electrically driven stirrer. The e.m.f. of the cell was compensated and measured by means of a potentiometer, with the aid of a quadrant electrometer as null instrument.

The first and most striking of the early results of our work was the large e.m.f. of cells of the type just described when the acetic acid solution contained considerable concentrations of strong acids. For example, a chloranil electrode in a 0.064 *M* solution of sulfuric acid in acetic acid is 0.735 volt more positive than the saturated calomel electrode, when the measurement is made as just described. The corresponding figure for 1 *M* sulfuric acid is +0.756 volt, and for 1 *M* perchloric acid about +0.83 volt. A 1 *M* solution of trichloro-acetic acid gave a potential of only +0.615. These high potentials were reduced in an orderly manner whenever basic substances such as pyridine, urea or sodium acetate were added to the solution, and this fact permitted the *titration* of the various acids with bases, and of the bases with acids. Good titration curves were obtained in numerous instances, as is shown below (Figs. 1 and 3) in the case of bases. *The process of salt formation could thus be studied in as satisfactory a way as in water, by the aid of these titration curves. Indeed it was even possible to titrate such bases as acetamide, benzamide, and acetanilide, which cannot be titrated in water solution.* The titration and relative strengths of acids will be discussed in a later communication.

Apparatus and Materials

Platinum Electrodes.—Two or more electrodes of blank platinum foil or wire were used in each measurement. Foils of a considerable size (10 × 15 mm.) appeared to be most satisfactory. The electrodes were usually cleaned by scrubbing with sand, ignited and allowed to stand in a solution containing the chloranil mixture and some buffer mixture of a not too acid character. After ignition, or prolonged standing in the air, or washing with water, the electrodes often required a considerable time (fifteen to twenty minutes) to attain their equilibrium potentials. If, after use in one solution, they were simply washed in glacial acetic acid and placed in another, their subsequent recovery was much quicker, and if they were merely transferred from one glacial acetic acid mixture containing chloranil to another, the final potential was attained as rapidly as the solution could be completely mixed. This last point was important in titrations, where apparently with sufficiently vigorous stirring there was no lag whatever unless some slow reaction was taking place in the solution.

The criteria by which electrodes were judged were as follows: (1) agreement between many electrodes in the same solution; (2) rapid attainment of final potential; (3) rapid and complete recovery after polarization (in the earlier work with a low re-

sistance circuit); (4) attainment of a particular potential in a particular buffer (in the later work). In general, new electrodes satisfied these criteria very well and often could be used for weeks in solutions of low acidity without exhibiting any indication of poisoning. Agreement of four electrodes within one millivolt was frequently attained and on certain occasions within 0.2 millivolt.

On the other hand, in solutions containing high concentrations of acetic anhydride, perchloric acid, fuming sulfuric acid or even of ordinary sulfuric acid, the agreement between different electrodes was sometimes much less satisfactory, and certain ones exhibited a tendency to give divergent values (generally less positive than the average). After repeated use in such solutions these divergencies sometimes became very large (0.1 to 0.2 volt) so that the electrodes were completely useless. It was remarked that when an electrode gave values say 50 millivolts low in the most acid solutions, it generally gave values about 5 millivolts low in the ordinary solutions. Ignition, scouring and scraping were in some cases effective in restoring the original character to the electrode; at other times the poisoned character persisted. On prolonged standing in the air (several weeks) with subsequent ignition, almost all the poisoned electrodes recovered completely. After it was established that a certain buffer containing urea and sulfuric acid showed a definite potential difference against the saturated calomel half-cell, it was possible to test electrodes by their performances in this mixture, and this was done repeatedly in the later work.

Saturation of the Electrode and the Chemical Activity of Chloranil

Theoretically, the peculiar usefulness of the chloranil electrode depends upon the solution being really in equilibrium at all times with both the solid quinone and its hydroquinone. Therefore, although for many practical purposes such as titrations, considerable variation from the equilibrium conditions seemed to introduce no appreciable error, for the final measurements some pains were taken to devise a technique which at least would insure thoroughly comparable conditions in different experiments. It was found that if a large excess of both solid phases was stirred with the solution at the working temperature, the electrodes very quickly took up a potential which was near, but in general not identical with, the equilibrium potential, and the latter was only reached after a considerable time, sometimes as long as thirty to forty minutes. It therefore seemed best to warm the solvent with an excess of the solids. On cooling, both substances readily crystallized providing the supersaturation had been sufficient, and in five to ten minutes after cooling to room temperature, the equilibrium value of the potential was reached. If now to such a solution which is exactly saturated, a certain volume of titrating solution is added, obviously an at least momentary unsaturation will be introduced. With this in view, it was at first our practice previously to saturate the titrating solution also with both solids. Later we abandoned this practice, having convinced ourselves that no measurable error was introduced by so doing provided the relative volume of the solution added was small. This is to be expected if the solutions approach ideality, unless differences in the *solution rate* of the two solids introduce errors.

In order to save material, we ascertained by preliminary experiments how much of each solid was necessary to give a quick crystallization when the solution was vigorously shaken with the solids for about thirty seconds at a temperature not over 50°, and then cooled under the tap to 25°, the working temperature. The amounts added were always 0.8 g. of tetrachloro-hydroquinone and 0.6 g. of tetrachloroquinone per 100 cc. of acetic acid solution. No effect of a three- or four-fold excess over these amounts was observed. Whenever possible, the acetic acid alone was warmed with the solids and the solutes were added later, just before the final cooling was complete. No error was

introduced, however, in the majority of cases, when the various buffer solutions were themselves warmed with the chloranil. It was also found that solutions of urea and of sulfuric acid saturated with chloranil could be stored for a considerable time without altering in titer or other properties. Pyridine under such conditions developed a cherry red color, while bases of a more actively reducing character rapidly developed various vivid colors and clearly underwent rapid decomposition. We finally avoided storing any of the substances in contact with chloranil, but instead always saturated the portion to be measured or titrated immediately before use, as just described.

Reference Electrodes

The saturated aqueous calomel half-cell was used as a reference electrode. Several of these were prepared and frequently checked. They always agreed within one millivolt with each other and with similar electrodes prepared by other workers. Their siphons dipped either into a beaker of saturated potassium chloride solution, or for special purposes directly into the solution to be measured. In the latter case the end of the siphon was always stoppered with glass.

Salt Bridge

The liquid used as a salt bridge was a supersaturated solution of lithium chloride in acetic acid, which was prevented from crystallizing by dissolving a small amount of gelatin in the acetic acid. The concentration of the two solutes was varied within wide limits without apparent effect on the performance of the bridge. This solution was enclosed in a glass-stoppered U-tube about 35 cm. long and whose internal diameter was about 4 mm.

Measuring Instruments

At first a simple galvanometer was used as a null point indicator in connection with a Leeds and Northrup Type K potentiometer. Later when the lithium chloride bridge was used the resistance of the system became too great for this apparatus and a quadrant electrometer of the Compton type was substituted for the galvanometer. The needle was charged to a constant potential between 67.5 and 180 volts by a "B" battery. One pair of quadrants was permanently earthed, and the other could be connected either to earth or to the system comprising the potentiometer and the cell to be measured. The polarity of the cell could be reversed at will, while the negative side of the potentiometer was permanently earthed. The high-potential part of the system was very carefully insulated and the entire apparatus protected by an earthed shield. The functioning of the electrometer was very satisfactory and its sensitivity was high (up to 25 mm. of scale per millivolt). (The lamp and scale were about 2.5 meters from the mirror.) Its insensitiveness to abuse in the form of large accidental voltages, and its complete prevention of polarizing currents in the system, are advantageous. It also permitted the use of the clean and convenient but high-resistance ground-glass junctions. Serious difficulty was occasionally encountered in adjusting the electrometer to a high sensitivity. The method described by Compton and Compton⁶ was found useful when simple trial and error failed to secure a satisfactory setting. There was also a slow but capricious drift of the zero point, so that a scale with a widely movable zero was a great convenience.

Materials Used

Our principal object was to develop a method of medium accuracy which could be easily applied by others, and to make a rapid exploration of a wide field, rather than

⁶ Compton and Compton, *Phys. Rev.*, 14, 85 (1919).

to obtain data of high accuracy. We, therefore, whenever possible, used materials of commercial grade, but of definite and reproducible character, instead of subjecting our substances to careful purification.

Acetic Acid.—In all of the work described in this paper, a single grade of glacial acetic acid was used, the P. W. R. analytical reagent. This was supposed to contain "at least 99.5% acetic acid." No attempt was made to free it from water or other impurities. In many preliminary experiments the ordinary "U. S. P. 99.5%" grade purchased in carboys was used and no difference in behavior was detected. In making up the solutions described in the following paper, still another grade of analyzed acid was employed, but no difference in behavior was found.

Tetrachloroquinone (chloranil).—This was the Eastman Kodak Company's "No. 603 MP 283-284°." Recrystallization from acetic acid had no effect on its electrochemical behavior and was generally omitted.

Tetrachlorohydroquinone.—This was prepared from the previous material substantially as described by Conant and Fieser,⁴ except that it was not precipitated by alcohol from glacial acetic acid solution. When thoroughly purified it melted very sharply at 236-237°, but certain samples of lower melting point showed identical electromotive behavior.

Perchloric Acid.—The 60 per cent. aqueous solution was added slowly to five times its volume of chilled acetic anhydride reagent and further diluted to the desired volume with acetic acid. The resulting solution was then titrated against a urea, pyridine or sodium acetate solution of known concentration.

Other Materials.—The other acids and bases used were of the best c. p. grade ordinarily obtainable.

Experimental Results

Titration of Bases.—Fig. 1 shows the potentials (E) obtained when small volumes of 2 M sulfuric acid were added to large volumes of solutions of the various bases, at such concentration that they were 0.2 M in total base at the mid-point of neutralization. The temperature was $25 \pm 0.5^\circ$. The solutions were all prepared and saturated in the same way and the potentials measured against the saturated calomel half-cell, through the lithium chloride bridge, with the quadrant electrometer. The choice of substances was such as to give as wide a range of base strength as possible. Thus acetanilide, at the top of the diagram, is a very weak base indeed. Passing through progressively stronger bases, one notes the appearance of a slight inflection with urea, and this becomes steadily more marked as the strong bases are reached. A double bend is shown by the two strongest bases, *p*-toluidine and pyridine, which is due to the successive action of the two hydrogens of the sulfuric acid molecule. It will be noted that two bases which do not contain nitrogen are included, the two xanthydrols. It was necessary to titrate these in more dilute solution (0.05 M and 0.04 M) on account of their low solubility. The relative position of the curves is reliable to about 0.010 volt at least.

In Fig. 2 the logarithm of R , the ratio of salt to free base, is plotted against the e.m.f. data of Fig. 1. The numbering of the curves is the same in the two figures. "One hundred per cent. neutralized" means 1

mole of sulfuric acid per mole of base. If the curves of Fig. 1 had exactly the theoretical shape, the points for each substance would fall on a straight line in Fig. 2 and the slope of these lines would be

$$\frac{\Delta \log R}{\Delta E} = \frac{1}{.0591}$$

as shown by the lines marked "theoretical slope."⁷ Departure from these conditions must be due to changes in the activity coefficients of various

Fig. 1.—Titration curves of bases with sulfuric acid in glacial acetic acid (mono-amines and carbinols).

molecular species concerned in the equilibria, or to changes in the liquid junction potential. That these departures are no greater, especially in the less acid solutions, is fortunate, and perhaps surprising.

Polyamines

None of the substances in Fig. 1 adds more than one hydrogen ion per molecule. Fig. 3 shows the titration curves of four polyamines, each of

⁷ For convenience in studying the diagram, percentage neutralizations are shown at the left, as well as the corresponding values of the true ordinate ($\log R$) at the right.

which shows distinctive behavior. These curves were obtained under the same conditions as those of Fig. 1. It will be noted that substance No. 1, Michler's ketone, tetramethyldiaminobenzophenone (4,4'), shows scarcely a trace of inflection until two moles of acid have been added. Hexamethylenetetramine shows a sharp inflection when only one-half mole of acid has been added per mole of base. This must represent the formation of the salt $(RN_4H)_2^+(SO_4)^-$. This point once passed, a heavy white precipitate appears in the solution, which acts as a very efficient buffer, the potential remaining constant while 0.8 mole of acid is being added per mole

Fig. 2.—Logarithmic titration curves of bases in acetic acid.

of base originally present. Then once more a break occurs, steeper this time, corresponding to the complete formation of $(RN_4H_2)^{++}(HSO_4)_2^-$ or of $(RN_4H_4)^{++++}(SO_4)_2^{--}$. The addition of acid was continued until four moles of sulfuric acid were present per mole of base, but no additional inflection was noted.

No. 3, hydrobenzamide, shows a slight, but distinct, inflection at one mole of acid $[(RN_2H)^+(HSO_4)^- \text{ or } (RN_2H_2)^{++}(SO_4)^-]$ and a much sharper one at two moles. The substance smelled strongly of benzaldehyde, indicating partial decomposition.

No. 4, *p*-phenylenediamine, formed dark-colored solutions, indicating oxidation by the chloranil, and at least one substance was precipitated

in the course of the titration. Nevertheless, it seemed worth while to exhibit its striking curve

The data of Figs. 1, 2 and 3 demonstrate the existence in acetic acid solutions of a system of acids and bases quite similar to the familiar water system, and show that this system may be explored with the aid of the chloranil electrode.

Fig. 3. —Titration curves of polyamines with sulfuric acid in glacial acetic acid. 1. Michler's ketone; 2. hexamethylene tetramine; 3. hydrobenzamide; 4. *p*-phenylenediamine.

Effect of Water and Alcohol on the Potentials

It seemed interesting to determine the effect on the potentials of our solutions of adding small amounts of water or alcohol. The results of such an inquiry are summarized in Fig. 4. The abscissas are percentages of water or alcohol; the left-hand scale of ordinates, potentials measured in the usual way. The measurements were obtained as follows. (1) (Top curve). An acetic acid solution 0.2 *M* in perchloric acid, half neu-

tralized with urea (and containing some acetic anhydride), was prepared and saturated with chloranil mixture. It was 0.802 volt more positive than the calomel electrode. Small amounts of absolute alcohol were then added until the total alcohol content of the solution reached 70% by volume. The potential had now fallen to +0.525 volt. The other solutions studied were 0.2 *M* sulfuric acid half neutralized with urea and 0.2

Fig. 4.—Effect of alcohol and water on potentials of buffer mixtures in glacial acetic acid. The first formula or name on each curve gives the principal solute, which is in each case half neutralized with urea (or sulfuric acid), and at an initial concentration of 0.2 *M*.

M urea half-neutralized with sulfuric acid. To each of these three, water and alcohol were separately added. The effect of water was much the greater, particularly at the beginning of the curve. The exact course of the curves is doubtless affected by changing liquid junction potentials. These data show clearly that a variation in the water content of the acetic acid of the order of one per cent. is not serious in the urea solutions but becomes very important as the highest acidities are reached. A few scattered experiments indicated that the addition even of small amounts

of acetic anhydride produced a slight but significant increase in the potentials, particularly in the most acid solutions.

Effect of Concentration and of Various Ions

In order to limit as far as possible the number of variables in our preliminary work, we made our final comparisons all at the same concentration and with no other anions present than those furnished by sulfuric acid. The concentration chosen, largely for convenience and to secure good buffer capacity, was 0.2 *M*. A few preliminary tests indicated that between 0.1 *M* and 0.4 *M* the effect of change of concentration was slight. At concentrations below 0.1 *M* rather large variations were encountered. We have reserved for a later paper the question whether these are due to activity changes incident to changes in the ionic strength of the solutions or to changes in the liquid junction potentials. Preliminary calculations support the former view.

In general, when a base was titrated with perchloric acid rather than with sulfuric, the corresponding potentials were slightly higher. The presence of acetic anhydride in the perchloric acid solutions, coupled with the extreme water-sensitivity of their potentials, makes it difficult to be certain whether this effect is really due to a difference in anion or to a difference in the effective water content of the solutions. This point also will form the subject of later work.

Discussion of Results

The Magnitude of the Potentials and the Use of the Lithium Chloride Bridge

The high values of the potentials, especially in the most acid solutions (see p. 3049), raise the question of the extent to which they are affected by the unknown liquid junction potentials in the cell. It also remains to justify the use of the lithium chloride bridge in all our final measurements. A salt bridge in measurements of this kind may be said to have three functions.

- (1). To promote the reproducibility of the measurements.
- (2). To neutralize the effect of varying liquid junction potential between the different acetic acid solutions.
- (3). To eliminate if possible the potential at the junctions between the saturated aqueous potassium chloride and the various acetic acid solutions, or at least to promote its constancy.

(1). When two acetic acid solutions were directly joined through a porous cup or a ground-glass stopper, it was found that their difference of potential generally, but not always, had the same value within 0.005 volt. When these solutions were then each separately measured against a third solution, the difference of the potentials thus obtained often varied

from the "direct" value by $\pm .015$ volt or more. A number of solutions were tried as "reference electrodes" but in no case was the system of potentials measured against a wide variety of other solutions completely self-consistent. As it seemed that part of the difficulty might lie in the non-reproducibility of the various acetic acid chloranil half-cells, we next prepared a number of (aqueous) saturated calomel half-cells, whose siphons were stoppered rather tightly at the end with glass stoppers.

These stoppered ends, which thus formed potassium chloride bridges of a fairly reproducible type, were allowed to dip directly into the various acetic acid solutions and the measurements thus all referred to the saturated calomel half-cell. Under these conditions, reproducible values (within .005 volt) were nearly always obtained *except in the more acid solutions*, where gross discrepancies of the order of .04 volt made their appearance.

It now occurred to us to interpose, between the highly acid solutions and the saturated aqueous potassium chloride, another acetic acid solution, substantially "neutral" (in the acetic acid system), and containing a high concentration of some electrolyte. Lithium chloride seemed to be the best salt for our purpose.

In order to increase the available concentration range, we prepared supersaturated solutions which we prevented from crystallizing with the aid of gelatin. These solutions were enclosed in a U-tube with well ground stoppers, and the ends of this tube dipped, respectively, into the acetic acid solutions and into saturated potassium chloride connected with the calomel electrode.

With this experimental arrangement the reproducibility of all the measurements, even in the more acid solutions, appeared satisfactory for our purpose. The discrepancies were rarely as great as 0.005 volt.

(2). The self-consistency of the measurements made with the aid of the lithium chloride bridge, and the approximation of the lines of Fig. 2 to the theoretical slope, seem to indicate that there are no errors due to liquid junction potentials between the different acetic acid solutions, of a much higher order of magnitude than the extreme variation of the individual measurements (0.005 volt).

(3). The question of the magnitude of the junction potential between the saturated potassium chloride solution of the calomel electrode and the various acetic acid solutions through the lithium chloride bridge is much more uncertain. A small amount of evidence, as yet of a very uncertain character, leads us to believe that this potential is of the order of 0.15 volt, and of such sign as to increase the apparent e.m.f. of the cells. In preliminary work of this character the *magnitude* of such a potential is of much less importance than its *constancy*. The reproducibility and self-consistency of all our measurements in acetic acid seem to be evidence that the junction potential is effectively constant.

As they stand, our e.m.f. measurements give a direct measure of the hydrogen-ion activity of the acetic acid solutions, relatively to each other. As it is customary, however, in dealing with aqueous solutions, to think of hydrogen-ion activity in terms of " P_H units" (1 P_H unit = .0591 volt at 25°) instead of in volts, it has seemed desirable to employ a similar unit in discussing our results in glacial acetic acid. We have, therefore, adopted the symbol $(P_H)^{HAc}$ as a convenient designation for our purpose.

We are then confronted with the necessity of selecting a zero for the scale thus constituted. If it could be assumed that the liquid junction potential between water and acetic acid solutions was *eliminated* by the bridge in our measurements, it would be rational to choose as zero a potential of +0.418 volt against the calomel electrode, as this is the normal potential of the chloranil electrode when so measured in aqueous solution.⁴ Since we have no assurance that our liquid junction potential is negligible, we have arbitrarily taken the zero of our scale to correspond to a potential of 0.566 volt.⁸ This means merely that we have decided to call unity, for our present purposes, the hydrogen-ion activity of a solution in which the chloranil electrode has the stated potential (+0.566 volt) measured as above described.

The measured potentials (E) and the $(P_H)^{HAc}$ values are thus related as follows

$$(P_H)^{HAc} = \frac{0.566 - E}{0.0591} \text{ at } 25^\circ$$

We have inserted in our diagrams as alternative ordinates the $(P_H)^{HAc}$ values as thus defined. It will be noted that many of these values are negative, because of the high acidity of some of our solutions. In terms of the new unit, the acidities of the solutions mentioned on p. 3049 are as follows

TABLE I
ACIDITIES OF SOLUTIONS

Solution	E (volts)	$(P_H)^{HAc}$
1.0 M Cl_3CCO_2H	+0.615	-0.83
1.0 M H_2SO_4	+0.766	-3.23
1.0 M $HClO_4$	+0.83	-4.4

⁸ It is our hope that the zero point of this arbitrary scale will be shown eventually to be very near the zero point of the P_H scale in water. The two chief reasons which have led us to adopt tentatively this particular standard are as follows. (1) It seems probable that the strength of anhydro bases should be approximately the same in different solvents, and this is the case for urea, dimethylpyrone and acetamide in acetic acid and water as we have defined the $(P_H)^{HAc}$ scale (see Table II). (2) The solvent (acetic acid) half neutralized with a relatively strong base such as pyridine might be expected to have a hydrogen-ion activity of the same order of magnitude as the pK_A of acetic acid dissolved in water. The $(P_H)^{HAc}$ of an equimolar mixture of pyridine and pyridine acetate is about +4.4 as compared to the value +4.7 given for the pK_A of acetic acid in water.

Relative Strength of Bases

As a matter of interest we now present a list of numbers (Table II) intended to represent as closely as possible the relative strength of all the bases we have been able to titrate accurately, in the absence of complications such as the appearance of precipitates. This list includes not only most of the bases of Figs. 1 and 3, but also several others for which the measurements, for lack of space, are not reported in detail. In this table we designate by $(pK_A)^{HAc}$ the $(P_H)^{HAc}$ value of a 0.2 *M* solution of each base half neutralized with sulfuric acid. These $(pK_A)^{HAc}$ values should be more or less closely related to the negative logarithms of the hydrolysis constants of strong-acid salts of the base in water solution.

$$pK_B^{H_2O} = -\log K_B^{H_2O}, K_B^{H_2O} = \frac{10^{-14}}{K_B^{H_2O}}$$

where $K_B^{H_2O}$ is the ordinary dissociation constant of the base. Where they are known, values of $pK_B^{H_2O}$ at 25° are given for comparison.

Most of the water values are taken from Landolt-Börnstein's "Tabellen." The figures for *p*-toluidine and triethylamine are from unpublished measurements by one of us. The essential identity of behavior in acetic acid shown

TABLE II
RELATIVE STRENGTH OF BASES IN ACETIC ACID SOLUTION

Substance	$(pK_A)^{HAc}$	$(pK_B)^{H_2O}$
Triphenylcarbinol	Too weak to measure	Too weak to measure
Triphenylamine		
2,4-Dinitroaniline		
Acetanilide	-1.75	Too weak to measure
N- <i>p</i> -methylbenzyl formamide	about -1.65	Too weak to measure
N- <i>p</i> -methylbenzyl acetamide		
N- <i>p</i> -methylbenzyl butyramide		
Benzamide	-1.60	Too weak to measure
Acetamide	-0.9	-0.5
Urea	-0.05	+0.18
Dimethylpyrone	about 0.0	+0.3
Diphenylamine		?
<i>p</i> -Nitro-aniline		+2.0 (?)
<i>p</i> -Dimethylaminobenzaldehyde	+0.4	?
Michler's ketone (2nd stage)	+1.0	?
Hydrobenzamide (2nd stage)	+1.0	?
Phenylxanthidrol	+1.5	?
Michler's ketone (1st stage)	+2.5	?
Dinaphthoxanthidrol	+2.65	?
"Nitron"	strong	?
<i>p</i> -Toluidine	strong	+5.11
Pyridine	strong	+5.36
Triethylamine	strong	+10.75

NOTE: In the case of the methyl benzyl amides, the measured values have been increased by 0.1 unit to allow for differences in the concentration of their solutions from the standard concentration.

by urea and *p*-nitro-aniline leads us to believe that a redetermination of the constant of the latter substance in water is desirable.

It is necessary to add that while the picture of relative base strength thus presented is undoubtedly correct in its main outlines, the possibility remains that the zero of our scale is improperly placed by as much as one or two units and that the "constants" we have given would be modified in the presence of water, acetic anhydride or other substances, or by changes in concentration.

It is perhaps entertaining at this point to pursue somewhat further the implications of our choice of zero for the acetic acid scale. If, as we hope, we have estimated the junction potential between acetic acid and aqueous solutions with approximate correctness, then our $(P_H)^{HAc}$ values become approximate measures of the hydrogen-ion activity of the various solutions referred to the water standard. The hydrogen-ion activities (or activity coefficients, since we are dealing with unit concentrations) of the three solutions listed in Table I, are then respectively 6.7, 700, and 25,000. That such high activities are possible, even in water solutions, is indicated by the work of Lewis and Randall⁹ on concentrated HCl solutions. Their most acid solution (16 molal hydrochloric acid) showed a mean ionic activity coefficient of 43.2, or a mean ionic activity of 691, which compares favorably with the values for our (much less concentrated) solutions in acetic acid. The " P_H value" of such a solution is -2.84 on the assumption that the two individual ion activities are equal. The true value is doubtless still more negative. We feel that our work indicates that the proximate cause of superacidity in a solution is an abnormally high value of the hydrogen-ion activity. An hypothesis to account for this phenomenon is tentatively proposed in the following paper.

We take pleasure in expressing our thanks to Mr. Edwin B. Damon, who kindly gave us the benefit of his experience with quadrant electrometers.

Summary

1. A method has been developed in which the chloranil electrode is used to measure hydrogen-ion activities in glacial acetic acid solutions.
2. The reliability and significance of such measurements are discussed.
3. Titration curves are given for several bases in this solvent and their significance noted.
4. The bases studied are arranged in order of increasing strength and characterized by a set of constants allied to the hydrolysis constants of their salts in water solution.

A STUDY OF SUPERACID SOLUTIONS. II. A CHEMICAL INVESTIGATION OF THE HYDROGEN-ION ACTIVITY OF ACETIC ACID SOLUTIONS

BY JAMES B. CONANT AND NORRIS F. HALL

RECEIVED AUGUST 16, 1927

PUBLISHED DECEMBER 10, 1927

The preceding paper of this series has demonstrated that the hydrogen-ion activity of glacial acetic acid solutions may be estimated by means of the chloranil electrode. In this paper we shall show that the halochromism of triarylcarbinols, the halochromism of unsaturated ketones and the rate of inversion of cane sugar are controlled by the hydrogen-ion activity as measured electrochemically. The general agreement between the four independent methods seems to us to establish beyond doubt the possibility of measuring in this solvent hydrogen-ion activities which have the same general significance as those measured in water.

The Halochromism of Arylcarbinols and Unsaturated Ketones

Triarylcarbinols such as triphenylcarbinol and certain diarylcarbinols give intensely colored salts when treated with acid in suitable media. Some of the derivatives of triphenylcarbinol which contain a number of methoxy groups form halochromic salts even in aqueous solutions. A careful quantitative study of these compounds has recently been made by Lund¹ and by Kolthoff² who have shown that they may be used as indicators in aqueous and alcoholic solutions. From this work of Lund and from that of Hantzsch³ it seems quite clear that the triarylcarbinols are pseudo bases of varying strength. Indeed this was essentially Baeyer's original idea. The equilibrium involved in the formation of the colored ion may be represented as follows

If we use a medium in which the carbinol and salt are both soluble, the appearance of color will be a function both of the hydrogen-ion activity and the water activity. If the latter is constant in a series of solutions the appearance of color may be used as a method of estimating the hydrogen-ion activity.

Unsaturated ketones such as benzalacetophenone ($\text{C}_6\text{H}_5\text{CH}=\text{CHCOC}_6\text{H}_5$) also give intense colors with concentrated mineral acids. Hantzsch⁴ be-

lieves this to be also an example of salt formation and we may write the equilibrium

The unsaturated ketones are thus anhydro bases which form a colored ion. They would be expected to differ from the carbinols only in that the appearance of color is a function solely of the hydrogen-ion activity; the activity of the water *per se* should not affect the composition of the equilibrium mixture.

In order to investigate the halochromism of a number of carbinols and unsaturated ketones we prepared a series of acetic acid solutions of graded hydrogen-ion activity and with a constant and small water content. With the exception of the two most acidic they were mixtures of sulfuric acid and very weak bases dissolved in acetic acid. Thus, they were "buffered" in respect to both the increase and decrease of hydrogen-ion activity.

The results are summarized in Table I, which is self-explanatory. The data are remarkably consistent with each other and with the e.m.f. measurements. It seems certain from these more than 100 experiments that the halochromism of both the carbinols and the unsaturated ketones is determined within at least 0.5 of a $(P_H)^{\text{HAc}}$ unit by the hydrogen-ion activity of the solution as found from e.m.f. measurements.

A further test of the general consistency of the results is made possible by the fact that the titration curves of a number of the very weak bases lie close together (Fig. 1, preceding paper). Since this is the case it should be possible to titrate with an indicator a given weak base with sulfuric acid to the same color as that shown by the same indicator in one of the buffered solutions. The result should agree with the e.m.f. titration data. Thus, the acetamide buffer (No. 5, $(P_H)^{\text{HAc}} = -1.0$) was used as a standard, and benzamide was titrated with sulfuric acid, using indicator F' in both the standard and the titrating solution. The same relative concentration of indicator was used and the same concentration of base (0.2 M). A color match was obtained when 0.1 cc. of M sulfuric acid was added (1 cc. required for total neutralization); from the e.m.f. titration curve the calculated quantity for $(P_H)^{\text{HAc}} = -1.0$ would be 0.1 cc. The other results were as follows: Urea titrated to match $(P_H)^{\text{HAc}} = -1.0$ (indicator F') required 0.9 cc., calcd. 0.9 cc.; acetamide to match $(P_H)^{\text{HAc}} = -0.5$ (indicator F') required 0.2 cc., calcd. 0.2 cc.; benzamide to match $(P_H)^{\text{HAc}} = -2.0$ (acetanilide buffer) (indicator C) required 1.4, calcd. 0.9; titrating acetanilide to match $(P_H)^{\text{HAc}} = -1.5$ (benzamide buffer) with indicator D' required 0.1 cc., calculated 0.2 cc.

The differences between the required and the calculated amount of acid in titrating acetanilide or comparing benzamide with the acetanilide buffer amount to 0.3 of a $(P_H)^{\text{HAc}}$ unit. This is an indication of the magni-

11	Hexamethylenetetramine 0.15 neutralized	+3.6	+3.62	-	-	-	-	-	-	-	-	-	-

* Col. 1. Each buffer, except the first two, contained the base named in 0.2 M concentration, dissolved in glacial acetic acid. To this had been added sufficient sulfuric acid to neutralize the stated fraction of the base, on the assumption that one mole of the base was neutralized by one mole of acid. The acetic acid was "P. W. R. analytical, complying with dichromate test." The sulfuric acid was "P. W. R. analytical 94 to 97%." It was assumed to contain 95% H₂SO₄. The acetanilide showed an extremely faint brownish color. The benzamide left a very slight white residue on dissolving. The hexamethylenetetramine "1.20 neutralized" contained a large amount of white precipitate (sulfate or hydrosulfate). The hydrobenzamide developed a pronounced yellow color on standing, smelt of benzaldehyde, and formed a slight precipitate when treated with sulfuric acid. The other solutions were clear and colorless.

Col. 2. The "(P_H)_{HAo} predicted" was read from titration curves previously obtained (see Fig. 1 preceding paper).

Col. 3. The "(P_H)_{HAo} of each solution was measured directly with the technique previously described (p. 3049 preceding paper). The benzamide values showed a slight drift with time, a phenomenon previously observed. Acetanilide, whether alone or in the presence of sulfuric acid, gives an orange color with chloranil.

Indicators. These were unsaturated ketones (denoted by "primed" letters) or substituted carbinols. They were all 0.05 *M* in glacial acetic acid as a solvent. The meaning of the signs used is as follows: +, halochromic color; ++, +++, +++++, etc., very intense color; -, no halochromic color; +-, transitional color; (+-), doubtful color.

The comparison was carried out by adding the stated number of drops to 5 cc. of each buffer. The tubes were shaken slightly to mix the solutions.

A' Benzalacetophenone. 10 drops. Buffer No. 1, pale yellow; all others colorless.

B Triphenylcarbinol. 10 drops. No. 1, full yellow; 2 and 3, pale yellow; all others colorless.

C Diphenyl- α -naphthylcarbinol, 5 drops. No. 1, inky greenish-blue; 2 and 3, clear greenish blue. All others colorless.

D' Piperonalacetophenone. 8 drops. No. 1, red-orange; 2 and 3, strong yellow; all others very pale yellow.

E Dianisylcarbinol. 5 drops. No. 1, pinkish orange; 2 and 3, pale salmon; 4, almost invisible salmon; all others colorless.

F' Anisalcinnamalacetone. 1 drop. No. 1, carmine; 2 and 3, full red; 4, orange-red; 5, orange; 6, orange-yellow. All others clear yellow.

G' Dipiperonalacetone. 2 drops. No. 1, purplish-red; 2 and 3, full red; 4, salmon; 5, orange-yellow; 6 full yellow; all others pale yellow.

H' Dianisalacetone. 2 drops. No. 1, pinkish red; 2 and 3, full red; 4 and 5, orange-red; 6, reddish-orange; 7, brownish yellow. All others pale yellow.

I Diphenylanisylcarbinol. 5 drops. 1 to 3, brown-orange; 4 and 5, orange; 6, yellow-orange; 7, yellow; 8, pale yellow; others colorless.

J Phenylxanthidrol. 1 drop. 1 to 8, clear yellow with greenish fluorescence; 9 and 10, pale yellow; 11, colorless.

tude of the discrepancy which may be expected to arise from time to time in determining the hydrogen-ion activity by different methods in glacial acetic acid. Similar errors, often referred to as salt errors, have been found frequently in using indicators in aqueous solutions. Undoubtedly if we had varied our concentrations of base and experimented with the addition of considerable amounts of neutral salt, still larger discrepancies would have been found between the indicators and the e.m.f. measurements.

The difference in behavior of the two types of indicators in regard to the influence of the water activity was shown by several experiments. Both diphenyl- α -naphthylcarbinol (C) and piperonalacetophenone (D') show a color change at about $(P_H)^{HAc} = -2.0$. When 5 drops of acetic anhydride were added to one of two 5cc. portions of the buffer containing the carbinol indicator (C), the color rapidly became much deeper. The unsaturated ketone (D') color was unaffected. We interpret this difference as showing that the acetic anhydride combined with the small amount of water present in the solution and therefore the equilibrium with the carbinol shifted. In the case of the unsaturated ketone there was no shift as water is not involved in the reaction. In a similar experiment with diphenylanisylcarbinol in the series of 11 buffers there was no noticeable effect after several days on adding the acetic anhydride. This may

be due to the fact that the reaction between small amounts of water and acetic anhydride is slow in solutions of $(P_H)^{HAc} = -0.5$ to $+0.5$ where this indicator turns.

A few experiments in which absolute alcohol was added to the buffer solutions containing the indicators are of interest. Equal quantities (2.22 cc.) of absolute ethyl alcohol were added to 5cc. portions of buffer solution No. 4 ($(P_H)^{HAc} = -1.5$) containing, respectively, indicator F' (an unsaturated ketone) and I (a carbinol). Both solutions showed a diminution in color corresponding to a decrease in hydrogen-ion activity as would be expected from the results reported in the preceding paper. The carbinol indicator, however, showed a decrease amounting to 2 $(P_H)^{HAc}$ units (as determined by matching colors) while the change with the unsaturated ketone was only about 1 unit. Similarly 0.3 cc. of alcohol in 5 cc. of buffer No. 3 was sufficient to discharge the color of indicator C (diphenyl- α -naphthylcarbinol). With D' (an unsaturated ketone) 1.3 cc. of alcohol was necessary to produce a corresponding decrease in hydrogen-ion activity as measured by the color.

These experiments illustrate the caution which must be employed in attempting to use these indicators in solvents containing varying amounts of alcohol. Apparently alcohol can produce an alcoholysis of the carbinol salt in addition to its effect in diminishing the acidity of the solution.

In this connection it should be emphasized that the data in Table I permit of only a very rough estimation of the basicity of each carbinol or unsaturated ketone used as an indicator. As we have employed them, the turning point of the indicator is a function both of its basicity and the intensity of color of the ion. The turning point must be at such an acidity that only a fraction of the base is present as salt but what that fraction may be depends on the sensitivity of the eye for that particular color. The true measure of the basicity can only be obtained by carrying out an e.m.f. titration curve (cf. phenylxanthidrol, Fig. 1, preceding paper) or by careful colorimetric measurements in which the intensity of color is determined. Baeyer's method⁵ of determining the basicity of the halo-chromic salts by titration with alcohol suffers from this error. In his method alcohol is added until the solution is colorless; the amount of alcohol added would be a true measure of the basicity only if the sensitivity of the eye were the same for all the colored ions. It also is in error since there is not an absolute proportionality between the amount of alcohol added and the hydrogen-ion activity (cf. Fig. 4, preceding paper).

The Catalytic Effect of the Hydrogen Ion in Glacial Acetic Acid Solution

Some rough measurements were made of the rate of inversion of cane sugar in the buffer solutions listed in Table II to which a small amount

⁵ Baeyer, *Ber.*, 35, 1189, 3013 (1902).

of water was added. To 5 cc. of each buffer was added 0.1 cc. of a solution of cane sugar in water containing 7 g. in 11 cc. (7 g. of sucrose and 7 g. of water). The mixtures were kept at $25 \pm 2^\circ$ and after a given time diluted with water, neutralized with sodium carbonate and the amount of reducing sugar determined by the titration of Benedict's solution. It was assumed that the inversion was complete in 1 *M* sulfuric acid in acetic acid after five minutes; the titration of such a reaction mixture corresponded approximately to the amount of invert sugar that would be formed from the sucrose employed. Duplicate experiments agreed within 20%. Enough determinations were made in each buffer solution so that a curve representing the rate of reaction could be plotted. From this curve the time for half reaction was determined. This half reaction time is given in Table II for solutions 5 to 9 inclusive; the data were not of sufficient accuracy to warrant the calculation of a reaction constant. It is evident that the rate of inversion of the sucrose parallels in a general way with hydrogen-ion activity of the solutions. In the measurable range, $((P_H)^{HAc} = -0.8$ to $+2.2$), the rate increases 2.5 to 4.5 fold per 0.5 $(P_H)^{HAc}$ unit. If the rate were directly proportional to the hydrogen-ion activity the change would be 3.2-fold per half unit. The small amount of water added with the sucrose in each experiment made the water concentration in each experiment about 1.4 g. per 100 cc.; it is presumably this water which is involved in the inversion of the sucrose, though the acetic acid itself might take part in the reaction. The $(P_H)^{HAc}$ of the reaction mixture (Col. 3, Table II) was estimated on the basis of the experiments in the preceding paper in which water was added to various solutions (Fig. 4). Since the effect is approximately the same for all the buffer solutions except those containing sulfuric acid, the exact value for this correction is not of great importance in our preliminary work. In the range represented by solutions 4-9, the scale of hydrogen-ion activity as determined by the c.m.f. and colorimetric measurements in 99.5% acid is obviously a close measure of the rate of inversion of sucrose in the presence of small amounts of water.

TABLE II
RATE OF INVERSION OF CANE SUGAR IN 98% ACETIC ACID BUFFER SOLUTIONS

Solution	$(P_H)^{HAc}$ buffer	Est. $(P_H)^{HAc}$ of reaction mixture	Rate of inversion %	Time in minutes

9	+2.0	+2.2	50	1400

The Behavior of Acids and Bases in Different Solvents

In themselves the results presented in this paper throw no light on the hydrogen-ion activities of acetic acid solutions compared to aqueous solutions. The excellent agreement between the electrochemical measurements and the three other methods just described only shows that each method is satisfactory for determining the relative hydrogen-ion activities in a series of acetic acid solutions. That certain acids are "stronger" in acetic acid solutions than in water rests on the electrochemical evidence presented in the last paper (with the admitted uncertainties in regard to the liquid junction) and on certain chemical facts. This chemical evidence will now be briefly reviewed.

Many very weak anhydro bases which do not form salts in aqueous solutions are neutralized by perchloric or sulfuric acids in glacial acetic acid solutions. This is shown by the titration curves which can be obtained by using the chloranil electrode or by the use of indicators. It should be noted that in the formation of salts from anhydro bases, no water is eliminated and the water activity is not involved except in so far as it affects the hydrogen-ion activity. In the second place, although perchloric, sulfuric and trichloro-acetic acids are all strong acids in water, they are of widely different strengths when dissolved in glacial acetic acid. This fact again rests not only on the electrochemical evidence but on the use of two different types of indicators.⁶ Thus whether we define the strength of acids in terms of the relative hydrogen-ion activities of their equimolal solutions or in terms of salt formation with anhydro bases, the evidence is clear that perchloric and sulfuric acids are stronger acids in acetic acid than in water. The reader of Hantzsch's papers⁷ will be familiar with the mass of evidence which he has accumulated dealing with the behavior of strong acids in non-aqueous solvents. We should like to stress Hantzsch's point that the classification of acids into strong and weak on the basis of their behavior in water is inadequate. Much important chemistry (particularly important to the organic chemist) has been obscured by our slavish devotion to water.

At present we have some information about the behavior of acids and bases in at least four common solvents, ammonia (liquid), alcohol, water and glacial acetic acid. All the facts point to a close resemblance between alcohol and water as regards the strength of acids and bases dissolved in them. We may, therefore, consider them together. Following Brönsted,⁸ we may imagine that in water the hydrogen ion (the proton) is largely hydrated. In liquid ammonia probably no one would contend that there

⁶ The determination of the $(P_H)^{HA}$ value of 0.2 *M* trichloro-acetic acid gave: electrometric -0.1; colorimetric +0.5 with both types of indicators.

⁷ Ref. 4 and other papers.

⁸ Brönsted and Guggenheim, *THIS JOURNAL*, 49, 2554 (1927).

was any large proportion of free hydrogen ion in equilibrium with the solvated hydrogen ion which is the ammonium ion. We are thus led to imagine that the essential difference between glacial acetic acid and water is similar to that between water and liquid ammonia. The acetic acid molecule has less affinity for a proton than water; the ion $\text{CH}_3\text{COOH}_2^+$ more readily gives up its extra proton than the ion H_2OH^+ .

The formation of a salt from an anhydro base is the reverse of the dissociation of an acid. Indeed, if we accept Brönsted's definition of a base, the anhydro base (B), the anion of an acid ($\bar{\text{X}}$) and the solvent molecule (S) may all be regarded as bases competing for the proton (H^+). We may, therefore, write the following equations

Probably in most solvents the amount of unhydrated hydrogen ion (free proton) is very small⁸ but this does not prevent our formulating the reaction

in terms of the competing reactions 2 and 3 above. A very weak base, B, (corresponding to a very strong acid BH^+) will only form stable salts in a solvent which has considerably less affinity for the proton than B itself. Obviously salt formation can only take place with an acid whose anion ($\bar{\text{X}}$) will release the proton to B.

The inter-relation of the three competing reactions can best be illustrated qualitatively by a diagram. This is shown in Fig. 1; the affinities of the three competing bases ($\bar{\text{X}}$, S and B) are plotted vertically on lines 1, 2 and 3, respectively. The position of some common acids, anhydro bases and three solvents are indicated by their formulas. The scale is arbitrary and no attempt has been made to evaluate the exact relation-

Fig. 1.—Diagram illustrating the relationship of acids and anhydro bases in a variety of solvents.

ships as this would involve data in regard to the activities which are lacking. According to the general scheme which is roughly outlined in Fig. 1, acids are "strong" only in the solvents which lie above them on the diagram. Thus perchloric acid is strong in all three solvents; sulfuric and hydrochloric acids in ammonia and water and RCOOH only in ammonia. Anhydro bases are neutralized by one equivalent of any acid which is a stronger acid than their "onium ions," provided the action takes place in a solvent which lies below the position of their ions on the scale. Thus an amide (RCONH_2) will be neutralized only in acetic acid and only by perchloric or sulfuric acid. We have not yet found a solvent in which triphenylamine can be titrated even with perchloric acid. If such a solvent is found it will lie below acetic acid in the diagram.

We take pleasure in expressing our indebtedness to Mr. N. M. Bigelow for assistance in carrying out the experiments on the inversion of sucrose.

Summary

1. Five arylcarbinols and five unsaturated ketones have been tested for the appearance of halochromic color by introducing them into eleven buffer solutions in glacial acetic acid. The results are all consistent with the determination of the hydrogen-ion activities of the solution by means of the chloranil electrode. The ten substances form a graded series of indicators suitable for use in superacid solutions.

2. The rate of inversion of sucrose in 98% acetic acid solutions of definite acidity has been studied. The rate is approximately proportional to the hydrogen-ion activity as measured by the chloranil electrode or by the use of indicators.

**APPLICATION OF THE INTERFERENCE REFRACTOMETER TO
THE MEASUREMENT OF THE CONCENTRATION OF DILUTE
SOLUTIONS¹**

BY RUDOLPH MACY

RECEIVED AUGUST 19, 1927

PUBLISHED DECEMBER 10, 1927

In this Laboratory an extended series of measurements has been made involving accurate determinations of the concentrations in water of various types of organic compounds. A more accurate, more general and more rapid method of determining concentrations in liquid solvents was sought than is afforded by the usual methods of analysis. The instrument selected for this purpose is the interference refractometer designed by Professor F. Haber and made by the Zeiss Company. Although measurements can be made very quickly by means of this instrument, and with a high degree

¹ Published by permission of Chief, Chemical Warfare Service.

of accuracy, it is also found to be very misleading if some of the precautions to be explained in this paper are not observed. Since it is likely that this type of interferometer is being used by other investigators for analogous purposes, it was thought advisable to publish this account of some anomalies in its behavior. It is hoped that the interpretation given here will be of value to other users. The writer is not aware of any published articles referring to the nature of the calibration lines which are essential in the routine analyses made with the interferometer.²

The Instrument

The principle employed in the Zeiss type of interferometer was developed originally by Rayleigh in order to measure the refractive indices of the rare gases. A discussion of the fundamental principle involved can be found in the textbooks by Travers,³ and by Reilly.⁴ Pamphlets describing the instrument can be obtained from the manufacturer,⁵ these contain a complete bibliography which includes references to the original articles by Rayleigh and Haber.

The instrument used in the work reported in this article is the portable type in which an easily accessible cell is employed to hold liquids. The interferometer cell consists of two parallel compartments separated by a narrow partition, with plane lenses cemented at each end. It rests in a bath of water at constant temperature. By means of a system of prisms and mirrors two vertical beams of white light from a 4-volt lamp are passed through the cell. Each beam passes *through* one compartment of the cell and also *underneath* the cell through the water in the bath. The two lower halves of the beams interfere and give rise to a series of interference bands which are represented by the lower set in Fig. 1. The interference of the two upper halves of the beams which traverse the cell yields the upper series of bands. These spectra are observed through a microscope arrangement.

When both compartments of the interferometer cell are filled with water the upper interference spectrum is identical with the lower. There are three distinct transverse bands, the middle one being dense black, with practically no color fringes. The bands to the right and left of the central black reference line, however, are fringed with colors as shown in the accompanying illustration. If now the water in the left compartment

Fig. 1.—Appearance of the colored fringe systems when upper movable spectrum and lower fixed spectrum are matched.

² Since the time this article was written and submitted for approval to the military authorities a recent paper by W. Barth, *Z. wiss. Phot.*, 24, 145 (1926), has come to the author's attention through *C. A.*, 21, 1749 (1927). The paper by Barth includes a large number of references which are not cited by Carl Zeiss and which discuss the same phenomena presented in this article. On some important points there are discrepancies between the experimental observations by Barth and by myself.

⁵ "Industrial Interferometers," and "Interferometers for Gases and Water," Carl Zeiss, New York.

be removed and replaced by a very dilute solution the upper system of bands will be displaced to the left. By means of a compensating lens, operated by a graduated micrometer screw which reads from 0 to 3000 units, the bands are brought back into the field of vision and the spectra are matched up once more. By varying the concentration of the solution and noting the micrometer reading after the bands are matched, a straight calibration line can be constructed as indicated in Fig. 2 by the segment OC of the curve OD.

From this calibration line the concentration of an unknown solution can be read off when its interferometer reading has been determined. Instead of plotting a line as in Fig. 2 it is convenient simply to find the slope of the line, thus

$$\text{factor, or value of 1 scale unit} = \frac{y \text{ mg. per liter}}{x \text{ units}}$$

The slope of the line, or factor, can be found by reading one solution of known concentration, which involves just one or two weighings. The concentration of any solution of the same substance can then be determined simply by multiplying this factor into its interferometer reading.

Observations on the Instrument

I. Additive Properties.—A number of determinations have shown that the interferometer reading for two substances in the same solution is very nearly, although not exactly, the sum of the readings of each taken separately. This phenomenon had an important bearing on some of the work done in this Laboratory.

II. Relation between Sensitivity of the Instrument and Molecular Structure.—A number of organic compounds have been studied in the course of other work and several generalizations can be drawn from the data already at hand. In the following table, instead of expressing the concentrations in milligrams per liter, they are given in millimoles per liter in order to present figures which

Fig. 2.—Typical calibration curves (schematic).

are theoretically more comparable. These figures indicate that for the simpler aliphatic and aromatic compounds it requires a smaller concentration of an aromatic compound to change the scale reading one unit or, in general, the interferometer is more sensitive to aromatic compounds. For both types of compounds there is a general increase in sensitivity with increase in molecular complexity.

TABLE I
FACTOR, OR VALUE OF 1 SCALE UNIT IN MILLIMOLES PER LITER
(Length of cell = 4 cm.)

Aliphatic compounds		Aromatic compounds	
Acetone	0.115	Phenol	0.025
Urethan	.059	Phenylurethan	.018
Chloro-acetone	.058	Chloro-acetophenone	.018
Sulfonal	.019	Piperonal	.017
Sucrose	.011	Coumarin	.00685

III. Anomalies in the Calibration Lines.—When a solution is placed in one compartment of the interferometer cell, with pure water in the other, and the spectra are matched up by turning the micrometer screw, it is found that the central black band of the upper spectrum is usually no longer pure black but is tinged with green. However, even though this reference band suffers a slight change in its appearance it is easily followed and is readily matched. This is proved by the fact that the calibration line of such a compound as urethan is a straight line up to the appreciably high concentration of 3 g. per liter. (See the straight segment OC of the curve OD in Fig. 2.)

When urethan is studied at higher concentrations than 3 g. per liter it is found that the calibration line OD deviates slightly from a straight line function and becomes a smooth continuous curve which has been followed up to a concentration of 10 g. per liter. The phenomenon of curvature has been proved for a large number of compounds which have comparatively high solubilities in water. The deviation from a straight line at high concentrations may be due to a closer packing of the solute molecules and may therefore be considered simply another abnormal behavior of concentrated solutions.

A large number of compounds have been studied whose solubilities in water are less than 1 g. per liter. In these cases, moreover, since it was necessary to determine concentrations to at least 5 mg. per liter, the calibration curves had to be constructed with great care. Most of these slightly soluble compounds were benzene derivatives, and all these aromatic compounds yielded calibration curves illustrated in Fig. 2 by the series of broken lines beginning with OA. These lines for any one compound are all of the same slope and overlap slightly; and the horizontal distance between two adjacent lines is 13 interferometer scale units for all compounds.

The writer's interpretation of this phenomenon of the stepwise breaks in the calibration line is as follows. It has been stated that when a solution is placed in the cell the central black band of the upper interference spectrum becomes tinged with green. In the case of most compounds this green fringe grows wider as the concentration increases; as this reference band grows wider the next band to the left of it grows narrower and the red

fringe originally on it becomes less distinct. In a certain range of concentrations it is difficult to distinguish between these two bands since they have practically no red coloration. In such a case it is best to record the readings of both lines; expressed graphically in Fig. 2 the scale readings would be 13 units apart as represented by points A and B. The calibration lines are removed from one another by 13 units on the horizontal axis because of the fact that the distance between two adjacent bands in the interference spectrum is equivalent to that number of divisions on the micrometer screw.⁶

At concentrations slightly higher than that represented by points A and B, the lines become more easily differentiated again and it is a simple matter to match up the two interference spectra. However, the black line which

⁶ According to Barth (ref. 2) the distance between spectral lines varies along the scale, in his instrument the variation being from about 18 to 28 scale units. On this basis Barth builds up an equation by means of which a standard calibration line can be calculated.

is now being used as a reference originally held a red fringe. The process by which the central black band gains a red fringe and the adjacent band to the left loses its red fringe continues with marked regularity for most aromatic compounds. For example, phenylurethan solutions show the phenomenon at every increase in concentration of 180 to 200 mg. per liter. The data in Table II are grouped according to the number of broken lines; when plotted on millimeter cross section paper the lines appear as illustrated in Fig. 2. Dilutions were all made by means of calibrated burets

That the change in coloration of these spectral lines is due to the difference in dispersion of white light by the solution and by pure solvent has already been noted quite often in the literature⁷ In Table II are given the data for the calibration of the yellow solution of potassium dichromate which was studied in order to observe the effect of color on the calibration lines. Even at the low concentration of 25 mg. per liter in a 4cm. cell this causes a shift of one wave length in the spectrum. The complete calibration of the compound resulted in a stepwise shift of eight bands up to a concentration of one gram per liter, but the phenomenon did not occur at periodical increases in concentration as found for colorless solutions. In the same range of concentrations the colorless solution of sodium nitrate causes only one shift in the black reference line and this occurs just above the concentration of 500 mg. per liter.

It is evident, therefore, that a complete calibration curve over the entire range to be studied is essential in the case of most compounds. The aliphatic compounds do not, as a rule, bring about a break in the calibration curve below one gram per liter. Even a more complex substance such as sucrose has been found to give a straight, unbroken line. In regard to the curvature of the calibration lines of aliphatic compounds at higher concentrations, which has already been noted, it may be stated that there has been no explanation in the literature and none will be offered here.

The abnormal effect of the benzene ring on white light is shown by the results obtained with thymol and menthol. These are very much alike, but differ in that thymol contains the benzene ring in the unreduced state. Over a range of 500 mg. per liter thymol causes a shift of 2 bands in the spectrum, while menthol causes none.

It may be noted that Mitchell⁸ reported the use of a Jamin⁹ type of interferometer for solubility measurements. This instrument employs monochromatic light and the calibration lines obtained with it by Mitchell are all continuous. The technique in the use of the Jamin instrument is not so simple as for the Zeiss type in that the interference bands of mono-

⁷ Barth and his references (ref. 2) ascribe the breaks in the calibration lines to differences in the refraction between glass lenses, solution and distilled water.

⁸ Mitchell, *J. Chem. Soc.*, 129, 1333 (1926).

⁹ Jamin, *Ann. chim. phys.*, 52, 171 (1858).

chromatic light are all alike and the displacement must be carefully followed on the cross hairs of a telescope.

IV. Length of Cell.—The maker of the instrument supplies cells varying in length from 0.1 cm. to 8 cm. The observation has been confirmed that the micrometer reading, that is, the displacement of the bands, is proportional to the length of the cell. The longer cell, therefore, increases the accuracy of the measurements.

In the case of benzene derivatives the longer cell increases the optical effects which have just been described. For example, using a 4cm. cell the breaks in the calibration of thymol occurred regularly with each increase in concentration of about 200 mg. per liter. When using an 8cm. cell this phenomenon occurred at about every 100 mg. per liter.

The writer wishes to express his thanks to Dr. A. L. Kibler, Chief of the Physical Chemistry Department for his advice, and to Mr. G. A. Sachs for his assistance in the laboratory.

Summary

Some observations are reported on the use of the Zeiss interference refractometer as a means of determining the concentrations of dilute solutions

SELENO COMPOUNDS OF TUNGSTEN¹

BY VICTOR LENHER AND AUGUST G. FRUEHAN

RECEIVED AUGUST 26, 1927

PUBLISHED DECEMBER 10, 1927

Since selenium is similar to sulfur in many respects, it was believed to be possible to prepare some new compounds of selenium which would be analogous to known compounds of sulfur. Thus, seleno-antimonates, seleno-arsenates and seleno-stannates are known which are analogous to the thio-antimonates, thio-arsenates and thio-stannates. Many mixed compounds such as $\text{Na}_3\text{SbSeS}_3 \cdot 9\text{H}_2\text{O}$ and $\text{Na}_3\text{AsSe}_2\text{S}_2 \cdot 9\text{H}_2\text{O}$ have also been prepared. Thio-compounds of tungsten, molybdenum and vanadium such as $(\text{NH}_4)_2\text{WS}_4$, $(\text{NH}_4)_2\text{WO}_2\text{S}_2$, $(\text{NH}_4)_2\text{MoS}_4$ and $(\text{NH}_4)_3\text{VS}_4$ are known, but analogous seleno compounds have not been reported. It is the purpose of this investigation to attempt the preparation of seleno compounds which are analogous to the thio-tungstates.

Uelsmann² prepared tungsten triselenide by saturating a tungstate with hydrogen selenide and then acidifying the solution with sulfuric acid, when the tungsten triselenide was precipitated. It was logical to

¹ From part of a thesis to be submitted by August Fruehan in partial fulfillment of the requirements for the degree of Doctor of Philosophy at the University of Wisconsin.

² Uelsmann, *Jahresbericht*, 1860, 92.

believe that the solution which he had saturated with hydrogen selenide contained a seleno-tungstate and efforts were directed to crystallize a seleno-tungstate from a concentrated solution of ammonium tungstate which had been saturated with hydrogen selenide.

Preparation of Materials

Elementary Selenium.—A rapid stream of sulfur dioxide was passed into a hot hydrochloric acid solution of selenium dioxide. The selenium was filtered, washed with hot water, then with alcohol and finally with ether. It was dried at 105°.

Hydrogen Selenide.—The method of Moser and Doctor³ was used to prepare the hydrogen selenide.

Tungstic Oxide.—Tungstic oxide, WO_3 , was prepared from well-crystallized sodium tungstate. Sodium tungstate was treated with hydrochloric acid and evaporated to dryness. The sodium chloride was dissolved out of the dried mass with hot water and the tungstic oxide was filtered, washed and dried. An analysis of the sodium tungstate showed good agreement with the formula $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$.

Preparation of Seleno-tungstates

Procedure

A solution of ammonium tungstate was prepared by adding an excess of tungstic oxide to ammonium hydroxide of specific gravity 0.90 and filtering off the excess of the oxide. The ammonium tungstate solution was placed in a reaction chamber which consisted of a 250cc. wash bottle with an enlarged delivery tube to prevent stoppering of the tube with the crystalline product. Nitrogen was used to sweep the air out of the system. Hydrogen selenide was then passed through the ammonium tungstate solution. During the course of the reaction heat was liberated, the solution changed to a dark brown color and crystals deposited on the sides of the container. Cooling of the reaction chamber caused more crystals to deposit from solution. During some of the early experiments it was noted that sometimes dark green crystals would be formed and at other times red ones would be obtained.

The green crystals were found to be ammonium seleno-tungstate $(\text{NH}_4)_2\text{WSe}_4$, as will be shown later, and the red ones ammonium diseleno-tungstate $(\text{NH}_4)_2\text{WSe}_2\text{O}_2$. When the ammonium tungstate solution was saturated with hydrogen selenide, the green crystals were obtained, and the red crystals deposited from the solution when it was incompletely saturated with hydrogen selenide.

From the knowledge of the ease of oxidation of other seleno compounds it was anticipated that the preparation, filtration and washing of the crystals would necessitate the process being carried out in the absence of oxygen. Both crystalline compounds were treated in the same manner after removal from the chamber.

The crystals, together with enough of the mother liquor to cover them, were transferred to the filter as rapidly as possible to avoid oxidation. The small amount of oxidation which occurred during the transfer was confined to the mother liquor. The crystals were washed first with alcohol, then with ether to displace the alcohol and finally with carbon disulfide to dissolve traces of selenium which might cling to the crystals from the mother liquor. The carbon disulfide was purified by shaking it with phosphorus pentoxide and mercury and then distilling it. The crystals were finally dried for several hours in a current of hydrogen. Oxygen was removed from the hydrogen by passing the gas over hot copper gauze and moisture was removed by passing the gas through sulfuric acid and phosphorus pentoxide.

³ Moser and Doctor, *Z. anorg. Chem.*, **118**, 284-292 (1921).

Methods of Analysis

Determination of Ammonia.—Ammonia was determined by adding an excess of sodium hydroxide and distilling the liberated ammonia. Tenth normal acid was used to collect the ammonia and the excess acid was titrated with tenth normal alkali, using methyl orange as an indicator.

Determination of Tungsten.—Tungsten was determined by igniting the sample in a porcelain crucible over a Bunsen burner. The tungstic oxide, WO_3 , which remained after the ignition was weighed.

Determination of Hydrogen.—Although the analysis of the red crystals showed good agreement with the formula $(NH_4)_2WSe_2O_2$, it was thought advisable to determine the hydrogen. Such a determination would necessarily reveal the presence of water. Combustion of the compound was carried out in the ordinary manner with the exception that a plug of potassium chromate was placed in the combustion tube to retain selenium dioxide.⁴ The sample in the boat was also covered with potassium chromate.

Determination of Selenium.—The determination of selenium required an oxidation of the compounds, a separation of the tungsten from the selenium and a precipitation of selenium as the element. Oxidation was carried out in a Parr sulfur bomb. The charge was made up in the following manner. Approximately 14.0 g. of sodium peroxide was mixed with 0.60 g. of starch and the mixture divided into two equal parts. The sample was mixed in the bomb with one of these parts and the second part placed on top of the mixture containing the sample. The fuse wire was arranged so that it was suspended in the upper mixture. After firing the charge, the material in the bomb was dissolved out with water and the solution boiled for a few minutes to decompose the hydrogen peroxide. The solution was then cooled and strongly acidified with hydrochloric acid. Tungstic acid was precipitated in the acid solution. Precipitation and coagulation were completed by adding a few cubic centimeters of a hydrochloric acid solution of cinchonine. The precipitate was filtered on a Gooch crucible and washed with a cinchonine solution. Repeated tests for selenium in the precipitate containing the tungsten showed that a good separation of tungsten from selenium was obtained with a single precipitation.

To one volume of the filtrate containing the selenium in the form of selenic acid were added one volume of hydrochloric acid (sp. gr. 1.20) and one volume of the same acid which had been saturated with sulfur dioxide. The solution was allowed to stand until most of the selenium had settled to the bottom of the beaker. The supernatant liquid was poured through a Gooch crucible and the sodium chloride which had precipitated with the selenium from the strong hydrochloric acid solution was dissolved with water. Before transferring the selenium to the Gooch crucible it was washed with strong hydrochloric acid and then changed to

⁴ Julien, *THIS JOURNAL*, **47**, 1799 (1925).

the black variety by treatment with hot water. The selenium was washed first with hot water, then with alcohol and finally with ether. It was dried at 105° and weighed.

Results

The results of the analysis are given in the following tables.

TABLE I
AMMONIUM SELENO-TUNGSTATE, $(\text{NH}_4)_2\text{WSe}_4$

	Found, %			Calcd., % $(\text{NH}_4)_2\text{WSe}_4$
	1	2	3	
W	34.22	34.04	34.38	34.27
NH_4	6.34	6.44	6.50	6.33
Se	59.45	58.85	58.90	59.01

TABLE II
AMMONIUM DISELENO TUNGSTATE, $(\text{NH}_4)_2\text{WSe}_2\text{O}_2$

	Found, %			Calcd., % $(\text{NH}_4)_2\text{WSe}_2\text{O}_2$
	1	2	3	
W	44.92	44.91	44.73	44.83
NH_4	8.40	8.38	8.45	8.30
Se	38.30	38.45	38.60	38.50
H_2	1.97	1.99	...	1.96

The experimental values are seen to be in close agreement with the calculated ones. The results for the hydrogen show that the compound contains no water of crystallization.

Properties of Seleno-tungstates

Crystals of ammonium seleno-tungstate and ammonium diseleno-tungstate which have been carefully washed and dried do not show any discoloration when kept in a calcium chloride desiccator for several months. However, a slight odor which resembles hydrogen selenide can be detected.

Both the seleno-tungstate and the diseleno-tungstate are readily soluble in water, somewhat soluble in alcohol, but insoluble in ether, benzene and carbon disulfide. The seleno-tungstate yields a red aqueous solution which is slowly decomposed in the air, giving a brown precipitate. The precipitate is probably a mixture of selenium and tungsten triselenide, WSe_3 . The diseleno-tungstate gives an aqueous solution which is similar in color to a solution of potassium dichromate but the color of concentrated solutions is also red. Aqueous solutions of the diseleno-tungstate are slowly decomposed in the air and a precipitate of red selenium is formed.

Green crystals of ammonium seleno-tungstate are reddish-brown in a finely pulverized state. In order to minimize oxidation, the crystals were pulverized under benzene.

Through the kindness of Professor A. N. Winchell of the Department of Geology of the University of Wisconsin we are publishing the following optical study which he has made of these new compounds.

Crystals of ammonium seleno-tungstate are yellowish-green in color with bright metallic luster; they gradually tarnish to a dark purple. The streak is reddish-brown which alters to black in a few days' time. The crystals are not entirely opaque under the microscope, although they are very dark and are opaque except with maximum illumination, high power and very thin flakes, which transmit a deep red color. The crystals seem to be rectangular parallelepipeds; they are not isotropic and are, therefore, not isometric; a thin flake probably parallel with a cleavage seems to be normal to a bisectrix, but the mineral is so dark-colored that greater precision is not possible. If these properties are correctly determined, the crystals are biaxial and orthorhombic and are bounded by 001, 010 and 100. They are probably isomorphous with the analogous sulfur compound $(\text{NH}_4)_2\text{WS}_4$.

The indices of refraction seem to be higher than 1.74.

Crystals of ammonium diseleno-tungstate have a brownish-red color and an adamantine luster; they are complex with numerous small faces, but have a short prismatic habit. Under the microscope a fragment nearly normal to an optic axis shows very little curvature of the isogyre; consequently the optic angle ($2V$) is nearly 90° ; the optic sign is positive. The birefringence is extreme and the dispersion is very strong; in both of these characters the mineral resembles titanite, though quantitative measures have not been made. One optic axis is nearly normal to a cleavage, which may be taken for a basal cleavage, since one such fragment shows four very low pyramid faces, nearly symmetrical; in this case the optic axis is out of center about one-third the radius of the field and roughly in the 100 plane. The angle between the prism faces (110 to $1\bar{1}0$) measured in this fragment and therefore presumably in the 001 plane is 109° . The dispersion seems to be unsymmetrical, and extinction in white light is incomplete in some cases because the dispersion is so strong.

In thin plates, probably about .03 mm. in thickness, the pleochroic colors are as follows: X = light (yellowish) green; Y = greenish-yellow; Z = brownish-yellow. All the indices of refraction are above 1.74.

Assuming a thickness of .03 mm. in one plate, the interference colors indicate that $N_m - N_p = 0.045$.

All these properties make it probable that these crystals are triclinic and isomorphous with crystals of $(\text{NH}_4)_2\text{WS}_2\text{O}_2$.

Summary

Ammonium seleno-tungstate, $(\text{NH}_4)_2\text{WSe}_4$, and ammonium diseleno-tungstate, $(\text{NH}_4)_2\text{WSe}_2\text{O}_2$, have been prepared and analyzed. Some of their properties, including the crystal form, have been studied.

**SELF-INTEGRATING CHEMICAL ACTINOMETRY FOR
ULTRAVIOLET DOSAGE OR OTHER SPECIFIC PURPOSES**

BY MERRILL JAMES DORCAS AND GEORGE SHANNON FORBES

RECEIVED AUGUST 30, 1927

PUBLISHED DECEMBER 10, 1927

A good chemical actinometer must accurately predict the photochemical reaction rate, x , in a second system as a definite function of, y , its own rate when exposed to the same light source. The implied condition is, of course, that absorption is complete and $x_{\lambda_1}/y_{\lambda_1} = x_{\lambda_2}/y_{\lambda_2} = x_{\lambda_3}/y_{\lambda_3}$ for all wave lengths involved. While all this has long been realized, actinometers in general have relied upon guess work or lucky compensations of effects to attain the desired end.

The Ives physical photometer^{1,2} automatically integrates, at any instant, in terms of thermopile deflection, the luminous equivalent of a polychromatic light source as seen by the average human eye. A filter, between source and thermopile, transmits for each wave length a fraction of incident radiation proportional to its luminous efficiency. Thus the total relative "brightness" of two sources differing widely in spectral energy distribution can properly be compared. The magnitude of any other photochemical effect could be similarly referred to the response of any non-selective radiometer if the sensitivity curve for the effect were given.

Radiometry by thermopile or bolometer requires cumbersome apparatus, favorable environment and considerable experience. A device for integrating, by chemical means, the total efficiency, for a given photochemical purpose, of any polychromatic light source ought to be widely useful. Because of the present interest in ultraviolet dosage we submit the following, with emphasis upon the general applicability of the method. Eidenow³ has discussed (with bibliography) six different devices, physical or chemical, for predicting relative efficiencies of various light sources in producing erythema (sunburn) on human skin. These include liberation of iodine from hydriodic acid, silver halide papers, selenium cell, Keller's modified iodide solution, time required to kill infusoria and Webster's methylene blue acetone. Other devices are the darkening of lithopone,^{4,5} the uranyl oxalate actinometer,⁶ cadmium photoelectric cell,⁷ and total energy transmitted by a silver film.⁸ Of these methylene blue, the cad-

mium cell and the silver film have sensitivity curves very roughly corresponding to that of the erythema reaction. But evidence is lacking that any of the above give reliable predictions when used with light sources of widely differing spectral energy distributions, and theory predicts that they could not do so, especially as they respond to light of wave lengths outside of the range productive of erythema.

Hausser and Vahle⁹ isolated seven monochromatic radiations, measured intensities by thermopile and times required to produce a standard erythema. Their plot of efficiency against wave length is unsymmetrical and extends from 313 $m\mu$ to 254 $m\mu$ and beyond with a peak at 297 $m\mu$.

We selected for the actinometer reaction the photolysis of *p*-benzoquinone in fifty per cent. alcohol. Dr. P. A. Leighton, instructor in chemistry in this Laboratory, has investigated this reaction, proving the quantum yield practically constant between 313 $m\mu$ and 254 $m\mu$. Analysis by iodimetry proved a further advantage. We are very grateful to Dr. Leighton for permission to use these and other facts in advance of the publication of his own paper.

As the curve of Hausser and Vahle is based on ergs, not quanta, we multiplied its ordinates by numbers inversely proportional to the corresponding wave lengths, and replotted. The ordinates thus corrected gave directly the proper relative transmissions of the ideal filter, since the amount of light transmitted at any wave length must photolyze a mass of quinone proportional to the erythema-producing power of the corresponding light component in the original source. The assumption that all the monochromatic effects can be integrated by summation appears reasonable in this case, as no induction period exists and only a few per cent. of the reaction mixture is decomposed. The rate of photolysis of quinone behind the filter is then proportional to the physiological effect of the naked source if the reciprocity law holds for both reactions.

Examination of data on light transmission suggested that the following, plus a suitable absorbent for the visible spectrum, might meet our requirements: quinine, α - and β -naphthylamine, triphenylmethane, auramine, Sudan G, tartrazine, α - and β -naphthol, stypticine (cotarnine) and carbostyryl. Using a spectro-radiometer kindly loaned by Dr. P. A. Leighton, we measured their transmissions and found that none would do even when the solvent was varied. Later we discovered a promising spectrogram of picric acid by Uhler and Wood¹⁰ and developed a filter having 1 cm. of 0.00025 *M* picric acid between a sheet of red-purple Corex glass 2.5 mm. thick and one of clear Corex. Fig. 1 superposes the transmission curve, B, of this combination upon the ideal transmission curve described above, A. The transmissions on the left are too great, but roughly com-

pensate for the complete extinction of the relatively inefficient region beyond 270 $m\mu$. We know of no practical light source whose emission in the last-mentioned region is large in comparison with that between 313 $m\mu$ and 270 $m\mu$. Red light, which is transmitted by this filter, has no effect on quinone. While this filter is not perfect, it sufficed for present purposes. The picric acid solution was changed after each experiment in spite of the fact that its transmission was not greatly altered by the exposure. To the back of the clear Corex plate was cemented a second glass ring, 5 cm. in diameter and 3 cm. long, also having a tubulure. To the rear edge of this ring was cemented a plate of ordinary glass completing a cell of 45cc. capacity.

Fig. 1.

Quinone, three times sublimed at the lowest possible temperature, was dissolved in 50% ethyl alcohol to form 100 cc. of 0.002 M solution. The alcohol had been fractionated, preserving only the middle portions. This solution must be made up just before use, as its absorption spectrum varies somewhat with time. It absorbs the "erythema light" completely.

Figure 2 shows the arrangement of apparatus, unchanged during the measurements. The light source was an arc between 5 mm. carbon rods, cored or uncored,¹¹ set up in a feeding mechanism regulated constantly by hand, maintaining always an alternating current of 10 amperes with an

¹¹ Spectral energy distribution curves by Coblentz, Dorcas and Hughes, *Bur. Standards Sci. Paper*, 539, 548 (1926).

arc voltage of 50. To accelerate the photolysis we used two quartz condensers each 11 cm. in diameter and 17 cm. in focal length, such as are found in moving picture projectors. Next came a quartz cell 50 mm. square and 2 cm. thick, filled with circulating water to cut down the infrared. We believe that the spectral energy distribution of the source was not affected seriously, for our purposes, through absorption and reflection by condensers and water cell. The filter and reaction cell followed, kept cool by an air blast. The diverging cone of long ultraviolet just filled the cell.

Forty-five cc. of quinone was delivered into the cell by a special pipet and the same volume into a dark vessel beside it. After irradiating the

Fig. 2.

first for about two hours, both were cooled in ice and titrated simultaneously with 0.004 *N* thiosulfate, adding 10 cc. of 1 *N* iodide and of 1.5 *N* hydrochloric acid at the start, with starch at the end. The difference was taken as a measure of photolyzed quinone, with elimination of the small dark reaction, and of oxidation by air during titration.

The results appear in Fig. 3. Quinone photolyzed per hours, y , is plotted vertically against x , the reciprocal of the time necessary to produce a uniform erythema upon the skin of one of us, using the same carbons with 20 amperes instead of 10, a variation not likely to upset *relative* efficiencies. The point *K* was closely checked by a duplicate experiment; as the spectral energy distribution of the cobalt arc¹⁰ is not extraordinary its small divergence can safely be attributed to uncertainties in comparing skin colorations. Roughly, $y = ax$. For the more efficient sources, a line of the type $y = ax + b$, where b is relatively small, is a better approximation. The change in slope is not due to absorption by reaction products

but this might make trouble if quinone photolysis exceeded 15% of the whole. We hope to follow up the indication of a threshold intensity. Apparently the reciprocity law does not hold exactly for the erythema reaction and here our results are at variance with those of Hausser and Vahle. We believe that the actinometer described above is more sound in principle and reliable in performance than others proposed for the purpose in question. It will integrate variations in total intensity and in spectral energy distribution over the period of its use. Such actinometers could not be recommended for general photochemical research, because

Fig. 3.

the radiometric work with monochromatic light needful to establish the two sensitivity curves and the proper filter would better be applied directly to the solution of the problem in hand. They should be useful, however, to study any single photochemical effect where many experiments must be made in various places. Among these are photography, where sensitivity curves are known; antirachitic therapy, whose curve should soon be available, and even chlorophyll assimilation, whose curve or curves, when known, might prove hard to reproduce in a filter.

Summary

Red-purple Correx glass, plus 1 cm. of 0.00025 *M* picric acid, transmits, at each frequency, light wattage proportional to efficiency in producing erythema (sunburn) in human skin. Quinone in 50% alcohol was photo-

lyzed behind this filter which was compensated, at each wave length, for the photochemical efficiency of this photolysis according to (unpublished) data by P. A. Leighton. Changes in total intensity and in spectral energy distribution are integrated by this device. The losses per hour in iodine value y were for seven carbon arcs, cored and uncored, plotted as ordinates against x , the reciprocals of times in which the same sources, without filters, produced a standard erythema. Roughly, $y = ax$. For the more efficient sources, $y = ax + b$ is preferable. The indicated threshold value will be further studied. Similar chemical actinometers for such purposes as photography, antirachitic therapy or even chlorophyll assimilation are possible.

THE CHEMICAL EFFECTS OF HIGH FREQUENCY SOUND WAVES I. A PRELIMINARY SURVEY

BY WILLIAM T. RICHARDS AND ALFRED L. LOOMIS

RECEIVED AUGUST 30, 1927

PUBLISHED DECEMBER 10, 1927

Introduction

Experiments on the production of sound waves for submarine signaling by a reversal of the Curie piezo-electric effect with quartz crystals in oscillating fields have been in progress for some time in several countries.¹ Since, however, the kinematic coefficient of viscosity increases as the square of the frequency, high frequencies would be absorbed rapidly in water, and these experiments have necessarily been conducted at relatively low frequencies. Recently one of us in conjunction with R. W. Wood² has shown that sound waves of great intensity may be similarly produced in high frequency fields, and that they are readily absorbed by liquids and solids. For this purpose a 2-kilowatt oscillator, capable of producing powerful oscillations with frequencies from 100,000 to 500,000 per second was employed; the quartz crystals, varying from 6 to 12 mm. in thickness and 50 to 80 mm. in diameter, were immersed in oil between two electrodes. The voltages used in submarine signaling are of the order of 1500, but the limiting voltage in our work is determined only by the sparking distance in oil between the two electrodes. In this way voltages of the order of 50,000 are possible and a corresponding increase in intensity of radiation is secured, since the amplitude of vibration

¹ A review of the literature on this subject is given in I. B. Krandall, "Theory of Vibrating Systems and Sound," McGraw-Hill Book Co., N. Y., 1926, p. 142.

² Wood and Loomis, *Phil. Mag.*, vii, 4, 417 (1927). This paper contains a comprehensive account of the physical and biological effects of supersonic waves, including detailed description of the apparatus for producing them.

of a quartz crystal increases directly with the voltage applied to it. The intense sound waves travel up through the oil into any vessel suspended in it.

Although no investigations on the chemical effects of compressional waves so produced have come to our attention, it is apparent that two correlated types of phenomena may be expected, and it is the purpose of this investigation to demonstrate their existence and order of magnitude. In the first place a series of standing waves set up by these vibrations consists of nodes and loops, matter in the nodes being relatively quiescent and in the loops being under varying tension. Therefore, at points of rarefaction in the standing waves, cavitation and similar phenomena involving the formation of a vapor phase are to be expected. Secondly, in the compressed regions of the standing waves an increase in kinetic energy density occurs, which corresponds to a local increase in temperature. Since the average temperature of the system is unaltered by this, the sound waves should have only an impalpable effect on the equilibrium constant of any chemical reaction. Such temperature changes should, however, affect the rate of a reaction, where temperature plays a considerable part, in so far as its temperature coefficient deviates from linearity, and a velocity constant corresponding to a higher temperature than that measured with a thermometer should be obtained. In the ordinary nearly balanced reaction, say the esterification of ethyl alcohol by acetic acid, it is possible that the increase in temperature of the condensed portion of the wave, and its corresponding increase in reaction velocity, would be so nearly balanced by the decrease in temperature in the rarefied portion that the measurable result on the reaction velocity would be negligible. On the other hand, in reactions which proceed irreversibly, or in any reaction extremely far from its equilibrium point, the gain in velocity of the condensed portion should not be offset by the loss in the rarefied portion, and the effect should be shown indisputably. It was a tentative argument of this kind which led to the experiments described below.

A third possible effect should be mentioned, although it cannot be treated in detail in this communication, namely, the effect of the vibration frequency of the sound wave itself on an unstable molecule, apart from its local kinetic effect upon molecules collectively. Although the frequencies used in the work described below (289,000 per second unless otherwise stated) were of a magnitude far below that of molecular vibration, certain effects, to be discussed later, seem to substantiate such an hypothesis.

General Effects

Many sensitive metastable systems are discharged by the sound waves in accordance with the foregoing discussion. Nitrogen tri-iodide is, for example, exploded when subjected to sufficiently intense radiation;

this cannot be produced by touching a watch glass containing the dried explosive to the radiated oil, but occurs only when the iodide, moist, is plastered on an "accumulator" of radiation—a fine filament drawn from the neck of an Erlenmeyer flask, the bottom of which is suspended in the radiated oil. Under these conditions the iodide collects in beads in standing waves in the glass filament, and is exploded progressively from the top to the bottom of the filament as it dries. Less sensitive explosives like ammonium nitrate, however, remain unaffected. Yellow mercuric iodide is converted to red below 120° by the sound waves, but the contact between the dry iodide and the glass is poor, and regular sound-patterns cannot be so produced. No other allotropic changes of those investigated (for example, sulfur, phosphorus, etc.) were sufficiently sensitive to give consistent results.

The sound waves have an explosively discharging effect on superheated liquids; carbon tetrachloride, for example, superheated 5° evaporates so violently as to half empty the test-tube which contains it. Similarly, carbon dioxide supersaturated in water is violently relieved, but without the spectacular consequences attendant upon the relief of superheating. Supersaturated solutions of crystalline solids in liquids and supercooled liquids are, on the other hand, little affected. A sirupy solution of sodium thiosulfate was discharged by radiation collected by an "accumulator," a metastable crystal modification being produced. A sugar "glass," liquid salol supercooled 30° , and similar solutions and liquids gave, however, no consistent results. This is easily understood when it is remembered that the effect favoring the relief of supersaturation is in this case only that corresponding to the increased probability of germ formation due to the rise in temperature in the compressional waves.

The effect of the radiation on the critical phenomena in ether was investigated in the hope that banded regions of opalescence would be produced just above and just below the critical point. A great difference in appearance rayed and unrayed was observed, the time of opalescence extending over a much greater period in the latter. During the instant when the critical point was being approached from above, mottled patterns of opalescence were unquestionably observed in the rayed tubes, but either the phenomenon was not sufficiently marked, or the interference pattern of the glass was too complex, to permit its assignation to standing waves. Cinematographic records have been made, and it is hoped that they will reveal greater regularity than the eye can perceive.

One further effect of a chemical nature is sufficiently marked to warrant special mention: namely, the "atomization" of a substance at a liquid or gaseous interface. In this way emulsions of metallic mercury in water were produced which reduce potassium permanganate and remain in suspension for several days. Similarly a test-tube of distilled water

clear to the Tyndall beam before raying, becomes faintly turbid after raying, due to small glass fragments which are "atomized" from the walls. Because of this the rays are of no value whatever for the coagulation of microscopic particles, even fairly coarse suspensions such as silver chloride precipitated in water remaining unflocculated on raying.

Certain more physical effects of the rays are also important from the point of view of the experiments detailed below. When a test-tube of liquid is suspended over the oil-bath in which the crystal is oscillating, the sound waves which rise through the oil pass through the walls of the test-tube into the liquid and are absorbed, heating it rapidly. They also set up standing waves in the glass which, by friction with the liquid, produce heat. Such heating changes the average or integral temperature by sound radiation, and must be carefully distinguished from the local temperature effects discussed above. This general heating affects the liquid as long as sound waves reach it; jacketing with ice and water diminishes the intensity of radiation which reaches a vessel but in no way diminishes the heating of the liquid by that portion which enters it. Any other thermostating device would be equally futile and, isothermal conditions being impossible, quantitative measurements in the sound waves can be made only by following the rise in temperature. Here, however, another peculiarity of the radiation intervenes. The compressional waves enter the mercury of an ordinary thermometer, setting up standing waves in the walls of the bulb, and causing it to read many degrees higher than the actual temperature in the liquid. Again, heat produced at the liquid-glass interface causes a rise in temperature greater than that in the surrounding liquid, which further invalidates any readings made during the progress of raying. A thermocouple is equally if not more ineffective for measuring temperature during raying, since heat is generated at the metal-liquid interface which causes a high local temperature (dependent largely on the viscosity of the liquid), and a lag in determining the true temperature after discontinuing the radiation which is greater even than that of a mercury thermometer. Thus a singular difficulty is encountered in quantitative work; it is impossible to work isothermally, yet no adequate measure of the temperature during radiation has been found. The methods of extrapolation and interpolation used below are not extremely satisfactory, but at least give the temperature at any instant within 0.1° .

Furthermore, when a vessel is immersed in the radiating oil-bath, its distance above the quartz crystal is of immense importance for the obtaining of reproducible results; when this distance is made an exact number of half wave lengths, standing waves are produced between the crystal and the bottom of the vessel which greatly increase the intensity of effect in the vessel. This is clearly illustrated by the following

results, obtained with a flat-bottomed beaker 5 cm. in diameter containing 50 cc. of water, which was lowered beneath the surface of the oil by a micrometer screw, being rayed at successive points in its descent.

TABLE I
THE RESONANCE EFFECT ON THE HEATING OF WATER

Distance from surface of oil in cm.....	0	0.164	0.218	0.246	0.310	0.385	0.447	0.492	0.556
Rise in temperature for 30 seconds raying.	2.7	2.2	0.85	1.5	2.2	2.0	0.8	0.6	1.5

This series of observations gives a value for the velocity of sound in oil at a frequency of 281,000 per second of 1420 meters per second, probably the only determination at anything like this frequency which was in existence at the time it was made. Recently J. C. Hubbard and one of us³ have utilized a similar principle to measure very exactly the velocity of sound in liquids.

Since, therefore, the amount of heating in the liquid is not exactly determinable, and since it is affected by the frequency of the oscillating circuit which is changed by the temperature of the quartz crystal, by the heating of the oil, by the height and configuration of the vessel, and even perhaps by the pressure hysteresis of the vessel, the reproduction of quantitative results by magnitude rather than by percentage error has alone been attempted in the sections which follow. A large test-tube with a hemispherical bottom has been found to minimize many of the sources of error outlined above, since it bridges several half wave lengths, and hence is almost devoid of tuning effects, but loses of course, in consequence, some of the energy of the waves by interference. It has been used wherever possible below.

The Lowered "Boiling" Temperature of Liquids

Preliminary measurements showed that, besides relieving superheated liquids, the sound waves would produce bubbles of vapor in air-free liquids at about 1° below their boiling temperature. Results of this kind were obtained with water, toluene, carbon tetrachloride and ether. It became, therefore, of interest to investigate the magnitude of this effect and its variation with the intensity of radiation.

Water and carbon tetrachloride were selected because of their ease of purification, chemical and associative dissimilarity and non-inflammability. A number of devices to secure slow cooling from the boiling point of these liquids were tried, the most satisfactory being jacketing the tube under observation with a spaced cage of German silver wire through which a voluntarily variable current was passed. In this way temperatures in the neighborhood of the boiling point of the liquid could be maintained to $\pm 0.05^\circ$ for several minutes. These were read by a thermometer held in the tube with a cork, through which passed also a ring stirrer to insure even heating throughout the liquid.

³ Hubbard and Loomis, *Nature*, 120, 189 (1927).

At a given temperature, the stirrer was clamped above the surface of the liquid to prevent local frictional heating, and the tube was lowered into the oil while the latter was being radiated with a predetermined intensity. The liquid had of course been scrupulously freed from dissolved gases by boiling. If bubbles of vapor at once appeared in the center of the tube, which was illuminated by a powerful beam of light to facilitate observation, the liquid was considered to "boil." If bubbles appeared only after five seconds it was considered not to "boil." The temperature was then readjusted and the observation repeated. Ten trials fixed the lowest temperature for which water would "boil" with a given intensity of radiation within $\pm 0.05^\circ$, with carbon tetrachloride within $\pm 0.10^\circ$. The intensities of radiation were determined by the heating effect of thirty seconds of radiation upon 25 cc. of water in a test-tube at 25° , the voltage in the oscillating circuit being altered at will. A relative intensity of 100% heated 25 cc. of water 2.8° , and 25 cc. of carbon tetrachloride 5.2° in thirty seconds.

A, carbon tetrachloride; B, water.

Fig. 1.—The lowering of the "boiling" point of water and carbon tetrachloride at atmospheric pressure by high-frequency sound waves as a function of the relative intensity of the radiation.

The results of this series of measurements are given below and are plotted in Fig. 1.

TABLE II

THE EBULLITION OF AIR-FREE WATER WITH VARIOUS RADIATION INTENSITIES AT ATMOSPHERIC PRESSURE

Relative intensity, %.....	100	79	70	63	54	46	40	0
"Boiling" point of water.....	97.8	98.2	98.5	98.8	99.1	99.2	99.3	99.4
"Boiling" point of CCl ₄	75.1	75.3	75.6	76.0	76.4	76.7	..	77.1

The actual boiling point at atmospheric pressure (0% intensity) was determined in the vapor of the liquid in a distilling flask, the barometric pressure being for the water determinations 744.8 mm. and for the carbon tetrachloride 743.5 mm.

In the hope of facilitating the interpretation of these results, measurements were also made in a very similar apparatus with air-free water

and carbon tetrachloride hermetically sealed under their own vapor pressures. The results for carbon tetrachloride were not reproducible, a lowering in the ebullition point of about 15° being observed for 100% intensity. Those for water were reproducible to $\pm 1.0^\circ$, but are not very satisfactory for the interpretation of the phenomenon since the exact point at which, under these conditions, water ceases to boil under its own vapor pressure is not clear.

TABLE III

THE EBULLITION OF AIR-FREE WATER UNDER ITS OWN VAPOR PRESSURE

Relative intensity, %.....	100	79	70	63
Temperature of ebullition.....	51.0	53.5	57.0	61.0

With lower intensities the results were scattered, an intensity of 30% producing no ebullition at 85° , a temperature far above 63° where ebullition could still be produced by jarring the tube without supersonic waves.

The interpretation of these results is difficult and can be attempted only tentatively. The falling off of the effect on the ebullition point with increasing intensity above 70% means, owing to its method of measurement, only that the heating effect of the waves increases more than their vapor-forming effect. That the function is of the same type in both cases plotted in Fig. 1 suggests that with increasing intensities complex interference patterns are set up in the vessel employed, and more of the radiation heats the liquid from contact with the walls, while less enters it to effect vaporization per unit rise in temperature of the system. This agrees with the qualitative observation that sound patterns on glass plates are best developed with low radiation intensities. The "boiling" point lowering of carbon tetrachloride is less than its greater heating effect per cubic centimeter would lead us to expect at high intensities, for carbon tetrachloride is raised in temperature 1.8 times as much as water, and $1.8 \times 1.6^\circ = 2.9^\circ$, whereas the "boiling" point lowering in carbon tetrachloride at 100% intensity is only 2.0° .

In attempting to discuss the significance of the results it must clearly be borne in mind that, as has been already indicated, sound waves hardly can produce a general effect on physical equilibria in such a system as water-water vapor, and hence that all explanations must be referred to local variations in the properties of the liquid in standing waves. Unfortunately the vapor pressure changes corresponding to different intensities in the three cases quoted above have no uniformity, and the fundamental mechanism of the local phenomenon must be left undetermined. Arguments of about equal weight may be advanced that this "boiling" takes place in the compressional or in the rarefied portion of the wave. In the former the temperature is higher and the pressure more intense; these changes tend to produce boiling in the liquid since both raise its vapor pressure.

Also, at a higher temperature, the surface tension of the liquid is diminished, making it easier to form a bubble of vapor which is not redissolved; this effect is probably negligible at atmospheric pressure, but seems to become very important when the liquid "boils" under its own vapor pressure. On the other hand, in the rarefied portion of the wave the liquid is under tension, which would tend to produce cavitation and the formation of vapor at less than atmospheric pressure. In this region, however, the temperature is lower, the surface tension higher, and the tendency of the vapor to form therefore diminished. No data are at hand to decide which of these two effects produces the result and we must be content with the statement that they cannot reinforce each other. If the former is effective, the artificial "boiling" may be said to be equivalent to actual local boiling, since the vapor is liberated at something more than atmospheric pressure; if the latter, the "boiling" must be considered merely a low-pressure ebullition. The sole observation which enables a choice to be made is that the bubbles rise, slowly diminishing in size to the surface through 5 cm. of liquid, and are hence probably at not less than atmospheric pressure, but this can by no means be considered conclusive evidence.

The Expulsion of Gases Dissolved in Water

A flask of water at 25° which has previously been saturated with air at 30° and then tightly stoppered becomes, upon being radiated, at once filled with bubbles of gas released by the sound waves. Similar results are obtained when the air-saturated liquid is carbon tetrachloride, methyl or ethyl alcohol, benzene, etc. Measurements were made to demonstrate the reality of this effect and the conditions which govern it.

The vessel in which the gases were liberated was constructed from a 200cc. Pyrex Erlenmeyer flask. A vertical side tube, goose-necked, and containing a small capillary constriction, was attached to this about half-way down its side, and a ring seal blown in the neck which projected a small bore test-tube almost to the bottom of the flask. This ring seal was sloped so that any gas caught under it would collect at a single point and at this point was sealed a stopcock. The volume of the flask was then measured from the under side of the barrel of the tap to the beginning of the capillary constriction. In filling the vessel with liquid to be rayed it was first dried and brought to the temperature of the thermostat, and the air which it contained swept out by the saturating gas under observation. It was then filled from a reservoir of gas-saturated liquid at the same temperature and, all bubbles of gas having been excluded, was rayed until its temperature, measured with a tested accuracy of 0.03° by a thermometer immersed in a little water in the test-tube set in the neck, had risen an appropriate amount. The gas liberated collected below the tap and was ejected into a gas buret of the usual type which gave its volume to 0.01 cc. Knowing the solubility-temperature function of the gas in the liquid under ordinary conditions, the saturation temperature and pressure, the final temperature after raying, the conditions under which the volume of the gas had been measured, and the volume of the flask, it was easy to calculate the amount ejected by supersonic rays in excess of that corresponding to the decreased solubility

of the gas due to the temperature rise. The only serious experimental difficulty in the procedure was that the sound waves occasionally produced vibrations in the flask which shattered it.

The saturating gases were nitrogen and oxygen, used from "air refined" tanks without especial purification. The water was saturated by bubbling at atmospheric pressure minus the pressure of aqueous tension at 30.2° in a large thermostat. It was demonstrated chemically that three hours' bubbling was necessary to free previously air-saturated water from all but 0.5% of its oxygen by nitrogen bubbling, hence the liquid was not considered suitable for use until at least this time had elapsed during the bubbling process.

The results obtained are given in Table IV.

TABLE IV
THE EFFECT OF RADIATION ON GASES DISSOLVED IN WATER

V	Expelling factor (III/IV).	2.8	2.6	2.8	2.7	2.7

^a The figures given after IV were obtained from the generally accepted results of Winkler for the solubilities of nitrogen and oxygen in water, and represent the difference between the volume of gas dissolved in the volume of water in question at the lower and at the higher temperature. V therefore represents the ratio between the volume of gas obtained and that calculated on the assumption that the sound waves would have no other effect than perfectly to relieve supersaturation resulting from the rise in temperature.

Each flask of different volume in the nitrogen determinations differed in type and weight. All determinations were made at 100% intensity except No. 9, which was at 70%. The constancy of the "expelling factor" for nitrogen indicates that the gas is uniformly given off throughout the period of raying and that the size and shape of the vessel and the intensity of the radiation do not affect the phenomenon; the effect of these variables has, however, been tested only over a limited range. The variations in this factor for oxygen are due to other causes.

Similar observations with carbon dioxide in water gave positive but quantitatively unsatisfactory results owing to the great solubility of the gas. With air in water the results consistently presented an interesting anomaly which will not be considered in this communication.

These measurements may be more easily interpreted than those discussed in the foregoing section, since small variations in the properties of the solvent should not, in this case, influence the result. The phenomenon may, therefore, be considered one of cavitation in the tensional regions of the standing waves, a pressure lower than atmospheric being produced locally which causes the dissolution of the gas. Therefore, it cannot be considered that the solubility of the gas is diminished in the thermodynamic sense, but only that in certain regions in the liquid conditions deviating from the average ("equilibrium") conditions are produced which cause the expulsion of gas bubbles which, rising through the liquid, are not considerably redissolved.

The Acceleration of Chemical Reactions

The purpose of this section is to demonstrate that certain chemical reactions when radiated by sound waves proceed more rapidly than is to be inferred from a strict consideration of their thermometric or integral temperature. The reactions studied must evidently be homogeneous liquid reactions since gases conduct the waves very little at ordinary pressures and solids, especially powders, are unreliable conductors. Electrometric measurements being difficult because of the exceedingly high voltages in the immediate neighborhood of the reaction under observation, the field for preliminary investigation is further narrowed to time reactions with a visual end-point, that is, "clock" reactions. A conclusively positive effect was obtained with two of the three of these which were studied.

The first, the induction period of the reduction of potassium permanganate by oxalic acid was unsatisfactory. The end-point, when the reaction was adjusted to be slow enough to allow radiation for one minute, was indefinite. Any effect of the radiation was therefore within the limit of error of observation.

The second reaction employed a familiar principle in a manner which had not come to our attention; it will later be described in detail by one of us. Dimethyl sulfate was hydrolyzed in basic solution in the presence of an indicator, in this case "brom-thymol blue." The solution contained only enough base to neutralize a quarter of the sulfuric acid liberated by hydrolysis and consequently, when neutralization had taken place, a sharp change in hydrogen-ion concentration (roughly from P_H 8 to P_H 3) occurred in a very few seconds, and the indicator was almost instantaneously changed in color. This reaction is especially satisfactory for the work in hand because it is easily adjustable to a wide range of reaction times, because it is not affected by oxygen in the air, and because the gradual inevitable heating due to sound waves caused the end-point only to become more sharp. The most satisfactory concentrations of constituents were obtained by adding 2 cc. of dimethyl sulfate to 100 cc. of 0.01 *N* sodium

hydroxide strongly colored with neutral "brom-thymol blue." Under these conditions the end-point of the reaction was reached in 335 seconds at 23.0°, 155 seconds at 30.2° and 82 seconds at 35.3°, the end-point of a single determination being clear ± 3 seconds at the lower temperature and ± 1 second at the higher.

In order to determine the effect of raying, the reaction was begun in a flask and as quickly as possible transferred to two scrupulously cleaned test-tubes, one of these being subjected to radiation at zero time. The other, used as a control, was simultaneously dipped into a bath of water at about 50° and held there, vigorously stirred, for a measured length of time just sufficient to bring its temperature above that of the rayed sample after 15 seconds' radiation. After radiation had been discontinued, the next 15 seconds were occupied in ascertaining the temperature of both portions of the solution with compared thermometers. Raying was then resumed for 15 seconds with one sample while the control was again warmed to follow the new rise in temperature. The process was continued until the blue color of the indicator became suddenly yellow in both, when the total time for each was recorded. By practice it became possible to follow with the control the temperature of the rayed sample within a few tenths of a degree, keeping the former always slightly higher in temperature to make temperature errors adverse to the effect desired.

A complete temperature-time picture of two parallel rayed and unrayed samples is given graphically by curve A, Fig. 2. This represents Determination 2, Table V; by a study of this chart the method of reporting the reactions will become sufficiently clear.

TABLE V

THE EFFECT OF SOUND WAVES ON THE HYDROLYSIS OF DIMETHYL SULFATE

Determination 1. Starting temperature, 20.4°

Temperature rayed, °C.....	24.7	26.9	28.6	30.8	32.6	34.4	36.2
Temperature unrayed, °C.....	23.8	26.1	28.5	31.0	33.2	35.0	36.2
Immersion of unrayed, seconds.....	4	11	12	14	16	14	15

Reaction time rayed, uncorrected, 195 seconds; corrected to 30.0°, 177 seconds.

Reaction time unrayed, uncorrected, 195 seconds; corrected to 30.0°, 178 seconds.

Determination 2. Starting temperature, 22.5°

Temperature rayed, °C.....	22.9	24.9	27.0	29.0	30.8	32.4	34.0
Temperature unrayed, °C.....	23.2	25.4	27.8	30.2	31.4	32.4	34.0
Immersion of unrayed, seconds....	3	5	8	7	4	6	13

Reaction time rayed, uncorrected, 195 seconds; corrected to 30.0°, 204 seconds.

Reaction time unrayed, uncorrected, 193 seconds; corrected to 30.0°, 218 seconds.

Only two determinations are reported since they represent the most conclusive and the most inconclusive results obtained, and the space which they require is disproportionate to their importance. In Deter-

mination 1 the effect of raying is within the limit of error of observation and the result must be considered doubtful. In the other an acceleration by raying has been obtained, as is made clear by the corrected reaction time value at 30.0° . This was obtained by use of the temperature coefficient, the data for which are given above, on the assumption that it is independent of concentration over a small range, and by use of the approximation that over 2° intervals the temperature-reaction-time function is linear. Because both these simplifications are entirely reasonable, and because, moreover, any errors introduced by them affect equally

Fig. 2.—A temperature-time picture of two reactions accelerated by sound waves. *A* represents the hydrolysis of dimethyl sulfate, *B* the iodine "clock" reaction; in each case the temperature of the unrayed control solution is indicated by a dotted line. The starting temperature of *A* was 20.4° , of *B* 23.8° .

the control and the rayed portion of the solution, it is estimated that the reaction times corrected to 30.0° are accurate to better than 1%. The acceleration of the reaction, averaged from all results, was 10 seconds at 30.0° .

It is perhaps disappointing that no more conclusive uniformity in the accelerating effect of the sound waves is here observed. To account for the divergence of the results it is only necessary, however, to recall the great difficulties encountered in reproducing the experimental conditions in any two parallel determinations.

The third reaction observed was the long familiar iodine "clock" depending upon the reduction of potassium iodate by sulfurous acid. This gave a much more clearly positive, although more difficultly interpretable,

result. Solutions 0.01 *M* to KIO_3 and 0.0164 *M* to Na_2SO_3 were prepared, the latter being made 4.6×10^{-4} *N* in sulfuric acid and containing also a suitable quantity of boiled starch. At a given instant 25 cc. of iodate solution was mixed with 55 cc. of sulfite solution, both at a measured temperature, and thoroughly shaken. After mixing the solution was at once poured into two large scrupulously clean test-tubes, and one of them subjected to 15 seconds' radiation while the other was externally warmed. The tubes were subsequently treated exactly as in the study of the previous reaction. The results obtained are reported in Table VI.

TABLE VI
THE EFFECT OF SOUND WAVES ON THE IODINE "CLOCK" REACTION

Detn. no.	Rel. intens., %	Time elapsed before raying, seconds	Temp. at start, °C.	Average temp. during raying, °C.	Final temp., °C.	Time end-point reached, seconds
1a	100	45	23.5	26.8	29.5	190

12b	0			26.9	28.9	214

^a This determination was carried out at a frequency of 324,000 per second, all others being at 289,000 per second.

In this table the *a* determinations have been subjected to radiation and the *b* determinations heated to follow their rise in temperature. A temperature-time picture of Determination 11 is presented graphically in Curve B, Fig. 2; here the time that elapsed before radiation was begun has also been plotted to give a complete picture of the reaction. Determination 10 was subjected to six 15-second periods of raying, and the other determinations each to five 15-second periods. The measurements

included in Table VI are representative of over thirty similar observations made. In no case were anomalous results observed which are not represented in the table. Number 9 of these determinations is a very important check upon the general conditions of the reaction; it was carried out exactly as the others except that the tube containing the radiated sample barely touched the radiated oil, and the intensity of sound waves entering it was therefore negligible, the slight heating effect observed being due only to the fact that the oil temperature was about 30°. This determination eliminates at once the possibility that the reaction is accelerated by the high frequency field.

It is unnecessary to apply a correction for the difference in temperature between the rayed and unrayed solutions in these measurements, and hence individual heating curves have been averaged during the period of raying. The temperature coefficient of this reaction is abnormal, varying considerably with the concentrations of the components. The reaction times of these solutions were 244 seconds at 20.7°, 188 seconds at 30.2° and 174 seconds at 33.1°. Since this function is nearly linear and its slope very abnormally low, the small difference in temperature between the two solutions affects their reaction times only by a factor of the second order. Since each control is at all times kept slightly above the temperature of the corresponding rayed solution, acceleration of the latter due to temperature errors is impossible, and the results are most clearly reported as they were actually observed.

Several aspects of this reaction, in contradistinction to that preceding it, strongly suggest that a factor much more powerful than the mere deviation of its temperature coefficient from linearity is involved. In the first place, the temperature coefficient of the reaction is abnormally low, a change from 25° to 35° decreasing the time by only about 25%. Furthermore, the lack of variation of the accelerating effect with intensity of radiation is exceedingly puzzling if the higher temperature of the condensed region alone is the activating agent. Finally, the excessively large effect upon the reaction velocity in comparison with that of the hydrolysis of dimethyl sulfate, and its far greater reproducibility, at once suggest a difference in action in the two cases. As a tentative explanation for these phenomena it does not seem unreasonable to suppose that the frequency of the sound waves themselves had a disintegrating effect upon some compound found in the complex chain of reactions which led to the ultimate liberation of iodine. In order to test this hypothesis Reaction 12 was carried out at a higher frequency, no quartz crystal of lower being readily available. The results show that if frequency of vibration is a determining factor it is a "band" rather than a "line" effect, but this does not in the least invalidate the hypothesis. A systematic potentiometric investigation into the stability of the various com-

pounds involved in this reaction and of other unstable molecules under sound radiation of various frequencies will at once be undertaken. In this field, as well as in several others which we can only suggest in so cursory a survey of the chemical phenomena produced by high frequency sound waves, we hope to obtain further information in the near future.

Summary

It has been demonstrated that intense high frequency compressional waves produce certain chemical effects, especially discharging metastable systems of great sensibility. They furthermore expel gases from liquids, cause ebullition in pure liquids at temperatures considerably below their boiling points at atmospheric pressure, and accelerate certain chemical reactions. The conditions of intensity and frequency affecting these phenomena have been considered. The reasons for this action are discussed, tentative explanations for various anomalous effects being advanced.

PHOTOCHEMICAL STUDIES. VI. THE PHOTOCHEMICAL REACTION BETWEEN OXYGEN AND MERCURY VAPOR AT RELATIVELY LOW PRESSURES

BY W. ALBERT NOYES, JR.

RECEIVED SEPTEMBER 6, 1927

PUBLISHED DECEMBER 10, 1927

The fundamental researches of Cario and Franck,¹ which showed that active hydrogen is produced by the illumination of a mixture of hydrogen and mercury vapor with the resonance radiation of mercury, have led to many interesting results in photochemical work. Nearly all of the reactions studied have involved hydrogen or molecules containing hydrogen atoms.

Dickinson and Sherrill² have shown that ozone is formed when a mixture of oxygen and mercury vapor is exposed to the resonance radiation of mercury in a dynamic system. They also observed the formation of a brown deposit which they assumed to be mercuric oxide. It is difficult to make determinations of the quantum efficiencies of reactions involving the resonance radiation of mercury due to the exceedingly small width of the absorption line of mercury vapor at $253.7m\mu$, but Dickinson and Sherrill showed that at least seven molecules of ozone were produced per mercury atom passing through the reaction vessel.

The present work was started with the object of ascertaining whether

¹ Cario and Franck, *Z. Physik*, **11**, 161 (1922).

² Dickinson and Sherrill, *Proc. Nat. Acad. Sci.*, **12**, 175 (1926).

mercuric oxide is formed as a primary process in the reaction between oxygen molecules and excited mercury. The results to be reported conflict in no way with the findings of Dickinson and Sherrill and will, it is hoped, throw some light on the mechanism of the pressure decrease accompanying the photochemical reaction of oxygen with mercury vapor.

I. Experimental Procedure and Results

The oxygen used in these experiments was prepared by heating solid potassium permanganate. It was dried by standing over phosphorus pentoxide.

No stopcocks were used in the main apparatus. The only source of impurity of this sort would be the wax used to attach the window to the reaction vessel. In most of the experiments a special vacuum wax was used. The edge of the vessel was well ground and the windows were plane so that relatively little surface of wax was exposed. In order to obtain evidence as to the possible effect of the wax, sealing wax was used in part of the experiments with no noticeable change in results.

Previous to making a run the vacuum system was always evacuated for several hours with continual flaming of all parts except the reaction vessel proper. Due to the wax the reaction vessel could not be heated.

The window was of plane, transparent, crystalline quartz. To eliminate the short wave lengths two different varieties of special glass were used. The first of these showed no transmission below $245\text{ m}\mu$ when photographed with a quartz spectrograph, even with a relatively long exposure. The transmission of this glass was obtained with the use of the quartz spectrograph and rotating sector. It showed approximately 50% transmission at $253\text{ m}\mu$. The second glass showed faint transmission as far as $230\text{ m}\mu$ and a somewhat greater transmission than the other variety at $253\text{ m}\mu$. In addition it showed only extremely faint transmission in the visible spectrum for wave lengths longer than $440\text{ m}\mu$. Both of these glasses eliminated those wave lengths which cause direct, unsensitized ozone formation and in addition the second of the two absorbed most of those radiations in the visible spectrum which cause ozone decomposition.³

The quartz mercury arc lamp was made in the laboratory. The arc played in a tube about 5 mm. in diameter. In most of the experiments the arc was operated under water. One series of experiments was made with the warm arc. However, the reversal of the $253.7\text{ m}\mu$ line is not complete in an arc of this type and, moreover, the general characteristics of the spectrum changed when the arc was allowed to warm up, so that in the final runs partial reversal of the resonance radiation was obtained in two different manners: (1) by interposing a cylinder open to the air at both ends, but containing a ring of liquid mercury at the lower end; (2) the apparatus shown in Fig. 1 was adopted in most of the runs. The reaction vessel is represented by D. A is a quartz window about 3.5 cm. in diameter while B is a second quartz window about 3.0 cm. in diameter. C is connected to the McLeod gage and to the vacuum pumps. E is connected to the vacuum pumps through the trap F. The trap could be isolated from the main apparatus by means of a mercury cut-off. The quartz mercury arc lamp was placed below A and the level of water is shown by the dotted line.

It is difficult to make an exact estimate of the extent to which the intensity of the $253.7\text{ m}\mu$ is reduced by the method used. Wood⁴ has stated that mercury vapor at room temperature (which he gives as 22°) reduces the intensity of the resonance radiation of mercury by 50% in a distance of 5 mm. He states that a simple exponential

³ Griffith and Shutt, *J. Chem. Soc.*, 119, 1948 (1922).

⁴ Wood, *Phil. Mag.*, 23, 689 (1912); *Physik. Z.*, 13, 353 (1912). The recent work of Hughes and Thomas [*Phys. Rev.*, 30, 466 (1927)] agrees approximately with this work.

law is not exactly followed, but that it may be used approximately for thicknesses of mercury vapor up to one or two centimeters. This absorption line of mercury vapor should be broadened by the presence of foreign gases. However, the oxygen used in these experiments was at sufficiently low pressure so that little effect of this sort would be noticed. Nevertheless a few runs were made in which nitrogen at a pressure of six or seven centimeters was admitted to the absorption cell E. Theoretically this addition of nitrogen should produce a slight effect, but this seemed to be less than the experimental error. The thickness of mercury vapor traversed by the radiation was about 2.1 cm. The temperatures used in these experiments were slightly higher than 22°, but if calculations based on the above figures are made the intensity of the resonance radiation of mercury should be reduced by 90 to 95% by the arrangement described. When reversal of the resonance radiation was not desired the trap F was immersed in liquid air.

Fig. 1.

Liquid mercury in the reaction system was about a meter distant from the reaction vessel. The vapor pressure of the mercury was that at room temperature in most of the experiments. In a few of the experiments it was lowered by immersing the trap G in an ice-water mixture.

Exact calculations based on pressure change are impossible due to the fact that the quartz window became covered with a film. This film when dissolved in nitric acid showed characteristic tests for mercury with hydrogen sulfide and with a copper wire. Since the mercuric oxide was deposited on the window and on the walls for a distance of 1.0 to 1.5 cm. from the window, this is evidence that the resonance radiation of mercury is important.

With the experimental devices described, it was possible to carry out the following series of experiments.

A. The reaction between mercury vapor and oxygen in the presence of radiation from the cooled mercury arc, that is, with radiation which causes direct ozone formation and the resonance radiation of mercury both present.

B. In the presence of radiation from the cooled mercury arc with the exception of radiation which causes direct (unsensitized) ozone formation.

C. In the presence of radiation from the cooled mercury arc with the exception of the resonance radiation which was partially reversed.

D. In the presence of radiation from the cooled mercury arc with the exception of the resonance radiation of mercury which was partially reversed and the radiation which causes direct ozone formation.

The following tables show various examples of the data obtained. Due to the fact that the mercuric oxide film caused a gradual decrease in the intensity of the radiation, only those values listed together should be compared.

TABLE I
EFFECT OF MERCURIC OXIDE FILM ON REACTION RATE

Time, min.	Pressure of oxygen, mm.	$\frac{dp}{dt}$, mm./min. $\times 10^4$	Experimental conditions
0-100	0.1986-0.1834	1.52	Full radiation from cooled mercury arc
150-200	.1768- .1703	1.30	
300-350	.1602- .1562	0.80	
500-550	.1468- .1438	.60	
1000-1100	.1248- .1230	.18	

TABLE II
EFFECT OF ELIMINATING SHORT WAVE LENGTHS AND OF PARTIAL REVERSAL OF THE RESONANCE RADIATION

Time interval, min.	Pressure of oxygen, mm.	$\frac{dp}{dt}$, mm./min. $\times 10^4$	Experimental conditions
136	0.2226-0.2196	0.221	Full radiation
685	.2196- .2192	.006	Without wave lengths shorter than 245 $m\mu$
205	.2192- .2161	.151	Full radiation
365	.2161- .2159	.005	Without wave lengths shorter than 230 $m\mu$ and visible radiation
60	.2159- .2146	.217	Full radiation
645	.2146- .2119	.0419	Full radiation except with partial reversal of 253.7 $m\mu$
650	.2119- .2049	.108	Full radiation
800	.2049- .2025	.030	Full radiation except with partial reversal of 253.7 $m\mu$
120	.2105- .2105	.00	Full radiation from warm arc without wave lengths shorter than 245 $m\mu$

The data given in the tables are examples chosen from a large number of runs. The effect of eliminating the short wave lengths is practically to stop the reaction, in many cases the change in pressure being less than the experimental error. As the average of a large number of determinations, it is found that the reaction rate with the short wave lengths absent is about 3% of the reaction rate with the full mercury arc. The results with partial reversal of the resonance line are somewhat less constant, but the average of a large number of determinations shows that the reversal of the resonance radiation reduces the reaction rate to approximately 25% of the rate obtained with the full mercury arc.

II. Discussion of Results and Conclusions

We may summarize the results obtained in the following table if the reaction rate with radiation from the full cooled mercury arc is taken as 100 and the intensity of each part of the spectrum is expressed in per cent. of radiation from the cooled mercury arc.

TABLE III
SUMMARY OF RESULTS

Approximate intensity of resonance radiation, %	Approximate intensity of short wave lengths, %	Relative reaction rates
100	100	100
50	0	3
10	100	25
10	0	0

The ionization potential of mercury vapor is 10.4 volts, while the resonance potential is 4.9 volts. The ionization potential of excited mercury vapor should be 5.5 volts. If the formation of mercuric oxide involves the transfer of electrons from the mercury to the oxygen, the reaction between excited mercury and normal oxygen should take place if molecular oxygen has an electron affinity of the proper magnitude. The work of Gibson and Noyes⁵ indicates that molecular oxygen does not have a pronounced tendency to pick up electrons. That the reaction between excited mercury and normal oxygen to form mercuric oxide is not appreciable is indicated by the above results.

The results described indicate fairly definitely that the reduction in pressure in the system is to be ascribed to a reaction between mercury vapor and ozone. Ozone may be formed in the system by two methods, viz., by the direct unsensitized reaction and by the action of excited mercury and oxygen as indicated by Dickinson and Sherrill.² However, the quantity of ozone present in a static system when a mixture of mercury vapor and oxygen is illuminated with the resonance radiation of mercury must be exceedingly small since the reaction rate is practically zero under these conditions.

⁵ Gibson and Noyes, *THIS JOURNAL*, **43**, 1255 (1921).

At a first glance it might seem that the reaction is largely between excited mercury and ozone. A simple calculation based on kinetic theory shows that the average time between collisions of a mercury atom with oxygen is of the order of 10^{-6} second. Since the duration of mercury in the excited state is of the order of 10^{-7} second⁶ and the pressure of ozone in the system is certainly small compared to the pressure of the oxygen, it would appear that collisions between excited mercury and ozone would be exceedingly rare. It might be possible to avoid this difficulty by postulating an intermediate complex of some sort with relatively long life, or by ascribing a large diameter to excited mercury atoms. The latter assumption would necessitate the additional assumption of low efficiency of collision between excited mercury and oxygen.

It is possible to show that, if the short wave lengths and the 253.7 m μ line act independently and the effects of the two types of radiation are additive, the reaction rate due to resonance radiation must be proportional to about the fourth power of its intensity. This is an unreasonable value. It seems necessary to conclude, therefore, that there is some interaction between the products formed by the radiation of short wave length and the products formed by the action of the resonance radiation. It can be shown that the reaction between excited mercury and ozone to produce mercuric oxide and two atoms of monatomic oxygen is thermodynamically possible. The result of this reaction would be to increase the rate of formation of ozone in the system.

Dickinson and Sherrill² consider that activated oxygen molecules (or perhaps monatomic oxygen) may be formed by the interaction of excited mercury with oxygen. It is probable that the action of the short wave lengths is to produce activated oxygen molecules which may dissociate upon collision.⁷ It does not seem possible at the present time to ascertain whether these two types of activated molecules would be at all similar. Since the heat of dissociation of oxygen is now considered to be approximately 160,000 calories per mole, active mercury atoms would only be able to dissociate oxygen under exceptional circumstances due to a deficiency of some 45,000 calories per mole in energy content. However, it may not be unreasonable to expect a temporary combination of the nature of a mercury peroxide, for oxygen is paramagnetic, a fact which has led Lewis to conclude that the structure of the oxygen molecule may be represented by the formula $:\ddot{O}:\ddot{O}:$.⁸ This sort of compound would in all probability

⁶ See Tolman, "Statistical Mechanics with Applications to Physics and Chemistry," The Chemical Catalog Company, New York, 1927, p. 176-177.

⁷ See Franck, *Trans. Faraday Soc.*, 21, 536 (1926); Birge and Sponer, *Phys. Rev.*, 28, 250 (1926). This applies, of course, to those wave lengths longer than the region of continuous absorption (below 175 m μ).

⁸ Lewis, *Chemical Reviews*, 1, 231 (1924); *THIS JOURNAL*, 46, 2027 (1924).

be analogous to such unstable compounds as Hg_2 and Na_2 , which Franck⁷ considers to be formed only when one of the atoms entering into combination is in the excited state. If the formation of such a complex is postulated, ozone may result upon collision of the complex with oxygen, or perhaps a larger amount of ozone upon collision of the complex with an activated oxygen or an ozone molecule. This would offer an explanation of the results herein reported. It is not possible, however, to draw such conclusions with entire certainty, as other conclusions may appear more plausible to various workers in this field. Lind and his co-workers⁹ have, however, used the ionic cluster in the explanation of reactions produced by alpha particles.

The possible effect of the mercury line at $184.9\text{ m}\mu$ has been neglected in this discussion. The intensity of this line should be negligible in the apparatus described.

The results reported in the present article do not conflict in any way with the findings of Dickinson and Sherrill,² but offer a possible explanation of the relatively large amount of ozone found by them. Unless it is assumed that each mercury atom passed through several complete cycles resulting in ozone formation while traversing their reaction vessel, it is necessary to find some means to explain the formation of at least seven molecules of ozone per mercury atom in their experiments. The above explanation, while somewhat artificial, would indicate that several molecules of ozone might be formed by the action of the unstable complex with excited oxygen or ozone.

Summary

1. The photochemical reaction between oxygen and mercury vapor is found to be due largely to the reaction between ozone and mercury vapor.

2. It is not possible to explain the phenomena observed by assuming that ozone is formed by both the sensitized and unsensitized reactions and that the effects are additive. It is suggested, therefore, that a complex (relatively unstable) may be formed between excited mercury and oxygen and that this complex may give ozone through collision with oxygen molecules, or perhaps a larger amount of ozone through collision with activated oxygen or ozone molecules.

THE CRYSTAL STRUCTURES OF TWO INTERMETALLIC COMPOUNDS

BY JAMES B. FRIAUF

RECEIVED OCTOBER 10, 1927

PUBLISHED DECEMBER 10, 1927

Introduction

The elementary constituents of alloys can be divided into three general classes:¹ pure metals and metalloids, solid solutions and intermetallic compounds. The application of x-ray methods to the study of these constituents has led to the determination of the crystal structures of the metals commonly used in alloys and has thrown considerable light on the structure of solid solutions and some of the intermetallic compounds. In order to obtain more information regarding the structure of the third class of constituents, the crystal structures of two of the intermetallic compounds formed by copper, Cu_2Mg and CuAl_2 , have been determined by x-ray methods. Cu_2Mg is one of the two compounds formed in the copper-magnesium system.^{2,3} CuAl_2 is the most important intermetallic compound formed in the copper-aluminum system^{4,5,6,7} and is likewise an important constituent in duralumin and some of the other light alloys.

Crystals of these intermetallic compounds were formed by melting together the necessary amounts of the constituent metals and slowly cooling the melt in an electric furnace. In this way a coarsely crystalline mass was obtained from which individual crystals were separated for the production of Laue and rotation photographs.

The Crystal Structure of Cu_2Mg

The size and shape of the unit cell for crystals of this compound were determined from data furnished by powder and rotation photographs taken with the K-radiation from molybdenum. The observed spacings, d , from a powder photograph are shown in the second column of Table I. Comparison with the charts of Hull and Davey⁸ shows that these spacings are among those to be expected from a face-centered cubic lattice. The indices of the reflecting planes are shown in the first column of the table,

and the values for the side of the unit cube computed from the observed spacing of a plane and its indices are given in the third column. The mean of these values for the side of the unit cube is 6.99 Å., which is in agreement with values of 6.98 Å. and 7.00 Å., obtained from another powder photograph and from a rotation photograph taken with one of the crystals used for producing the Laue photographs. The mean of these three values gives 6.99 Å. for the side of the unit cube. This unit cell is also in agreement with the data from the Laue photographs.

TABLE I
OBSERVED SPACINGS FROM A POWDER PHOTOGRAPH

hkl	d	a
111	4.045	7.007
220	2.473	6.995
113	2.107	6.987
222	2.019	6.995
400	1.745	6.979
133	1.604	6.992
151-333	1.345	6.990
440	1.236	6.992
135	1.184	7.008
260	1.100	6.957
226	1.055	6.997

Cubic axes, $a = 6.99$ Å.

The density of the compound was found to be 5.85 by a direct determination in a specific gravity bottle. The computed number of molecules in the unit cube is 8.00.

The Laue photographs obtained from crystals of this compound have the symmetry to be expected from the point groups T^d , O , or O^h . No first-order reflections were found from any planes save those with all indices odd; consequently only atomic arrangements based on a face-centered cubic lattice were considered.

Reference to a tabulation of the results of the theory of space groups⁹ shows that the possible atomic arrangements which must be considered are those which arise from space-groups T_d^2 and O_h^7 (or O^4). The structures which may be obtained from T_d^2 contain a variable parameter and should give second-order reflections from planes having two indices even and one odd, except for special values of the parameter. No second-order reflections were found from any such planes, although a number were in a position to produce a reflection at a favorable wave length. It is consequently concluded that the parameter must have a value close to the special values which give zero intensity of reflection for planes of this kind. With this restriction on the value of the parameter, certain of the structures

⁹ Wyckoff, "The Analytical Expression of the Results of the Theory of Space Groups," The Carnegie Institution of Washington, Washington, 1922.

obtained from T_d^2 can be readily eliminated, and the others can be shown to be indistinguishable from the structures obtained from O_h^7 .

Two distinct atomic arrangements may be obtained from O_h^7 (or O^4). One of these gives results which are not in agreement with the data. In the other the atoms have the following positions.

Mg: 0, $\frac{1}{2}$, $\frac{1}{2}$; $\frac{1}{2}$, 0, $\frac{1}{2}$; $\frac{1}{2}$, $\frac{1}{2}$, 0; 0, 0, 0; $\frac{1}{4}$, $\frac{3}{4}$, $\frac{3}{4}$; $\frac{3}{4}$, $\frac{1}{4}$, $\frac{3}{4}$; $\frac{3}{4}$, $\frac{3}{4}$, $\frac{1}{4}$; $\frac{1}{4}$, $\frac{1}{4}$, $\frac{1}{4}$.

Cu: $\frac{1}{8}$, $\frac{3}{8}$, $\frac{7}{8}$; $\frac{7}{8}$, $\frac{1}{8}$, $\frac{3}{8}$; $\frac{3}{8}$, $\frac{7}{8}$, $\frac{1}{8}$; $\frac{3}{8}$, $\frac{5}{8}$, $\frac{3}{8}$; $\frac{1}{8}$, $\frac{5}{8}$, $\frac{1}{8}$; $\frac{1}{8}$, $\frac{1}{8}$, $\frac{5}{8}$; $\frac{5}{8}$, $\frac{1}{8}$, $\frac{5}{8}$; $\frac{5}{8}$, $\frac{5}{8}$, $\frac{7}{8}$; $\frac{7}{8}$, $\frac{3}{8}$, $\frac{1}{8}$; $\frac{1}{8}$, $\frac{7}{8}$, $\frac{3}{8}$; $\frac{3}{8}$, $\frac{1}{8}$, $\frac{7}{8}$; $\frac{5}{8}$, $\frac{3}{8}$, $\frac{3}{8}$; $\frac{7}{8}$, $\frac{5}{8}$, $\frac{7}{8}$; $\frac{7}{8}$, $\frac{7}{8}$, $\frac{5}{8}$; $\frac{5}{8}$, $\frac{7}{8}$, $\frac{7}{8}$; $\frac{3}{8}$, $\frac{3}{8}$, $\frac{5}{8}$.

This structure gives predicted intensities which are in qualitative agreement with the observed intensities as shown in Table II, which contains

data from a Laue photograph taken with the incident beam of x-rays nearly perpendicular to a (111) plane of the crystal. The first column contains hkl , the indices of the form to which the reflecting plane belongs, followed by the order of reflection, n , if this is different from unity; the second column, the spacing of the plane divided by the order of reflection; the third column the wave length of the x-rays producing the reflection; while the fourth and fifth columns contain the observed intensity, I , and the square of the amplitude factor, S . The greatest intensity of reflection is for wave lengths between 0.35 Å. and 0.40 Å. and the data have been given for these wave lengths when possible. The observed intensities are visual estimates made by comparison with a plate which had been given a series of known exposures. The structure factors have been computed on the assumption that the scattering powers of copper and aluminum atoms are proportional to their atomic numbers. The agree-

ment is probably as good as can be expected because of the approximations involved in the computation of S , and since none of the other possible structures is satisfactory, it is concluded that the proposed structure gives the atomic arrangement in crystals of Cu_2Mg .

The atoms in this crystal have the same arrangement that has been found for the metallic atoms in spinel,^{10,11} MgAl_2O_4 , and in the complex cyanides of potassium with zinc, cadmium and mercury,¹² $\text{K}_2\text{Zn}(\text{CN})_4$, $\text{K}_2\text{Cd}(\text{CN})_4$ and $\text{K}_2\text{Hg}(\text{CN})_4$.

The least distance between two magnesium atoms is 3.03 Å., between two copper atoms, 2.47 Å., and between a copper and a magnesium atom, 2.90 Å. The corresponding values found by adding the radii which magnesium and copper atoms have in metallic magnesium and copper are 3.22 Å., 2.55 Å. and 2.88 Å.

The Crystal Structure of CuAl_2

The crystal structure of this compound has been the subject of two previous investigations. Owen and Preston¹³ used the powder method and concluded that one molecule of CuAl_2 is contained in a tetragonal unit cell with $a = 4.28$ Å. and $c = 2.40$ Å. Somewhat later, Jette, Phragmén and Westgren¹⁴ obtained Laue and rotation photographs from crystals of this compound and found it necessary to use a larger tetragonal unit cell which contains four molecules and has the dimensions, $a = 6.052$ Å. and $c = 4.878$ Å. The atomic arrangement was not determined in detail but was said to be body-centered with the symmetry of one of the crystal classes, V^d , D_4 , C_4^v or D_4^h .

In the present investigation, the size and shape of the unit cell were determined from rotation photographs taken with the K-radiation of molybdenum. If a rotation photograph of a tetragonal crystal rotating about a vertical axis which coincides with the c axis of the crystal is taken on a flat photograph plate perpendicular to the incident beam of x-rays, it can be shown that¹⁵

$$\frac{\lambda}{c} = \frac{V}{(V^2 + H^2 + D^2)^{1/2}} \quad (1)$$

where l is the third Miller index of the plane which produces a given spot on the photograph; λ , the wave length of the x-rays; c , the height of the unit cell; D , the distance from the crystal to the plate; and V and H the vertical and horizontal coördinates of the spot measured from the place where the incident beam of x-rays strikes the plate. Table III contains

the data from a rotation photograph taken with the crystal oriented in this way. The first column contains the Miller indices, h, k, l , of the form to which the reflecting plane belongs; the second column, the values of $V(V^2 + H^2 + D^2)^{-1/2}$, computed from the observed quantities, V, H and D ; the third column, the values of the second column divided by l ; while the fourth and fifth columns contain, respectively the observed spacing, d , and the spacing computed for a tetragonal unit cell with $a = 6.04 \text{ \AA.}$ and $c = 4.86 \text{ \AA.}$ Since λ and c are constants and l is an integer, Equation (1) requires that the observed values of $V(V^2 + H^2 + D^2)^{-1/2}$ should be integral multiples of the constant λ/c . The constancy of the values in the third column of the table shows that this condition is satisfied and their mean gives 4.86 \AA. for the least value which can be assumed for c . Integral multiples of this are also possible. The data from this photograph and from a number of others taken with the crystal rotating about different crystal axes, indicate that the smallest unit cell which is possible has $a = 6.04 \text{ \AA.}$ and $c = 4.86 \text{ \AA.}$ No data were found on the rotation or the Laue photographs which would necessitate the use of a larger unit cell. These values for the dimensions agree well with those obtained by Jette, Phragmén and Westgren.

622	.2918	.1459	0.891	0.889

Tetragonal axes, $a = 6.04 \text{ \AA.}$; $c = 4.86 \text{ \AA.}$

The density of CuAl_2 was determined by weighing in a specific gravity bottle and was found to be 4.37. This gives 4.00 molecules in the unit cell.

The Laue photographs taken with the incident beam of x-rays perpendicular to the (001) plane have a four-fold symmetry axis and four planes of symmetry, while those taken with the incident beam perpendicular to a (100) or a (110) plane have a two-fold axis and two planes of symmetry. The atomic arrangement must consequently be obtained from some space group isomorphous with one of the point-groups V^d , C_4^v , D_4 or D_4^h , and since no reflections were observed from any planes save those for which the sum of the indices is an even number, only body-centered arrangements were considered. This restriction is in agreement with the conclusions regarding the atomic arrangement which were reached by Jette, Phragmén and Westgren.

Reference to a tabulation of the results of the theory of space groups⁹ shows that there are numerous possible body-centered arrangements with four atoms of one kind and eight of another kind in the unit cell. Many of these possibilities are readily eliminated. Careful consideration of the remaining possibilities shows that the most satisfactory agreement with the data is obtained for the atomic arrangement which places the atoms in the following positions.

Cu: 0, 0, 0; 0, 0, $\frac{1}{2}$; $\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$; $\frac{1}{2}$, $\frac{1}{2}$, 0.

Al: u , $u + \frac{1}{2}$, $\frac{1}{4}$; $\frac{1}{2} - u$, u , $\frac{1}{4}$; \bar{u} , $\frac{1}{2} - u$, $\frac{1}{4}$; $u + \frac{1}{2}$, \bar{u} , $\frac{1}{4}$; $u + \frac{1}{2}$, u , $\frac{3}{4}$; u , $\frac{1}{2} - u$, $\frac{3}{4}$; $\frac{1}{2} - u$, \bar{u} , $\frac{3}{4}$; \bar{u} , $u + \frac{1}{2}$, $\frac{3}{4}$.

This arrangement may be obtained from D_{4h}^{18} and equivalent arrangements may be obtained from several other space groups. One of the characteristic features of such an atomic arrangement is that it predicts zero intensity of reflection from all planes of the forms $(0kl)$ where k and l are both odd. No reflections from any planes of these forms were found on any of the photographs, although a considerable number of planes of this kind were in a position to produce reflections at favorable wave lengths. Furthermore, the copper atoms contribute nothing to reflections from planes of the forms (hkl) where l is odd, and h and k are one even and one odd. A large number of planes of this kind were present on the photographs and a consideration of their intensities enables the parameter, u , to be determined free from any uncertainty regarding the relative scattering powers of copper and aluminum atoms. In order to obtain satisfactory agreement with the data, u must be nearly equal to 0.158. Table IV contains the data from a Laue photograph taken with the incident beam of x-rays nearly perpendicular to a (110) plane of the crystal. The first column contains hkl , the indices of the form to which the reflecting plane belongs, followed by the order of reflection, n , if this is different from unity; the second column, the spacing of the plane divided by n ; the third column, the wave length of the x-rays producing the reflection; while the fourth and fifth columns contain the observed intensity, I , and the square of the structure factor, S . The most intense reflections are for wave lengths

between 0.40 Å. and 0.48 Å., and have been given in this region. The observed intensities are visual estimates made by comparison with a plate which had been given a series of graduated exposures. S^2 has been given instead of S , since the crystal is probably sufficiently imperfect to give reflections more nearly proportional to S^2 than to S . S has been computed in the usual way¹⁶ on the assumption that $u = 0.158$ and that the scattering powers of copper and aluminum atoms are proportional to their atomic numbers. The values of S^2 in the last column account quite satisfactorily for the observed intensities from planes which do not differ greatly in spacing, except that certain of the planes with l even give more intense reflections as compared to neighboring planes with l odd than is indicated by the corresponding values of S^2 . Discrepancies of this kind are to be expected, however, because of the approximations underlying the computation of S . A number of theoretical and experimental investigations have shown that the scattering power of an atom is not a constant proportional to the number of outer electrons it contains, but is a function of the glancing angle, θ , which decreases as θ increases. This decrease is more rapid for atoms with a small number of electrons than for atoms with a larger number, and the relative scattering powers of two atoms will con-

¹⁶ Wyckoff, "The Structure of Crystals," The Chemical Catalog Company, Inc., New York, 1924, p. 104.

sequently also be a function of θ . An exact evaluation of the changes which would be introduced into the calculated structure factors by this variation in scattering power cannot be made in the absence of a knowledge of the forms to be ascribed to the F curves for copper and aluminum atoms in crystals of CuAl_2 , but a qualitative estimate can readily be made and shows that the changes which would be introduced into S if the variation in scattering power were taken into account are in such a direction as to bring the calculated values of S^2 into better agreement with the observed intensities. The agreement is consequently thought to be satisfactory and since there is also good agreement with a Laue photograph which was taken with the incident beam of x-rays nearly perpendicular to the (001) plane of the crystal, it is concluded that the proposed structure gives a close approximation to the atomic arrangement in crystals of CuAl_2 . None of the other possible structures considered was found satisfactory.

The least distance between two copper atoms is 2.43 Å., between two aluminum atoms, 2.70 Å., and between a copper and aluminum atom 2.59 Å. These are somewhat less than the values 2.54 Å., 2.86 Å. and 2.70 Å. computed from the radii which copper and aluminum atoms have in metallic copper and aluminum.

Summary

The atomic arrangements in crystals of two of the intermetallic compounds formed by copper, Cu_2Mg and CuAl_2 , have been determined by x-ray methods.

THE REACTION BETWEEN POTASSIUM CARBONATE AND SULFUR IN ALCOHOL SOLUTION

BY TENNEY L. DAVIS AND JULIAN W. HILL

RECEIVED OCTOBER 24, 1927

PUBLISHED DECEMBER 10, 1927

In his "Experiments and Notes about the Producibleness of Chymical Principles," appended to the second English edition of "The Sceptical Chymist," Oxford, 1680, Robert Boyle discusses the possibility of transmuting or changing into one another the so-called elements of the alchemists. As evidence that "a disposition to be dissoluble in this or that liquor may be acquir'd by mixture," he points¹ to the fact that, whereas neither "salt of tartar" (potassium carbonate) nor sulfur is soluble in "spirit of wine" (alcohol), "yet if this Salt and Sulphur be mixt together, spirit of Wine will in less than an hour and sometimes in less than a quarter

¹ Robert Boyle, *op. cit.*, p. 4. Concerning the several editions of "The Sceptical Chymist," see *Isis*, 8, 71 (1926).

of that time dissolve enough of this matter to be richly color'd by it, and this without the help of external heat."

We have verified Boyle's observation. A mixture of powdered sulfur with anhydrous potassium carbonate does indeed impart a yellow color to alcohol after a few hours' standing. After a longer interval the color is deeper, and after three or four days no further change is apparent. With boiling alcohol the reaction is very rapid. We have not been able to find in the literature any explanation of this behavior or of the reaction itself—and have accordingly made experiments to determine the matter.

The deep yellow liquid is not a colloidal solution for it shows no Tyndall effect. On dilution with water it gives a precipitate of finely divided sulfur, about the same amount of precipitate as is produced by adding water to a saturated solution of sulfur in alcohol. On acidification it gives hydrogen sulfide and a precipitate of sulfur—evidence that it contains potassium polysulfide. On shaking with metallic mercury it is rendered colorless and produces black mercury sulfide. If air is bubbled through the yellow liquid or brought in contact with it by shaking in a capacious flask, the liquid quickly loses its color and deposits a precipitate of sulfur and potassium thiosulfate. These reactions are the same as those of an aqueous solution of potassium polysulfide except, of course, that potassium thiosulfate does not precipitate when the aqueous solution is oxidized.

The precipitate which was produced by agitating the yellow alcohol solution with air was collected, dried and freed from sulfur by washing with carbon disulfide. The white residue was recrystallized from water, in which it was very soluble, and was analyzed for potassium by fuming down twice with sulfuric acid, igniting with ammonium carbonate, and weighing as K_2SO_4 . Found: potassium 41.08%, 41.08%; calculated for $K_2S_2O_3$, potassium 41.11%. The thiosulfate was further identified by qualitative tests with hydrochloric acid, silver nitrate, ferric chloride and stannous chloride.

When powdered sulfur is allowed to stand at laboratory temperature with a strong aqueous solution of potassium carbonate, the liquid becomes pale yellow after about two weeks and does not become deeply colored even after long standing. In boiling water the reaction is more rapid, but still much less rapid than it is in boiling alcohol. Although potassium carbonate is readily soluble in water, sulfur is almost entirely insoluble, and the greater speed of the reaction in alcohol solution is due to the fact that alcohol dissolves an appreciable quantity of both reagents and that the mass-action product of the concentration of the reagents in that solvent is greater in consequence. We have found that absolute ethyl alcohol solutions saturated at 25° contain in 100 cc. 0.1114 g. of anhydrous potassium carbonate, 0.0088 g. of anhydrous sodium carbonate and 0.03926 g. of sulfur. When sodium carbonate and sulfur are boiled together in alcohol, the reaction is slight and the solution becomes only faintly colored.

We have attempted to isolate and analyze the pure potassium polysulfide from the alcohol solution. The yellow liquid was filtered and evaporated to dryness in a stream of dry nitrogen, and the residue was freed from sulfur by washing with carbon disulfide. Sulfur was determined by dissolving dried and weighed portions of the orange-brown material in water, oxidizing with bromine water, and precipitating as barium sulfate. Among many analyses several pairs of checks were obtained, but the checks were discordant with one another. Although the yellow alcohol solution did not smell of hydrogen sulfide, it was found that the vapors from its evaporation, even when the evaporation was carried out at laboratory temperature, contained hydrogen sulfide enough to blacken lead acetate paper. Alcoholysis evidently occurred, potassium ethylate was undoubtedly present in varying amounts in the residues from the evaporations—and an attempt at fractional crystallization of the polysulfide from alcohol was abandoned as impracticable.

Summary

The reaction between potassium carbonate and sulfur in alcohol solution is essentially the same as in water solution but is very much more rapid. Alcohol dissolves an appreciable amount of both substances, while water dissolves a large amount of one and exceedingly little of the other. The solubilities of potassium carbonate, sodium carbonate and sulfur in absolute ethyl alcohol at 25° have been determined.

THE ODOR AND STRUCTURE OF CERTAIN CYCLIC ACETALS¹

BY R. R. READ, HUBBEL LATHROP AND H. L. CHANDLER

RECEIVED APRIL 21, 1927

PUBLISHED DECEMBER 10, 1927

Verley² isolated an oil from jasmine blossoms that had as a principal constituent the cyclic acetal of phenylethyleneglycol and formaldehyde-1-phenyldioxolane. This compound was synthesized and found to have the same jasmine-like odor. The corresponding derivatives from acetaldehyde and valeraldehyde proved to have similar odors.

Shortly afterwards Hesse and Müller³ reported that no trace of this acetal was to be found in jasmine oil and that the odor was due to two compounds of unknown nature in addition to phenylethyl acetate and a terpene alcohol ester.

¹ For the odor evaluation of the products described in this paper the writers are indebted to Burton T. Bush, Inc., of New York City, particularly to Dr. Ph. Chaleyey of that Company.

² Verley, *Compt. rend.*, **128**, 314 (1899).

³ Hesse and Müller, *Ber.*, **32**, 565 (1899).

Whether or not the odor of jasmine oil is due to dioxolane derivatives, it was of interest to determine whether compounds related to those described by Verley were odorous and, if so, how the odor was affected by variations in structure.

Accordingly acetals based on the following glycols have been prepared: 1-phenoxy-2,3-propanediol, 1-phenyl-1,2-propanediol, 1-phenyl-2,3-propanediol, 1-*m*-methylphenyl-2,3-propanediol and 1-*p*-methylphenyl-2,3-propanediol, using as the other component formaldehyde, acetaldehyde and, in one case, heptaldehyde.

The following dioxolane derivatives were prepared: (a) 1-phenoxy-methyl-, (b) 1-phenoxy-methyl-4-methyl-, (c) 1-phenoxy-methyl-4-*n*-hexyl-, (d) 1-phenyl-2-methyl-, (e) 1-phenyl-2,4-dimethyl-, (f) 1-phenyl-2-methyl-4-*n*-hexyl-, (g) 1-benzyl-4-methyl-, (h) 1-benzyl-, (i) 1-*m*-methylbenzyl-4-methyl-, (j) 1-*m*-methylbenzyl-, (k) 1-*p*-methylbenzyl-4-methyl-.

Conclusions were drawn as follows:

(a) Phenoxy-methyldioxolanes have markedly less odor than the corresponding phenyl, benzyl and methylbenzyl derivatives.

(b) Methylbenzyldioxolanes are less odorous than the benzyl derivatives.

(c) A methyl group in the 4 position increases the original odor but not its persistence.

A summary of the character of the odors of the dioxolanes listed above is: (a) not agreeable or lasting, similar to (b) but weaker; (b) slight, not agreeable, somewhat like diphenyl or cresyl oxide; (c) very weak, oily; (d) when fresh reminiscent of Rumanian petroleum ether, on standing has faint sweet-pea character; (e) similar to phenylglycol acetate but milder; (f) slight, not floral; (g) when fresh similar to phenylglycol acetate, not lasting; (h) when fresh has a chemical odor, on standing reminiscent of phenylpropionaldehyde and lilac; (i) slight, similar to (a) and (b); (j) very similar to phenylglycol acetate, not lasting; (k) very slight.

These acetals are not extremely stable, apparently regenerating aldehyde on long standing although repeated distillation does not affect the boiling range.

Experimental

References, methods of preparation, constants and other data on the glycols used are given in the following table.

Preparation of Dioxolanes.—These were all prepared in the same way⁴ by heating equal molal fractions of the glycol and aldehyde on a steam-bath under a reflux condenser with stirring for six hours. Five drops of 40% sulfuric acid was used as a catalyst. An excess of solid sodium carbonate was added, the oil taken up in ether, washed once with dilute carbonate solution, twice with water and then dried over sodium sulfate. After the removal of the ether the product was vacuum distilled.

CHLORINATION OF β,β -DICHLORO-ETHYL SULFIDE. I¹

BY W. E. LAWSON AND T. P. DAWSON

RECEIVED JUNE 7, 1927

PUBLISHED DECEMBER 10, 1927

The only feasible methods for the destruction of Mustard Gas, or β,β -dichloro-ethyl sulfide, involve the use of chlorine. Small amounts in the laboratory may be oxidized with nitric acid to the sulfoxide, which is non-vesicant, that is, does not cause blistering of the skin, and under certain conditions clothing may be demustardized with live steam, but these are practically the only instances of other means for its destruction.

The ease and rapidity with which β,β -dichloro-ethyl sulfide is chlorinated suggests a preliminary addition of the chlorine followed by a molecular rearrangement involving substitution of one atom of chlorine and elimination of one molecule of hydrogen chloride² according to the equations

Certain facts that give support to this view have already been published. The sulfide is promptly oxidized to the sulfoxide by nitric acid;³ it reacts with chloramine-1 to form an addition product, $(\text{ClCH}_2\text{CH}_2)_2\text{S} = \text{NSO}_2\text{-C}_6\text{H}_4\text{CH}_3$;⁴ and it adds bromine to form a dibromide and perbromide.⁵

One paper on the chlorination of β,β -dichloro-ethyl sulfide has appeared, besides a number of chemical warfare studies. Mann and Pope⁶ chlorinated the compound to different stages with gaseous chlorine and

isolated three compounds which they termed α,β,β' -trichlorodiethyl sulfide, $\alpha,\beta,\beta,\beta'$ -tetrachlorodiethyl sulfide and $\alpha,\alpha,\beta,\beta,\beta,\beta'$ -hexachlorodiethyl sulfide. McCrumb and Reeves⁷ found that more than the theoretical quantity of hydrogen chloride was evolved on chlorination, and isolated a chloro-ethylchlorovinyl sulfide, without, however, determining the position of the chlorine atoms. Our own experience leads us to believe that it was a mixture of two isomeric compounds. Pfanstiel and Peakes⁸ also noted the evolution of hydrogen chloride in more than the theoretical amount on chlorinating the sulfide.

Our study of the chlorination of β,β -dichloro-ethyl sulfide was divided into three parts: (1) isolation of the intermediate addition product in chlorination; (2) preparation of the lower chlorinated derivatives; (3) tabulation of the different compounds theoretically possible in chlorination.

Isolation of Intermediate Addition Product

On treating a solution of β,β -dichloro-ethyl sulfide in carbon tetrachloride with chlorine at a temperature of -5 to 0° , the intermediate addition product in the process of chlorination, β,β -dichloro-ethyl sulfonium chloride, $(\text{ClCH}_2\text{CH}_2)_2\text{SCl}_2$, crystallizes from solution in white needles. The chlorine may be added directly or as a solution in carbon tetrachloride. No hydrogen chloride is liberated during this treatment. The compound is unstable at room temperature. It decomposes simultaneously in two ways, forming dichloro-ethyl sulfoxide and trichlorodiethyl sulfide, the main reaction being the formation of the latter. Solution in 95% alcohol, however, yields chiefly the sulfoxide.

Preparation of Chlorinated Sulfides

It was considered that the isolation and decomposition of β,β -dichlorodiethyl sulfonium chloride would give a very pure α,β,β' -trichlorodiethyl sulfide, one probably less contaminated by other chlorinated derivatives than the compound described as such by Mann and Pope.⁶ On distillation of this relatively pure trichlorodiethyl sulfide, great quantities of hydrogen chloride were evolved and no definite boiling point was observed. After ten distillations, two distinct fractions were obtained boiling at 73.5 – 74.5° (4 mm.) and 69.5 – 70.5° (4 mm.), respectively. Analysis showed both to have the same empirical formula, corresponding to chloro-ethylchlorovinyl sulfide. Both compounds were oxidized by dilute nitric acid to form β -chloro-ethane sulfonic acid, from which ammonium β -chloro-ethane sulfonate was obtained in small needles melting at 200° . This proved the presence of a β -chloro-ethyl group in each of the above compounds and left only the position of the chlorine on the vinyl group

⁷ McCrumb and Reeves, Chemical Warfare Report.

⁸ Pfanstiel and Peakes, Chemical Warfare Report.

in doubt. The higher-boiling compound had a sweet odor; the lower-boiling isomer had the penetrating odor of α,α -dichloro-ethyl sulfide, though the odor was not as strong. The α -chlorovinyl derivative should have a lower boiling point than the corresponding β -chlorovinyl compound. Both compounds were treated with the sodium salt of β -naphthol; the β -chloro-ethyl- β -chlorovinyl sulfide reacted with two moles, while the β -chloro-ethyl- α -chlorovinyl sulfide reacted with but one.

This would seem to complete the proof of structure, but as the proof was inferential rather than direct, the preparation and decomposition of α -bromo- β,β' -dichlorodiethyl sulfide was carried out following the method described for its chlorine analog. Decomposition during distillation was very great, but there was finally obtained a compound free from bromine having a boiling point of $77-77.5^\circ$ (4 mm.), as compared with $73.5-74.5^\circ$ (4 mm.) for the same compound in a slightly purer state made by chlorination instead of bromination. The only possible formula for this compound is β -chloro-ethyl- β -chlorovinyl sulfide, which is in accord with the inferential proof already given.

Compounds Theoretically Obtainable by Chlorination of Dichloro-ethyl Sulfide

The instability of α,β,β' -trichlorodiethyl sulfide and its decomposition on distillation to give the two isomers, β -chloro-ethyl- β -chlorovinyl and β -chloro-ethyl- α -chlorovinyl sulfides, affords an explanation for the failure of Mann and Pope⁶ to isolate pentachlorodiethyl sulfide. They considered their products to have been α,β,β' -trichlorodiethyl sulfide, analyzing 2.6% hydrogen with a theoretical value of 3.6; $\alpha,\beta,\beta,\beta'$ -tetrachlorodiethyl sulfide, analyzing 1.8% hydrogen with a theoretical value of 2.6; and $\alpha,\alpha,\beta,\beta,\beta,\beta'$ -hexachlorodiethyl sulfide, analyzing 1.3% hydrogen with a theoretical value of 1.4.

We have found that α,β,β' -trichlorodiethyl sulfide is so unstable that it is absolutely impossible to isolate it by distillation at pressures as low as 3.5 mm. of mercury. The compound isolated by Mann and Pope could not, therefore, have been the trichlorodiethyl sulfide. If, however, we postulate the splitting out of hydrogen chloride from tetrachlorodiethyl sulfide to give a chloro-ethyldichlorovinyl sulfide, and if we explain similarly the decomposition of pentachlorodiethyl sulfide to give chloro-ethyltrichlorovinyl sulfide, there is afforded an explanation for the low hydrogen values obtained by them in analyzing their tri- and tetrachlorinated derivatives, and also for their inability to isolate the pentachloro derivative.

By assuming the instability of the chlorinated ethyl group after chlorination of β,β -dichloro-ethyl sulfide, the following list of compounds is theoretically possible.

(1) Prepared in this paper.

(2) Prepared by Mann and Pope.

(3) Prepared but will be published in subsequent paper.

(4) Not prepared.

Both of the chloro-ethyl chlorovinyl compounds are irritating and slightly vesicant, but by no means comparable to their parent compound, β,β -dichloro-ethyl sulfide. The higher chlorinated derivatives, saturated or unsaturated, are non-vesicant. This is also in accord with the findings of Mann and Pope.

Experimental Part

Preparation of β,β -Dichloro-ethyl Sulfonium Chloride

A sample of β,β -dichloro-ethyl sulfide weighing 15.98 g. was diluted with 50 cc. of pure, dry carbon tetrachloride in a 500cc. Pyrex boiling flask whose paraffined stopper bore a stirrer, thermometer, dropping funnel, and an exit tube filled with calcium chloride. A solution of chlorine in dry carbon tetrachloride containing 7.13 g. of chlorine was also prepared. Flasks and solutions were chilled to -5° , after which the chlorine solution was slowly added, the temperature being maintained at -5 to 0° . A white precipitate appeared very soon after the addition of the chlorine solution was begun and increased in amount as more chlorine was added. The precipitate was filtered off on a Büchner funnel, washed with cold carbon tetrachloride, and transferred to a small Erlenmeyer flask. In about three minutes the mass began to liquefy; the reaction increased with rapidity and was complete in about two more minutes, leaving a colorless liquid. Hydrogen chloride was evolved in great quantity during the decomposition but was not evident before. The reaction was slightly endothermic. This decomposition does not take place when a thin layer is placed in a desiccator or spread out on filter paper in the open air. Instead, the chloride was found to be slowly converted to the sulfoxide. This suggests that the chlorination reaction may be catalyzed by hydrogen chloride. Alcohol increases sulfoxide formation, for pure sulfoxide was obtained by dissolving the sulfonium chloride in 95% alcohol.

Samples of the solid addition product were weighed into dry tared flasks and connected with bubblers containing sodium hydroxide solution. Dry air was used to sweep the liberated hydrogen chloride into the standard alkali solution. Only 64 to 73% of the theoretical amount of hydrogen chloride was collected, showing that considerable decomposition had taken place during the isolation and weighing of the material. This was confirmed by immersing the addition product in sodium hydroxide solution. After standing for ten days so as to insure complete hydrolysis of the chlorine, but 62.5% was accounted for.

Preparation of Chlorinated Sulfides

A modified Dufton column⁹ of Pyrex glass was constructed, 57 cm. in length from constriction to side outlet and with an internal diameter of 18 mm. The column was well lagged with asbestos paper and provided with a nichrome wire heating element. The distilling flask was immersed in a Wood's metal bath.

β,β -Dichloro-ethyl sulfide was chlorinated in four lots of 100 g. each diluted with 300 cc. of dry carbon tetrachloride. Chlorine gas was passed in at about 35 cc. per minute, the solution being stirred vigorously throughout the period of addition and maintained at a temperature below 35°. The reaction products from the four runs were combined, freed from carbon tetrachloride by distilling under reduced pressure, then distilled twice at 5 to 6 mm. pressure; yield, 358 g.

This product was then distilled through the Dufton column at the rate of one drop every three to four seconds; yield, 284 g. After seven more distillations through the column, collecting separate fractions every two or three degrees, the isomers were finally separated in a comparatively pure state: β -chloro-ethyl- β -chlorovinyl sulfide, b. p. 73.5–74.5° (4 mm.), yield 130 g.; β -chloro-ethyl- α -chlorovinyl sulfide, b. p. 69.5–70.5° (4 mm.), yield 60 g.

The greater stability of the β -halogen, indicated above by the respective yields of the two isomers, was also shown by an analysis of the exit gases from the decomposition of α -bromo- β,β' -dichlorodiethyl sulfide. This showed 74% of hydrogen bromide and 26% of hydrogen chloride.

The following new compounds were prepared and identified in connection with this study.

β,β -Dichloro-ethylsulfonium Chloride.—Formed by the addition of chlorine to β,β -dichloro-ethyl sulfide at about 0°. Colorless needles; insoluble in carbon tetrachloride; decomposes at room temperature to form α,β,β' -trichlorodiethyl sulfide and hydrogen chloride, the hydrogen chloride apparently acting as a catalyst to speed up the reaction. In the presence of water or water vapor another reaction takes place, giving β,β -dichloro-ethyl sulfoxide and hydrogen chloride.

α,β,β' -Trichlorodiethyl Sulfide.—Colorless liquid formed by the decomposition of β,β -dichloro-ethyl sulfonium chloride. It decomposes slowly at room temperature with evolution of hydrogen chloride and cannot be distilled at a pressure as low as 3.5 mm.; $d_4^{20} = 1.4038$; $n_D^{22.5} = 1.5309$.

⁹ Dufton, *J. Soc. Chem. Ind.*, **38**, 45 (1919).

β -Chloro-ethyl- β -chlorovinyl Sulfide.—Colorless oil obtained by repeated fractionation of the distillation product of α,β,β' -trichlorodiethyl sulfide; b. p. 73.5–74.5° (4 mm.); $d_4^{20} = 1.3280$, $n_D^{22.5} = 1.5483$.

Anal. Calcd., S, 20.42. Found: 20.03, 19.80. Calcd., Cl, 45.16. Found: 46.11, 46.27.

It was also obtained by repeated distillation of α -bromo- β,β' -dichlorodiethyl sulfide, but the purification was more difficult; b. p. 77.0–77.7° (4 mm.).

Anal. Calcd., S, 20.42. Found: 20.46, 20.35. Calcd., Cl, 45.16. Found: 43.87, 43.91; Br, none.

β -Chloro-ethyl- α -chlorovinyl Sulfide.—Colorless liquid obtained with the β -chlorovinyl compound by repeated fractionation of the distillation product of α,β,β' -trichlorodiethyl sulfide, b. p. 69.5–70.5° (4 mm.); $d_4^{20} = 1.3193$; $n_D^{22.5} = 1.550$. It is produced in only about one-half the quantity of its β -chlorovinyl isomer.

Anal. Calcd., S, 20.42. Found: 20.19, 20.27. Calcd., Cl, 45.16. Found: 45.10, 44.99.

α -Bromo- β,β' -dichlorodiethyl Sulfide.—Yellow oil obtained from β,β -dichloro-ethyl sulfonium bromide by allowing it to stand for several days in a flask. When kept in a desiccator this decomposition was found not to take place. The compound is unstable even at room temperature and shortly decomposes into a black, tarry mass. When distilled it decomposes to give a variety of products of which only β -chloro-ethyl- β -chlorovinyl sulfide has been isolated.

Bis(β -naphthoxy)-ethylvinyl Sulfide.—Crystals, tiny, diamond-shaped plates, obtained by refluxing a solution of β -chloro-ethyl- β -chlorovinyl sulfide in absolute alcohol with sodium naphthionate for twelve hours on the water-bath and recrystallizing the product from hot absolute alcohol; m. p. 129.5° (corr.).

Anal. Calcd., S, 9.40. Found: 8.51. Cl, none. Found: none by qualitative test.

β -Naphthoxy-ethyl- α -chlorovinyl Sulfide.—Secured by treatment of β -chloro-ethyl- α -chlorovinyl sulfide with sodium naphthionate in the same manner as described above. The oil at first obtained gives crystals on treatment with petroleum ether; m. p. 56–57° (corr.).

Anal. Calcd., S, 12.90. Cl present by qualitative test (not enough sample for both Cl and S analyses).

Summary

1. It has been shown that β,β -dichloro-ethyl sulfonium chloride is the intermediate addition product in the chlorination of β,β -dichloro-ethyl sulfide and that it decomposes to give α,β,β' -trichlorodiethyl sulfide.

2. Distillation of α,β,β' -trichlorodiethyl sulfide gives two isomeric vinyl compounds, β -chloro-ethyl- β -chlorovinyl and β -chloro-ethyl- α -chlorovinyl sulfide. These have been isolated and proof of their structure has been obtained.

3. On the basis of the splitting out of hydrogen chloride to give the corresponding vinyl compound, there has been formulated a theory to account for the absence of pentachlorodiethyl sulfide from the chlorination product of β,β -dichloro-ethyl sulfide obtained by Mann and Pope. In accordance with this theory, the two lower chlorinated products obtained by them were chloro-ethylchlorovinyl sulfides. Their analyses check such formulas very closely.

4. A number of the chlorinated and brominated products from β,β -dichloro-ethyl sulfide together with some of their derivatives have been prepared.

CHLORINATION OF β,β -DICHLORO-ETHYL SULFIDE. II¹

BY T. P. DAWSON AND W. F. LAWSON

RECEIVED JUNE 7, 1927

PUBLISHED DECEMBER 10, 1927

In a previous article² there was given a table showing the total number of compounds theoretically possible on treatment of β,β -dichloro-ethyl sulfide with chlorine. The hypothesis on which this table was based is, in brief, that β,β -dichloro-ethyl sulfide will react with one, two, three, or four molecules of chlorine to give the corresponding tri-, tetra-, penta-, and hexachloro derivatives, in each of which only one ethyl group takes part in the reaction. On distillation of the three lower chlorinated compounds one molecule of hydrogen chloride splits out to give a chloro-ethyl mono-, di-, or tri-chlorovinyl sulfide. The chlorine may split out from either the alpha or beta position. The hexachloro product, having no hydrogen in the chlorinated ethyl group, distills unchanged.

This article describes the preparation of practically all of the compounds theoretically possible which were not given in the first paper, that is, the tetra-, penta-, and hexachlorodiethyl sulfides and the tri- and tetrachloro-ethylvinyl sulfides. None of the compounds is vesicant, that is, has skin-blistering properties.

Tetrachlorodiethyl Sulfide and its Decomposition Products

According to the above hypothesis, two tetrachloro isomers are possible, with the chlorine in the $\alpha,\alpha,\beta,\beta'$ - and $\alpha,\beta,\beta,\beta'$ -positions, respectively. They may be made by the addition of one molecule of chlorine to the respective unsaturated dichloro derivative. The $\alpha,\alpha,\beta,\beta'$ -isomer may also be prepared by treatment of β,β -dichloro-ethyl sulfide with two equivalents of chlorine, both chlorine atoms substituting in the alpha position. This isomer is so unstable that when distilled it breaks down completely into β -chloro-ethyl- α,β -dichlorovinyl sulfide. No isomer of this vinyl compound is possible since hydrogen atoms are present only on the beta carbon of the saturated parent compound. A high yield is secured.

On treating a mixture of the two chloro-ethylchlorovinyl isomers with

¹ Published by permission of the Chief of the Chemical Warfare Service.

² Lawson and Dawson, *THIS JOURNAL*, 49, 3119 (1927).

one molar equivalent of chlorine and distilling the reaction product, there is obtained a good yield of β -chloro-ethyl- α,β -dichlorovinyl sulfide (from β -chloro-ethyl- α -chlorovinyl sulfide by addition of chlorine to form the unstable $\alpha,\alpha,\beta,\beta'$ -tetrachlorodiethyl sulfide) and, in addition, a comparatively stable saturated tetrachloro derivative. This must have originated from β -chloro-ethyl- β -chlorovinyl sulfide and has, therefore, the structure $\alpha,\beta,\beta,\beta'$ -tetrachlorodiethyl sulfide. When heated under reflux instead of distilled, this compound decomposes into an unsaturated trichloro derivative, boiling at $90-91^\circ$ (3.5 mm.) or 10° above its β -chloro-ethyl- α,β -dichlorovinyl isomer. Theoretically, $\alpha,\beta,\beta,\beta'$ -tetrachlorodiethyl sulfide should give two isomeric unsaturated trichloro compounds, but only the one was isolated, and this must have had the structure β -chloro-ethyl β,β -dichlorovinyl sulfide. Whether the other was formed in small amounts or was not formed at all we were not able to determine with the small amount of tetrachlorodiethyl sulfide on hand.

Pentachlorodiethyl Sulfide and its Decomposition Product

Mann and Pope³ were unable to isolate a pentachlorodiethyl sulfide by chlorination of β,β -dichloro-ethyl sulfide and distillation of the reaction product, a fact which is in agreement with its postulated instability. Two pentachloro derivatives are theoretically possible, $\alpha,\alpha,\beta,\beta,\beta'$ - and $\alpha,\beta,\beta,\beta,\beta'$ -. We obtained the former by adding exactly one molar equivalent of chlorine to pure β -chloro-ethyl- α,β -dichlorovinyl sulfide in carbon tetrachloride solution. The compound was isolated without distillation. Analysis of the product showed a pentachloro derivative. Because of the small amount of β -chloro-ethyl- β,β -dichlorovinyl sulfide on hand no effort was made to prepare the isomeric pentachloro sulfide.

When this addition product of chloro-ethyldichlorovinyl sulfide and chlorine was distilled, there was secured an unsaturated tetrachloro derivative in excellent yield, with no trace of a pentachloro compound. Pentachlorodiethyl sulfide decomposes slowly even at room temperature and on distillation gives an almost quantitative yield of β -chloro-ethyl- α,β,β -trichlorovinyl sulfide. No isomer of this compound is possible.

Hexachlorodiethyl Sulfide

When all the hydrogen atoms on the one ethyl group have been substituted by chlorine, formation of vinyl compounds becomes impossible and a stable saturated compound is first encountered. Mann and Pope³ isolated $\alpha,\alpha,\beta,\beta,\beta,\beta'$ -hexachlorodiethyl sulfide by chlorinating β,β -dichloro-ethyl sulfide. They were unable to secure any chlorination on the second ethyl group. Their findings have been confirmed by us.

³ Mann and Pope, *J. Chem. Soc.*, 121, 594 (1922).

Experimental Part

The same procedure was employed in the addition of chlorine to the higher chlorinated derivatives as was described in the previous paper on the chlorination of β,β -dichloro-ethyl sulfide. Chlorine was passed through an accurately calibrated flowmeter into a solution in carbon tetrachloride of the compound to be chlorinated. As an additional precaution beyond those previously observed, the exit tube from the reaction flask was immersed in potassium iodide solution and the escaping chlorine was titrated. This was found negligible in the case of reactions by which tetrachloro derivatives are formed. On completion of the reaction the solvent was distilled off and the residue was vacuum distilled twice from an ordinary distilling flask. The distillate was then fractionated with the aid of the modified Dufton column⁴ until constant-boiling products were obtained. Boiling points were obtained by making a final distillation from an ordinary distilling flask so as to avoid any danger of superheating the vapor in the electrically heated Dufton column. Isolation of comparatively pure products was obtained much more readily than expected in view of the difficulty in separating the two chloro-ethylchlorovinyl isomers previously described. Analyses for both sulfur and chlorine were carried out by the Parr bomb method.⁵

$\alpha,\beta,\beta,\beta'$ -Tetrachlorodiethyl Sulfide.—A solution of a 100g. mixture of the two isomeric chloro-ethylchlorovinyl sulfides in 200 cc. of dry carbon tetrachloride was treated with one molar equivalent of chlorine (45.2 g.), the chlorine being added at the rate of 35.2 cc. per minute. After four distillations from an ordinary distilling flask and eight through the Dufton column, a fraction boiling at 118.5–119° (3 mm.) was obtained; yield, 17 g.

Anal. Calcd. for $C_4H_6SCl_4$: Cl, 62.22. Found: 61.99, 62.53.

Accompanying this fraction was another which had a boiling point and chlorine content closely approaching those for β -chloro-ethyl- α,β -dichlorovinyl sulfide.

$\alpha,\alpha,\beta,\beta'$ -Tetrachlorodiethyl Sulfide.—This compound is too unstable to be isolated by distillation. On distillation its decomposition product, β -chloro-ethyl- α,β -dichlorovinyl sulfide, is always obtained.

β -Chloro-ethyl- α,β -dichlorovinyl Sulfide.—A sample of 100 g. of β,β -dichloro-ethyl sulfide dissolved in 200 cc. of dry carbon tetrachloride was treated with 89.25 g. of chlorine (2 molar equivalents) through a period of fourteen and one-half hours. After two distillations from an ordinary distilling flask and one through the Dufton column, a large fraction boiling at 79.7–80.5° (4 mm.) was secured; yield, 63 g.

A boiling point of 108.5–109° (15 mm.) was observed. Mann and Pope give 106.5–108° (15 mm.) for the compound they termed α,β,β' -trichlorodiethyl sulfide.

Anal. Calcd. for $C_4H_5SCl_3$: Cl, 55.55; S, 16.74. Found: Cl, 55.59, 55.51; S, 16.48, 16.63.

The compound was also formed by the addition of one molar equivalent of chlorine to a mixture of the two isomeric chloro-ethylchlorovinyl sulfides; b. p. 80–81° (4 mm.).

⁴ Dufton, *J. Soc. Chem. Ind.*, **38**, 45 (1919).

⁵ All analyses were made by the Analytical Department, Chemical Division.

After oxidation with dilute nitric acid, ammonium β -chloro-ethane sulfonate was isolated and identified, following the procedure described in the previous paper.

β -Chloro-ethyl- β,β -dichlorovinyl Sulfide.—A sample of 14 g. of $\alpha,\beta,\beta,\beta'$ -tetrachlorodiethyl sulfide was refluxed in an oil-bath at 150–160° for fourteen hours. On distillation there was readily obtained an unsaturated trichloro derivative boiling at 90–91° (3.5 mm.) as compared with 79.5–80.5° (4 mm.) for β -chloro-ethyl- α,β -dichlorovinyl sulfide. The only unsaturated isomer for the latter compound would have the structure corresponding to the formula given above, and such a compound would be expected from its synthesis; yield, 9 g.

Anal. Calcd. for $C_4H_5SCl_3$: Cl, 55.55; S, 16.74. Found: Cl, 56.01, 56.30; S, 16.12, 15.32.

β -Chloro-ethyl- α,β,β -trichlorovinyl Sulfide.—To a sample of 100 g. of β -chloro-ethyl- α,β -dichlorovinyl sulfide dissolved in 200 cc. of dry carbon tetrachloride was added one molar equivalent of chlorine (37.05 g.), at a reaction temperature of 50–60°. No hydrogen chloride was evolved during the entire run and all but 0.035 g. of the chlorine was absorbed. After but two distillations, once from an ordinary distilling flask and once through the Dufton column, a large fraction boiling at 97–98° (4 mm.) was secured; yield, 68 g. A boiling point of 123.5–124.5° (15 mm.) was observed. Mann and Pope give 123–125° (15 mm.) for the compound they termed $\alpha,\beta,\beta,\beta'$ -tetrachlorodiethyl sulfide.

Anal. Calcd. for $C_4H_4SCl_4$: Cl, 62.77; S, 14.19. Found: Cl, 62.68, 62.54; S, 13.84, 14.06.

Since no hydrogen chloride came off during the chlorination, a pentachlorodiethyl sulfide must have been formed and subsequently decomposed during distillation into the unsaturated tetrachloro compound.

$\alpha,\alpha,\beta,\beta,\beta'$ -Pentachlorodiethyl Sulfide.—A sample of pure β -chloro-ethyl- α,β -dichlorovinyl sulfide weighing 13 g. was dissolved in 100 cc. of carbon tetrachloride and 5.0 g. of chlorine (equivalent to one gram mole) was added. Absorption was almost complete. No hydrogen chloride was evolved. The bath in which the reaction flask was immersed was maintained at 60 to 70°. After the completion of the reaction, the solvent was removed under reduced pressure and the oil washed three times with a dilute aqueous solution of sodium bisulfite, then three times with a dilute solution of sodium carbonate, and finally shaken with water. The oil was extracted with ether, the ether solution dried with fused sodium sulfate, and the ether distilled off under vacuum. During this last operation some hydrogen chloride was evolved.

Anal. Calcd. for $C_4H_3SCl_5$: Cl, 67.55; S, 12.22. Found: Cl, 66.2, 67.3; S, 12.56, 12.55.

This compound breaks down completely on distillation to give the unsaturated β -chloro-ethyl- α,β,β -trichlorovinyl sulfide.

$\alpha,\alpha,\beta,\beta,\beta,\beta'$ -Hexachlorodiethyl Sulfide.—A sample of completely chlorinated β,β -dichloro-ethyl sulfide⁶ which had been made by treatment with an excess of chlorine at room temperature was separated into three main fractions by distillation through the Dufton column: (1) a mixture of low-boiling chlorinated hydrocarbons; (2) the unsaturated tetrachloro compound, β -chloro-ethyl- α,β,β -trichlorovinyl sulfide; (3) hexachlorodiethyl sulfide.

The hydrocarbons were not pure, analyzing 0.66% of sulfur and 81.26% of chlorine. The tetrachloro compound had the same boiling point as the one obtained by adding one gram mole equivalent of chlorine to β -chloro-ethyl- α,β -dichlorovinyl sulfide and

⁶ Furnished us through the courtesy of Dr. J. S. Reichert, Anti-Gas Department, Chemical Division.

distilling. It analyzed 62.52, 62.08% of chlorine and 13.39, 13.51% of sulfur, as compared with theoretical values of 62.77 and 14.19, respectively. $\alpha, \alpha, \beta, \beta, \beta, \beta'$ -Hexachlorodiethyl sulfide boils at 131–132° (4.5 mm.) or 159.5–160° (15 mm.). Mann and Pope³ give 160–161° (15 mm.) for the same compound.

Anal. Calcd. for $C_4H_4SCl_6$: Cl, 71.67; S, 10.80. Found: Cl, 70.88, 70.85; S, 11.05, 10.93.

This compound, since it contains no hydrogen in the chlorinated ethyl group, is stable and distills unchanged. Further chlorination under the conditions employed by us leads to a complete breaking up of the molecule with the formation of chlorinated hydrocarbons. This was also observed by Mann and Pope.

Summary

1. Practically all of the compounds theoretically possible on treating β, β -dichloro-ethyl sulfide with chlorine have been isolated and identified.

2. With one exception, all chlorinated derivatives below the hexachloro are unstable, splitting out hydrogen chloride on distillation with formation of unsaturated compounds. The exception, $\alpha, \beta, \beta, \beta'$ -tetrachlorodiethyl sulfide, may be distilled, but breaks up like the others on refluxing.

3. None of these compounds is vesicant.

ACYL DERIVATIVES OF ORTHO-AMINOPHENOL. III

BY R. E. NELSON, N. W. SHOCK AND W. H. SOWERS

RECEIVED JULY 21, 1927

PUBLISHED DECEMBER 10, 1927

Previous work published from this Laboratory¹ has shown that, "when *o*-aminophenol is acylated with the structural isomers, *n*-carbopropoxy and *isocarbopropoxy* groups, irrespective of their original positions, a partial rearrangement occurs. When the corresponding compounds with the *n*- and *isobutoxy* groups are made, their behavior is somewhat different. While the butyl carbonate of *isobutyl-o*-hydroxycarbanilate rearranges partially, giving a mixture of the two isomers, *isobutyl* carbonate of butyl *o*-hydroxycarbanilate was not found to change." In view of the behavior of these isomers against each other in the acylating of *o*-aminophenol it became of interest to us to investigate the behavior of such structural isomers against an aliphatic group and also against an aromatic group.

The following pairs of groups were used:

Iso-amyl-*o*-hydroxycarbanilate was acylated with *n*-butylchloro-carbonate and a stable diacyl obtained which yielded *iso*-amyl-*o*-hydroxycarbanilate on saponification. When *n*-butyl-*o*-hydroxycarbanilate was

¹ Nelson and Aitkenhead, *THIS JOURNAL*, **48**, 1680 (1926).

acylated with *iso*-amylchlorocarbonate the same diacyl was obtained as above and the saponification product was *iso*-amyl-*o*-hydroxycarbanilate. The *n*-carbobutoxy group in the second diacyl had migrated from the nitrogen to the oxygen during the preparation of the compound.

When *iso*-amyl-*o*-hydroxycarbanilate was acylated with *iso*-butylchlorocarbonate a stable diacyl was obtained which yielded *iso*-amyl-*o*-hydroxycarbanilate on saponification. Treatment of *iso*-butyl-*o*-hydroxycarbanilate with *iso*-amylchlorocarbonate resulted in the same diacyl as that from *iso*-amyl-*o*-hydroxycarbanilate and the saponification product was *iso*-amyl-*o*-hydroxycarbanilate. In this case the *iso*-carbobutoxy group had migrated from the nitrogen to the oxygen.

Benzoyl-*o*-aminophenol was acylated with *n*-propylchlorocarbonate and gave a diacyl which yielded benzoyl-*o*-aminophenol on saponification. When *n*-propyl-*o*-hydroxycarbanilate was acylated with benzoyl chloride the same diacyl was obtained and the saponification product was benzoyl-*o*-aminophenol. A rearrangement of the *n*-carbopropoxy from the nitrogen to the oxygen had taken place in the latter case.

When *isopropyl*-*o*-hydroxycarbanilate was acylated with benzoyl chloride a stable diacyl was obtained which yielded *isopropyl*-*o*-hydroxycarbanilate on saponification. Treatment of benzoyl-*o*-aminophenol with *isopropyl*chlorocarbonate yielded the same diacyl. Saponification gave *isopropyl*-*o*-hydroxycarbanilate. The benzoyl group had migrated from the nitrogen to the oxygen.

Experimental Part

All the mono-acyls used were prepared by Groenvik's method and are described in the literature.

The diacyl derivatives of *o*-aminophenol were prepared by the Schotten-Baumann method from the mono-acyl derivatives and the acyl chlorides as follows. About 3 g. of the mono-acyl derivative was dissolved in 75 cc. of water containing 1 g. of potassium hydroxide (slightly more than the calculated amount). After solution was complete, an excess (about 2 cc.) of the acyl chloride was added. The oil which formed was extracted with

nation of the compounds has shown that this was in fact the case and that they contained the impurity when we received them. This is confirmed by the results obtained by Orndorff, Gibbs, McNulty and Shapiro and contained in a paper which has been submitted to THIS JOURNAL. When these substances are repurified with a fore-knowledge of the fact that they contain benzene, the impurity can be partially or wholly removed, with the result that the absorption pattern is either greatly diminished in intensity or entirely absent.

It seems desirable to know how benzene was introduced into these compounds. Letters from the leading manufacturers in answer to inquiries as to the possibility of diethyl ether containing a trace of benzene are about equally divided between those who cannot account for its presence and those who state frankly that ether is sometimes prepared from alcohol which has been denatured by benzene. To quote from the letter of one producer:

The Internal Revenue Bureau have authorized two special denatured alcohols for use in the manufacture of ether.

1.—S. D. Formula 2-B is made up as follows: "To 100 gallons of ethyl alcohol add $\frac{1}{2}$ gallon of benzol."

2.—S.D. 13-A is made up as follows: "To 100 gallons of ethyl alcohol add 10 gallons of sulfuric ether."

"We hold permits to use either of these formulas."

Over a period of about three years we continuously found the absorption bands not only in the U.S.P. ether but also in the C.P. anhydrous ether (distilled over sodium). During this period two different brands of diethyl ether were used with perfectly uniform results. Several brands now on the market do not show the impurity, including one of those in which the absorption was previously found. Some producers state they have not used alcohol denatured according to Formula 2-B during the past year. Since the methyl-*n*-amyl ether is prepared by use of the Grignard reaction, the trace of benzene in that substance can now be attributed to the anhydrous ether used in its preparation.

In the light of these facts we wish to raise two questions of general interest. The first is: How generally does benzene occur as an impurity in liquid organic compounds of highest quality? It would seem that since benzene is frequently used in the dehydration processes and also in the dehydration of many crude products, its presence must be suspected in all compounds prepared in this way. It now appears that it may also be introduced whenever commercial U.S.P. ether or C.P. anhydrous ether (distilled over sodium) is used in a preparation process. These two groups serve to bring a very large number of liquid organic compounds under the suspicion of containing benzene. Certainly the amount of impurity is no more than a trace, but the possibility of its presence should be generally recognized.

The second question is: Does anesthetic ether ever contain benzene? We have examined four brands of anesthetic ether. In only one case was an absorption pattern obtained and this was much fainter than has been found with U.S.P. ether or c.p. anhydrous ether containing the impurity.

The latter part of Dr. de Laszlo's article does not deal with a question of fact but rather with the interpretation of ultraviolet absorption spectra. Since the validity of the experimental results contained in our paper has been disproved, a further discussion of interpretation does not seem profitable at this time. However, on the basis of the quantum theory, we find little reason for supposing any absorption or emission spectrum to be essentially continuous.

SALICYLSULFONPHTHALEIN AND ITS TETRABROMO AND MONOMERCURY DERIVATIVES

BY WILTON C. HARDEN

RECEIVED AUGUST 19, 1927

PUBLISHED DECEMBER 10, 1927

Since the synthesis of the first sulfonphthaleins by Remsen and his students¹ many new members of this class of compounds have been described by Orndorff and his co-workers,² Clark and Lubs,³ Cohen⁴ and others.

The purpose of the present paper is to describe still another sulfonphthalein, namely, salicylsulfonphthalein. The only mention of this compound in the literature is contained in some German patents⁵ describing certain dyestuffs prepared by the condensation of *o*-sulfobenzaldehyde with various phenols, cresols and substituted phenols and cresols. In this manner salicylic acid was condensed with *o*-sulfobenzaldehyde to give a red dye.

The author has prepared this compound by condensing salicylic acid with the anhydride of *o*-sulfobenzoic acid and found it to possess some interesting properties. Its tetrabromo and its monohydroxymercuri derivative have also been prepared and will be discussed.

Since nearly all of the sulfonphthaleins are useful indicators in the determination of hydrogen-ion concentration and since salicylsulfon-

⁵ Friedländer, (1908-1910), vol. 9, p. 195; D. R. P. 189,938-198,909 and others.

phthalein contains in addition to the sulfonic acid group two carboxyl groups, it was thought that a study of its color changes in solutions of varying P_H would be of interest. For this purpose a 0.1% solution in 70% alcohol was used. Five-tenths of a cc. of this solution was added to 10 cc. of various buffer mixtures prepared according to Clark.⁶ As would be expected the compound is an excellent indicator; it is yellow at all P_H 's below 6.6 and shades through a brown to a bluish red at P_H 8.2. The fact that at P_H 7.0–7.2 the color is distinctly brown, while below this point it is yellow and on the alkaline side red, should make the indicator a useful one in those cases where an indicator which shows a marked color change at the neutral point is desired. The color change of the tetrabromo derivative, that is, tetrabromosalicylsulfonphthalein, was determined in a similar manner. This indicator was found to change from a yellow at P_H 's lower than 3.2 through a brownish-purple to a clear purple at P_H 4.6. Color standards prepared using these indicators have shown no appreciable fading after several months' exposure to ordinary light. Since these compounds have at least a potential value as indicators, the author suggests that they be called, in accordance with the usual custom, Salicyl Red and Salicyl Purple in place of the longer salicylsulfonphthalein and tetrabromosalicylsulfonphthalein. No attempt has been made to determine the apparent dissociation constants or spectrophotometric data for these indicators.

The monohydroxymercuri derivative of the unhalogenated sulfonphthalein has also been prepared and the germicidal properties of the three compounds have been studied *in vitro*. The mercury derivative, as would be expected, is the only one to show any marked germicidal power.

Experimental Part

Preparation of Salicylsulfonphthalein (Salicyl Red).—The salicylic acid used was the ordinary U. S. P. variety. The anhydride of *o*-sulfobenzoic acid used was prepared by the method described by White and Acree.⁷ Fifty g. of salicylic acid was intimately ground in a mortar with 24 g. of the anhydride. This amount of salicylic acid represents about a 50% excess. This mixture was transferred to an Erlenmeyer flask, 2 cc. of concd. sulfuric acid and 10 cc. of fuming stannic chloride added and the flask heated in an oil-bath for four hours at 120–130°. At this temperature the mixture slowly melts and begins to redden. At the end of four hours the temperature was raised slowly (1/2 hour) to 160–180°. At this temperature the melt becomes more intense in color and begins to harden. The temperature was kept at 170° for several hours longer and the semi-fused mass then poured into 4 liters of hot water. If the melt is allowed to cool it becomes caked and great difficulty is experienced in removing it from the flask. Sodium carbonate was then added until the solution was alkaline. Since the dye is a relatively strong acid, care must be taken in this operation to prevent the solution

⁶ Clark, "The Determination of Hydrogen Ions," Williams and Wilkins Co., Baltimore, 1922, 2nd edition.

⁷ White and Acree, *THIS JOURNAL*, 41, 1190 (1919).

from frothing over. The purple alkaline solution was next heated to boiling and filtered while hot. It was then transferred to a large evaporating dish, strongly acidified with hydrochloric acid and concentrated on the water-bath. Some of the dye separates out at this stage as a green tar and should be removed, redissolved in sodium carbonate and reprecipitated. After several such treatments the dye is obtained in a pure form as a red, amorphous powder. The main body of the solution was evaporated to about one-third of its original volume and allowed to cool. The dye separates from this solution contaminated with large amounts of salicylic acid. This was removed by repeated extractions with ether, in which the dye is insoluble. The dye was then further purified by repeated solution in sodium carbonate and reprecipitation with hydrochloric acid.

Anal. Calcd. for $C_{21}H_{14}O_6S$: S, 7.24. Found: 7.38.

Preparation of Tetrabromosalicylsulfonphthalein (Salicyl Purple)—4.5 g. of Salicyl Red prepared as described above was suspended in 100 cc. of glacial acetic acid and a solution of 7.0 g. of bromine in glacial acetic acid added. The solution was warmed on the steam-bath for several hours and allowed to stand overnight. The next day it was again warmed on the steam-bath and aspirated while warm to remove hydrobromic acid and some of the acetic acid. This is essentially the method described by Cohen^{4a} for the preparation of tetrabromo-*m*-cresolsulfonphthalein. When the solution had been evaporated to about one-half its original volume, it was cooled in the ice-box for several hours, when a small crop of crystals separated. These were filtered off and the filtrate poured into dilute hydrochloric acid. The dye separated as an amorphous, yellow powder which was dissolved in sodium carbonate, reprecipitated, dried and analyzed.

Anal. Calcd. for $C_{21}H_{10}O_6Br_4S$: Br, 42.18; S, 4.20. Found: Br, 42.20; S, 4.52.

Preparation of Monohydroxymercuri-salicylsulfonphthalein.—4.4 g. of Salicyl Red was dissolved in sufficient normal sodium hydroxide to form the disodium salt. To this solution was added a solution of 3.18 g. of mercury acetate to which had been added several drops of acetic acid. There was no apparent action in the cold and no precipitation of the mercury salt of the dye. If such a salt is formed in this case, it is probably soluble. The solution was boiled for several hours when it lost its red color and became quite brown. The boiling was continued until a small test-tube portion showed no free mercury when tested with ammonium sulfide. It was then filtered and poured into dilute hydrochloric acid. The mercurated material came down at once as a brown powder which was filtered by suction and washed repeatedly with warm water.

Anal. Calcd. for $C_{21}H_{14}O_6SHg$: Hg, 30.4. Found: Hg, 29.84.

Bacteriological and Pharmacological Part

The method used for testing the germicidal properties of these compounds was a modification of the Hygienic Laboratory method for determining phenol coefficients. The procedures used are, briefly, as follows: 0.1 cc. of a twenty-four hour broth culture of the test organism is added to 5 cc. of the diluted sample at 37°. Body temperature is used because of the possible application of these materials for combating infections within the human body. At the end of one, five and fifteen minutes, subculture was made into 10 cc. of sterile broth and this incubated at 37° for forty-eight hours, at which time they were observed for growth. It was found that a 1% solution of the mercurated salicylsulfonphthalein kills *B. Typhosus* and *Staph. Aureus* within one minute. It also kills

B. Typhosus in 1-1000 dilution within five minutes and in 1-2000 dilution within fifteen minutes. *Staph. Aureus* is killed by a 1-500 dilution within five minutes but is not killed by 1-1000 dilution in fifteen minutes. One per cent. solutions of Salicyl Red and Salicyl Purple do not kill either *B. Typhosus* or *Staph. Aureus* in fifteen minutes under the same conditions.

A preliminary pharmacological investigation shows that the mercurated derivative apparently is eliminated from the body through the digestive system, while the other two compounds, like most sulfonphthaleins, are eliminated through the urinary tract.

The author wishes to express his thanks to Drs. G. F. Reddish and David L. Macht for the bacteriological and pharmacological investigation of these compounds.

Summary

1. Salicylsulfonphthalein (Salicyl Red) has been prepared and its indicator properties have been studied.

2. Tetrabromosalicylsulfonphthalein (Salicyl Purple) has been prepared and its indicator properties have been studied.

3. The monohydroxymercuri derivative of salicylsulfonphthalein has been prepared.

4. A preliminary bacteriological and pharmacological study of these compounds has been made.

BALTIMORE, MARYLAND

THE ALKYLATION OF BENZENE, TOLUENE AND NAPHTHALENE

By T. M. BERRY¹ AND E. EMMET REID

RECEIVED AUGUST 26, 1927

PUBLISHED DECEMBER 10, 1927

It was shown by Balsohn² that ethylene may be substituted for ethyl chloride in the Friedel and Crafts synthesis. Milligan and Reid³ found that the reaction is facilitated by high-speed stirring to such an extent that this becomes a convenient method for the ethylation of benzene.

The present investigation has to do with a further study of the reaction and with its extension to propylene and cyclohexene.

The ethylene (or propylene) is passed into the benzene at such a rate that only an occasional bubble escapes. If an excess of gas passes through, hydrogen chloride is carried away and the reaction slows down. It is

¹ From the Ph.D. dissertation of T. M. Berry, June, 1923.

² Balsohn, *Bull. soc. chim.*, [2], 31, 539 (1879).

³ (a) Milligan and Reid, *THIS JOURNAL*, 44, 206 (1922); (b) *Ind. Eng. Chem.*, 15, 1048 (1923).

usually possible to restore the original speed by passing in a small amount of dry hydrogen chloride.

In the ethylation of benzene, ethylene is not to be considered as simply a substitute for ethyl chloride. For every molecule of ethyl chloride that reacts, one of hydrogen chloride is eliminated. This escaping as a gas carries off with it much of the volatile ethyl chloride. The utilization of ethyl chloride depends on the rate at which it is passed. At 0.01 mole per minute per mole of benzene only 25% of it reacts, while at one-fourth of this rate 43% reacts. Ethylene may be completely absorbed at these rates.

Drying the benzene with sodium gave decidedly better results than using only calcium chloride. The runs were made at about 70°, though there appears to be little difference in the rate between 60° and 90°. There is usually an incubation period of about twenty minutes before much ethylene is absorbed. Refluxing for several minutes appears to shorten this. The addition of 10% of higher ethylated benzenes from a previous run may hasten the starting of the reaction. The speed increases with the accumulation of ethylated benzenes, reaching a maximum when about 4 equivalents of ethylene have been absorbed, remaining nearly constant for a while and then declining.

The apparatus used was that described by Milligan and Reid,^{8b} the stirrer being run at 7000 to 8000 r.p.m.

As is well known, all of the possible ethylation products are formed and no way has been found of directing the process to the production of any one, exclusively. Some hexa-ethylbenzene is present when less than 0.5 mole of ethylene has been absorbed and less than half of the benzene has been attacked. Data from a number of runs are given in the experimental part. As the conditions under which the runs were made were not all the same and as the separations were made by fractionation the figures are not strictly comparable or very exact but these conclusions may be drawn. As the reaction progresses, mono-ethylbenzene increases regularly to about 30% when about 1.1 mole of ethylene has been passed in. Diethyl- and tetra-ethylbenzene never go much above 20%. The penta-ethyl is present almost from the first but its concentration is remarkably low and nearly constant to the end. There seems to be a preferential formation of the triethyl which constitutes over 50% of the mixture when somewhat over 3 moles of ethylene have reacted. In subsequent work as high as 80% of triethyl has been found. Hexa-ethyl benzene appears early and always exceeds the tetra- or penta-. It steadily increases until it constitutes nearly 90% of the mixture, when the mixture becomes too nearly solid to stir. There is no difficulty in preparing hexa-ethylbenzene in one operation; but on account of the large increase in volume it is usually more convenient to stop the reaction when three equivalents of ethylene have been introduced, separate and use this material for a new run.

The best proportion of aluminum chloride seems to be 1 mole (AlCl_3) to about 13 of benzene. When the stirring is stopped the reaction mixture separates sharply into two layers. The top one is clear and colorless and contains only a trace of aluminum chloride. The lower layer is dark and viscous and consists of aluminum chloride associated with something like its own weight of hydrocarbons. In a few runs this lower layer has been worked up separately. As the amount of this layer is relatively small the results on it are not as exact as could be desired but they do show that each of the hydrocarbons present is partitioned between the two layers and that the aluminum chloride holds the higher ethylated benzenes in preference to the lower. From mono- to tetra-ethylbenzene the concentrations in the two layers do not differ greatly but there is a marked heaping up of penta-ethylbenzene in the lower layer which always contains more of it than of either the tetra- or hexa-. The hydrocarbon which is most abundant in the lower layer always contains one or two more ethyl groups than the one that predominates in the upper. Toluene is more readily ethylated than benzene, and bromobenzene less so. Both give complicated mixtures which contain the expected products.

Gustavson⁴ prepared *isopropylbenzene* from propyl bromide and benzene in the presence of aluminum chloride with 34% yield. Propylene does not seem to have been used for this purpose. Propylene is taken up by benzene under the same conditions as ethylene but only about 4% as rapidly. The product separates into two layers, the lower being relatively larger and slower to react with water than in the ethylation of benzene. It was impracticable to carry the fractionation above 290° as the residue above this was a tarry mass. Hence the propylated benzenes were separated only as far as the tetra-. From some of the higher fractions a well crystallized solid separates, m. p. 117° and b. p. 260° at 775 mm. This appears to be 1,2,4,5-tetra-*isopropylbenzene*. Of the di-*isopropylbenzenes* the meta seems to predominate, as does the symmetrical among the tri-.

As in ethylation the rate increases as propylation progresses. With mono-*isopropylbenzene* it is double and with the tri- it is 10 times what it is with benzene.

A curious phenomenon is the formation of two aliphatic hydrocarbons, b. p. 28° ; d_4 0.7095 and the other b. p. $56\text{--}59^\circ$. The latter is probably di-*isopropyl*.

Toluene is more readily propylated than benzene, the chief product seeming to be *p*-cymene. Naphthalene was propylated by the transfer of *isopropyl* groups from di-*isopropylbenzene*.

Cyclohexane reacts with benzene when aluminum chloride is added to a mixture of the two. Some cyclohexylbenzene is obtained but the most

⁴ Gustavson, *Ber.*, 11, 1251 (1878).

of the product is high boiling. The results are similar to those obtained by Kursanoff,⁵ who used cyclohexyl chloride.

Experimental

The details of the runs with ethylene are given in the table below. The regular amount of benzene was 300 g., 3.85 moles, but 455 g., 5.83 moles, was used in Runs 4 and 5. In Run 10, 363 g., 2.24 moles, of triethylbenzene was used instead of benzene as starting material and similarly 300 g., 2.24 moles, of diethylbenzene in Run 11. The ethyl groups in these were counted in calculating the ratio of ethylene to benzene. The rate of stirring was 7200 to 8200 r.p.m. The ethylene put in is in moles per mole of benzene. The largest amount of ethylene put in during a run was 352 l. in 675 minutes in Run 9. The highest rate was in Run 11, 402 cc. per minute per mole. At the end of a run the product was drowned, the oil layer washed, dried and fractionated through a Vigreux column. The results are given in the following tables.

TABLE I
COMPOSITION OF PRODUCT IN MOLES PER 100 MOLES OF BENZENE

Run	Moles of ethylene	Benzene	Mono-	Di-	Tri-	Tetra-	Penta-	Hexa-
1	0.20	87.9	10.9	1.24

⁵ Kursanoff, *Ann.*, 318, 310 (1901).

In four of these runs the two layers were separated and worked up separately. The compositions of the upper and lower layers and their ratios are given in Table II.

On account of the smallness of the amounts of the hydrocarbons in the lower layers, the figures for the lower layers are not as accurate as for the upper. Run 8 showed a high percentage of the penta- in both layers. The highest in each layer is starred. The relative weights of the hydrocarbons in the two layers were 16, 12, 12 and 13 to 1.

The Ethylation of Toluene.—Ethylene was passed into 280 g., 3.04 moles, of toluene under the usual conditions. Absorption was at the rate of 266 cc. per minute per mole of toluene and 0.9 equivalent was taken up in 81 minutes. Distillation of the product gave the following.

TABLE III
PRODUCTS FROM THE ETHYLATION OF TOLUENE

Boiling range, °C.	Weight, g.	Probable constituents
Up to 120	45	Toluene
120–145	42	Ethylbenzene and xylenes
145–164	121	Ethyltoluenes
164–207	93	Higher substitution products
Above 207	5	Higher substitution products

The part boiling from 198–203° was strongly fluorescent.

The Ethylation of Bromobenzene.—Into 484 g., 2.83 moles, of bromobenzene containing 0.37 mole of aluminum chloride one equivalent of ethylene was passed. It was taken up at the rate of 70 cc. per mole per minute.

Distillation of the product gave the following.

TABLE IV
PRODUCTS FROM THE ETHYLATION OF BROMOBENZENE

Boiling range, °C.	Weight, g.	Probable constituents
Up to 140	15	Benzene and ethylbenzene
140–180	135	Ethyl- diethylbenzenes
180–215	86	Brominated ethylbenzenes
215–250	115	Brominated ethylbenzenes
Above 250	85	Tarry residue

At 240–250° decomposition began with evolution of hydrobromic acid.

The Propylation of Benzene.—Propylene was made by dropping *iso*-propyl alcohol⁶ on to metaphosphoric acid heated to 500° or above. This method gives an excellent yield of pure propylene but is troublesome on account of the destructive action of the phosphoric acid on the Pyrex flask. Propylene was also prepared by passing the *isopropyl* alcohol vapor over pumice impregnated with alumina and kept at 600°. The propylene was collected over water and purified as was the ethylene.

⁶ Our thanks are due to the Standard Oil Co. of N. J. for a generous supply of *isopropyl* alcohol.

The runs with propylene were in every way similar to those with ethylene but were less numerous. Two runs were made starting with benzene, two with mono-*isopropyl*benzene and one with tri-*isopropyl*benzene. The distillations of the products were stopped at about 280°, as above that temperature decomposition seemed to set in. The penta- and hexa-*isopropyl*benzenes, if they were formed, were left in the residue.

The reaction product separates into two layers as in the ethylation of benzene, but with propylene the lower layer is relatively larger and the aluminum chloride complexes which it contains are decomposed by water more slowly than are those obtained in the ethylation of benzene. Usually only about three-fourths of the hydrocarbons contained in it boil below 285°.

For four runs the compositions of the product in percentages by weights were:

TABLE V
PRODUCTS FROM THE PROPYLATION OF BENZENE, PERCENTAGE BY WEIGHT

No.	Moles of propylene	Benzene	Mono	Di-	Tri-	Tetra-	Residue
1	0.6	16.3	42.5	27.0	6.1	2.1	6.1
2	0.75	18.9	52.0	20.0	3.0	1.3	4.8
3	1.97	1.4	0.6	3.9	87.6	3.3	3.3
4	1.93	1.3	15.6	46.7	31.0	5.4	...

In three of these runs the two layers were worked up separately with the following results.

TABLE VI
COMPOSITIONS OF THE TWO LAYERS IN PERCENTAGES BY WEIGHT AND THEIR RATIOS

Run	Propylene	Layer	Benzene	Mono-	Di-	Tri-	Tetra-	Residue
1	0.6	Upper	15.7	45.9	30.8	5.2	1.2	1.2
		Lower	18.8	28.6	11.1	9.7	5.6	26.1
		Ratio	1.2	0.62	0.36	1.9	4.7	22
2	0.75	Upper	19.2	55.0	22.4	2.2	..	1.2
		Lower	17.4	32.6	9.9	6.6	1.6	25.3
		Ratio	0.9	0.59	0.44	3.0	..	21
3	1.97	Upper	1.5	0.5	4.2	88.7	3.0	2.1
		Lower	..	1.1	1.1	71.7	15.2	10.9
		Ratio	..	2.2	0.25	0.9	5.1	5.2

In these runs the relative weights of the hydrocarbons in the upper and lower layers were 3.5, 4.5 and 10.3 to 1.

The product from Run 4 was fractionated repeatedly. The final results were as follows.

The indications are that about 65% of the di-*isopropyl* is the meta and that the 1,3,5-tri-*isopropyl* is about 75% of that group.

It was found particularly easy to propylate the tri-*isopropyl*benzene fraction; 250 g. of it took up 56 liters of propylene in twelve hours. On cooling,

TABLE VII
 FRACTIONATION OF THE PRODUCT FROM RUN 4

Temp. range, °C.	Weight, g.	Probable constituents
Up to 75	17	Aliphatic hydrocarbons
75 - 90	20	Benzene
152 -156	220	<i>Isopropylbenzene</i>
150 -201	25	Mono- and di-
201 -203.5	33	<i>m</i> -Di- <i>isopropylbenzene</i>
203.5-204.5	410	<i>m</i> -Di- <i>isopropylbenzene</i>
204.5-208.5	68	Mixture
208.5-209.5	119	Di- <i>isopropylbenzene</i> (?)
209.5-233	84	Mixture of di- and tri-
233.5-234.5	256	1,3,5-Tri- <i>isopropylbenzene</i>
234.5-246	164	Tri- <i>isopropylbenzenes</i>
Above 246	61	Tetra- and higher

the product solidified, and by centrifuging white crystals were obtained. After several recrystallizations from alcohol this material melted at 117° and boiled at 260° under 775 mm. Some of it was oxidized by long heating with potassium permanganate solution and an acid obtained which melted at 282°. Mellitic acid melts at 286° and the di-anhydride of 1,2,4,5-benzenetetracarboxylic acid melts at the same temperature. The hydrocarbon is probably the 1,2,4,5-tetra-*isopropylbenzene* as its boiling point, 260°, seems much too low for the hexa-*isopropyl*. Hexa-ethylbenzene boils at 294° and the hexa-*isopropyl* should boil at least that high. The 1,2,4,5-tetramethylbenzene is a solid and boils below its isomers.

 TABLE VIII
 ANALYSIS OF THE HYDROCARBON

	Found, %		Calculated for		Hexa-
Carbon	87.43	87.60	Tetra- 87.72	Penta- 87.41	87.18
Hydrogen	12.43	12.61	12.28	12.59	12.82

Assuming that the carbon found is low and the hydrogen high the analysis indicates the tetra-.

By repeated fractionation a quantity of 1,2,4-tri-*isopropylbenzene* was separated. It boils at 237-237.5° at 752 mm., 97-97.5° at 4 mm.; d_4^{20} 0.8764 and d_{25}^{25} 0.8593, N_D 1.4855 at 25°. It was identified by oxidation to an acid which melted, with formation of the anhydride, at 214°, which corresponds to the 1,2,4-benzenetricarboxylic acid.

The oils boiling below 75° were refractionated and separated into two hydrocarbons, one boiling at 28°, d_4^{20} 0.7095 and the other boiling at 56-59°. The latter is evidently di-*isopropyl*, which boils at 58°.

The Propylation of Toluene.—Toluene reacted somewhat faster than did benzene under the same circumstances. From 662 g. of toluene which had taken up 0.3 equivalent of propylene the following fractions were obtained.

TABLE IX

PROPYLATION OF TOLUENE		
Boiling range, °C.	Weight, g.	Probable constituents
Up to 105	5	Benzene
105-120	370	Toluene
120-145	17	Xylenes
145-170	25	Tri-ethylbenzene and cymenes
170-185	161	<i>m</i> - and <i>p</i> -Cymenes
Above 185	60	

As the cymenes boil too close together for fractionation, advantage was taken of the fact that their bromine derivatives boil 10° apart, that of the meta at 224° and that of the para at 234°. A portion of the 170-185° fraction was brominated and 80% of the product was found to boil between 228° and 240°, indicating a preponderance of the *p*-cymene.

The Propylation of Naphthalene.—Naphthalene was stirred with di-*isopropyl*benzene in the presence of aluminum chloride. From 217 g. of naphthalene and 132 g. of di-*isopropyl*benzene at 90° for 4.5 hours, 15 g. of a fraction boiling at 264-266° was obtained. This was probably *isopropyl*naphthalene. One third of the naphthalene was recovered unchanged and there were higher-boiling products which were not identified.

Cyclohexene and Benzene.—As cyclohexene resembles ethylene in many respects, it was thought that it should react with benzene under the usual conditions to give cyclohexylbenzene. To a mixture of 276 g. of benzene and 290 g. of cyclohexene, 60 g. of aluminum chloride was added. Even without stirring a violent reaction took place. Stirring for thirty seconds would bring the mixture to a boil. After a time the mixture could be stirred continuously. This was done for five hours, during which time the temperature remained at about 55°. The mixture was worked up as usual and gave 50 g. of cyclohexylbenzene, boiling from 230-245°, besides large amounts of high-boiling products. Kusanoff⁶ got similar results using cyclohexyl chloride.

Summary

The ethylation of benzene by ethylene in the presence of aluminum chloride with high-speed stirring has been studied. The ethylbenzenes from mono- to hexa- are readily obtained, their relative amounts depending on the proportion of ethylene taken up. Similar results were obtained using propylene. Cyclohexene also reacts with benzene under the same conditions. Toluene and naphthalene may be substituted for the benzene.

SOME DERIVATIVES OF ETHYLBENZENE¹BY E. L. CLINE² AND E. EMMET REID

RECEIVED AUGUST 29, 1927

PUBLISHED DECEMBER 10, 1927

Because of the close structural relationship to benzene and toluene, ethylbenzene has been a subject for investigation by several workers. These, however, had small quantities of material and many discrepancies are evident in the records of their results.

Recent researches^{3,4} have led to the development of a method for the production of ethylbenzene in large quantities. We, therefore, undertook the preparation of some new derivatives of ethylbenzene in order to make further comparisons and at the same time to straighten out the literature on some of the previously prepared compounds.

Historical

Beilstein and Kuhlberg,⁵ two of the earliest workers in this field, found an almost complete analogy between the nitro and amino compounds of toluene and ethylbenzene. Vorländer⁶ found that ethylbenzene acts more like benzene than toluene when treated with hydrocyanic acid, cyanogen, acid chlorides and acid cyanides. The same author further states that ethylbenzene does not react to give an aldehyde by the Gattermann-Koch synthesis, in which statement he is corroborated by several other investigators. However, J. von Braun and Hans Engel⁷ report the preparation of *p*-ethylbenzaldehyde by means of this reaction, so that, in this case, ethylbenzene reacts more like toluene than benzene.

Schultz and Flachsländer⁸ prepared a series of dyes of the Congo type from benzidine, toluidine and the corresponding ethylbenzene base. They found that the Congo type prepared from diethylbenzidine had a greater solubility, greater coloring power but less resistance to light than that from the other two benzidines. However, they stated that the actual differences were very small.

Beilstein and Kuhlberg,⁵ Schultz and Flachsländer⁸ and Béhal and Choay⁹ have studied the nitration of ethylbenzene and the separation of *o*- and *p*-nitro-ethylbenzenes. Beilstein and Kuhlberg attempted to separate the two isomers by differences in their melting points. After twenty

fractionations, they were not successful in getting complete separation, since the melting points are only nine degrees apart in contrast to the corresponding nitrotoluenes, where there is a difference of 61.5°. Schultz and Flachsländer fractionated eighty times in a vacuum in two-degree cuts to get two fractions 220–230° and 245–250° with a small intermediate fraction. Then they fractionated one hundred times at atmospheric pressure to obtain constant-boiling fractions at 223–224° for the *ortho* and 241–242° for the *para* isomer. Even with this painstaking procedure, the boiling points of the two isomers are wrong, due, perhaps, to defective thermometers.

The Present Investigation

The ethylbenzene was prepared according to a modification of the method of Milligan and Reid.³ Purified ethylene was introduced into benzene containing aluminum chloride, the mixture being stirred at the rate of 11,000 r.p.m. by a Witt stirrer, as described by Milligan and Reid.¹⁰

These investigators found that an "incubation period" of an hour or more was necessary to secure maximum absorption of the ethylene, whereas, if they used some of the higher ethylated benzenes (tri- to hexa-ethylbenzene), along with the above ingredients, the rate of absorption of the ethylene was greatly increased. With these facts in view, a process was worked out by which about 50% of the benzene used could be directly converted into ethylbenzene or, by returning the higher ethylated benzenes to the reaction flask, practically all of the benzene can be converted into ethylbenzene, due to the transfer of the ethyl groups from the higher alkylated ethylbenzenes to the free benzene.¹¹

Ethylbenzene was nitrated below 40°, thus avoiding to a large extent the formation of higher nitrated products. Instead of using the tedious method of fractional crystallization, as carried out by Schultz and Flachsländer, we built a high-precision vacuum still, similar to that described by Peters and Baker.¹²

Instead of the main outer glass jacket, we used a brass tube 5 cm. in diameter which was connected to two lead tubes leading to and from a xylene reservoir. The temperature of this jacket was maintained at about 140° by the boiling xylene instead of being electrically heated as described by the authors mentioned above. Except for some other minor details, the still was as described by Peters and Baker. By means of this still we were able to separate the *o*- and *p*-nitro-ethylbenzenes sharply by one distillation. This avoided high temperatures as well as loss of time and materials by repeated fractionation.

Beilstein and Kuhlberg obtained equal parts of the two nitro isomers,

¹⁰ Milligan and Reid, *Ind. Eng. Chem.*, **15**, 1048 (1923).

¹¹ Anschütz and Immendorff, *Ber.*, **18**, 657 (1885).

¹² Peters and Baker, *Ind. Eng. Chem.*, **18**, 69 (1926).

Schultz and Flachsländer report two parts of the *ortho* to one of the *para*, while Behal and Choay found one and a half parts of the *ortho* to one of the *para*. Our results averaged one and two-tenths parts of the *ortho* to one of the *para*. The boiling point of *o*-nitro-ethylbenzene is 135° at 37 mm. and that of *p*-nitro-ethylbenzene 154° at the same pressure.

Both the *o*- and *p*-nitro-ethylbenzenes are quite difficult to reduce to the corresponding amines. All of the earlier workers used tin and hydrochloric acid for both of these reductions but none of them report anything concerning the ease of reduction or the yields obtained. According to our observations this method is excellent in working with the *para* compound, the yield being about 90%, but with the *ortho* compound the yields are poor, probably on account of the entrance of chlorine into the ring as is the case in the reduction of *o*-nitrotoluene.^{13,14} The *para* isomer gives yields up to 80% with iron filings and hydrochloric acid but it is almost impossible to effect a complete reduction of the *ortho* isomer with these reagents. Ammonium sulfide in boiling alcohol solution is a good reducing agent for the *para* compound but is very slow with the *ortho*.

The reduction of 2,4-dinitro-ethylbenzene with ammonium sulfide has been studied by Schultz,¹⁵ who claimed to have obtained the 2-nitro-4-amino-ethylbenzene which had a melting point of 43°, with an acetyl derivative melting at 101°. We obtained proof that this reduction yields a mixture of 2-nitro-4-amino-ethylbenzene and the isomeric 2-amino-4-nitro-ethylbenzene. The former is an orange-yellow, crystalline solid which, after recrystallizing from alcohol, melts at 45° and gives an acetyl derivative melting at 110°. We were unable to isolate the latter in the pure form but we were successful in proving its presence by diazotizing a portion of the isomeric nitro-amino compounds and replacing the diazonium group with hydrogen. The products, *o*- and *p*-nitro-ethylbenzenes, were treated with zinc and hydrochloric acid, which would reduce the *para* and not affect the *ortho* isomer. The *p*-amino-ethylbenzene was separated from the *o*-nitro-ethylbenzene and an acetyl derivative prepared which, when recrystallized from water, melted at 94.5°, which is the melting point given for 4-acetyl-amino-ethylbenzene.

With these facts in view, there is little doubt that the low melting point given by Schultz for 2-nitro-4-acetyl-amino-ethylbenzene was due to the presence of an isomer.

The reduction of 2,4-dinitrotoluene with ammonium sulfide gives two isomers also, but due to the difference in stability of their hydrochlorides both have been isolated. We tried to separate the isomeric aminonitro-

¹⁵ Schultz, *Ber.*, 42, 2634 (1909).

ethylbenzenes by the same method but, due to the small percentage of 2-amino-4-nitro-ethylbenzene, which gives the less stable hydrochloride, we were unable to obtain it in the pure form.

From the *o*- and *p*-amino-ethylbenzenes, a number of derivatives have been prepared and their properties studied; among these is a series of azo dyes prepared from aniline, *o*- and *p*-methylaniline and *o*- and *p*-ethylaniline. The purpose in making these dyes was to determine the effect of the ethyl groups in comparison with the methyl group.

A distinct deepening in color is noticed in going from aniline to the methylaniline dye and a slight deepening in going from methylaniline to ethylaniline. In both the methylaniline and the ethylaniline series, the *para* isomer gives deeper shades than the *ortho*.

Experimental

Ethylbenzene.—Into a mixture of 300 g. (3.84 moles of benzene), 100 g. of higher ethylated benzenes, 15 g. of aluminum chloride (0.056 moles) and the lower layer from a previous experiment, three equivalents of ethylene were introduced in the course of two hours, the temperature being held between 70 and 80°. The ethylene was passed under the head of the Witt stirrer which was running at 11,000 r.p.m. After the addition of the ethylene, the reaction mixture was allowed to settle. It separated into two distinct layers, the top containing practically all of the hydrocarbons with a very little aluminum chloride and the lower which contained nearly all of the catalyst. This was left in the flask for the next run. The top layer was siphoned off, poured onto ice, washed and dried over calcium chloride and fractionated through a 90cm. punched-in column. By the first distillation it was divided into four fractions: one boiling between 80 and 100°, which was returned to the reaction vessel as benzene; one boiling from 100–150°, the ethylbenzene fraction; one boiling between 150 and 190°, the diethylbenzene fraction and a residue which was returned to the reaction vessel as higher alkylated benzenes. The ethylbenzene and the diethylbenzenes were purified in one distillation by passing them through the high-precision still. After purification, ethylbenzene boiled at 135°. Treating 300 g. of benzene with three equivalents of ethylene, the averages for seven runs were: recovered benzene 29 g., ethylbenzene 215 g., diethylbenzene 105 g., residue 39 g.

***o*- and *p*-Nitro-ethylbenzene.**—Into 700 g. (6.6 moles) of ethylbenzene, contained in a two-liter flask cooled by ice, a mixture of 510 g. of concd. nitric acid (sp. gr. 1.42) and 675 g. of concd. sulfuric acid was allowed to flow, dropwise, in the course of six hours. The contents of the flask was agitated with a Witt stirrer, revolving at 3000 r.p.m. and the temperature kept below 40°. After the addition of the acid, the mixture was stirred for three hours at room temperature and then the temperature was gradually raised to 100° in the course of four hours and kept there for two hours. The product was allowed to settle and the oil separated from the excess acid. The oil was washed several times with water, then with caustic soda solution and finally with water. It was distilled with steam in order to separate the mononitro-ethylbenzenes from the higher nitrated products. The oil remaining in the flask was principally 2-4-dinitro-ethylbenzene, previously described by Weisweiler.¹⁶

The oil volatile with steam was dried over calcium chloride and fractionated, using the high-precision vacuum still. The entire inner column was kept at 140° by the xylene vapors in the jacket. In the distilling flask was placed 760 g. of the nitro-ethylbenzenes

¹⁶ Weisweiler, *Monatsh.*, 21, 39 (1900).

and the pressure of the whole system brought to 37 mm. At this pressure the *o*-nitro-ethylbenzene distils at 135° while the *para* isomer boils at 154°. The water in the dephlegmator was regulated so that nine-tenths of the vapors was condensed. After practically all of the *ortho* compound has passed over the distillation ceases. At this point a cut is made. The liquid in the receiver is pure *o*-nitro-ethylbenzene, amounting to 384 g. The distillation is again resumed at 30 mm. and continued until the rate of distillation again slows down, when the pressure is lowered a few more millimeters. This process is continued until the temperature remains constant during the distillation of 30 cc., when it is stopped. The intermediate fraction (60 g.) is a mixture while that in the distillation flask is pure *p*-nitro-ethylbenzene (317 g.). Thus we were able to secure in the pure form 50.5% of *o*- and 41.7% of *p*-nitro-ethylbenzene.

Reduction of *p*-Nitro-ethylbenzene.—A mixture of 120 g. of granulated zinc and 75 g. of *p*-nitro-ethylbenzene was placed in a two-liter flask equipped with an air condenser. To this was added 250 g. of concd. hydrochloric acid in small portions, heat being applied at intervals. After all of the acid had been added, the mixture was heated on a water-bath for two hours to complete the reaction. The mixture was then made strongly alkaline with caustic soda and steam distilled. The distillate was saturated with salt, extracted with ether and the resulting solution dried and distilled; yield, 90%.

By reduction with iron filings and 10% hydrochloric acid, a yield of 80% was obtained.

Reduction of *o*-Ethyl-benzene.—Tin and hydrochloric acid gave a yield of 70% of *o*-nitro-ethylbenzene. With iron filings and 10% hydrochloric acid the reduction was not complete in sixteen hours at 130° so this method was abandoned.

Reduction of 2,4-Dinitro-ethylbenzene.—A solution of 50 g. of 2,4-dinitro-ethylbenzene in 150 g. of ethyl alcohol was treated with 150 g. of concd. ammonia water. The mixture was then alternately saturated with hydrogen sulfide and boiled until a gain in weight of 30 g. was effected. The solution was poured onto ice and the amine separated out. It was filtered off and dissolved in dilute hydrochloric acid. The acid solution was boiled with animal charcoal, filtered and allowed to cool. The hydrochloride separating out was purified by recrystallization several times from dilute acid, using animal charcoal each time. The free base was set free by ammonia and recrystallized from dilute alcohol. It melted at 45°. The sulfate was prepared by treating the amine with dilute sulfuric acid. It is slightly soluble in water but soluble in ordinary solvents. The acetyl derivative was prepared by treating the amine with acetyl chloride. It is soluble in alcohol and slightly soluble in water. When recrystallized from alcohol it melted at 110°.

Analyses. Amine hydrochloride for HCl: Calcd. 18.94. Found: 18.67, 18.61.

Amine sulfate for S: Calcd. 7.45. Found: 7.55, 7.37.

Acetyl derivative for N: Calcd. 13.46. Found: 13.18.

Amine Salts of Anthraquinone-1-butyl-thio-ether-5-sulfonic Acid.—The salts of *o*- and *p*-ethylaniline were prepared according to the method of Reid, Mackall and Miller.¹⁷ It was thought that possibly the ethyl group would lower the melting point enough to avoid decomposition and that these might prove good compounds for identification. However, they showed melting points with decomposition similar to the compounds of the toluidine. The following is a comparison with similar compounds prepared from *o*- and *p*-methylaniline.

Methylaniline		Ethylaniline	
<i>ortho</i>	<i>para</i>	<i>ortho</i>	<i>para</i>
234–237°	256–260°	237–239°	247–249°

¹⁷ Reid, Mackall and Miller, *THIS JOURNAL*, 43, 2104 (1921).

Anal. *Ortho* ethyl compound, calcd. for $C_{10}H_{11}O_4NS_2$: S, 12.92. Found: 12.68, 12.86.

Para ethyl compound, calcd. for $C_{10}H_{11}O_4NS_2$: S, 12.92. Found: 13.13, 13.93.

Sulfonation of *p*-Ethylaniline.—Sulfonations of *p*-methylaniline and of *p*-ethylaniline were carried out under the same conditions. Equally good results were obtained with both compounds. In both cases the sulfonic acid group enters the ring *ortho* to the amino group. A mixture of 30 g. of *p*-amino-ethylbenzene and 75 g. of concd. sulfuric acid was kept at 180° until sulfonation was complete. The reaction mixture was poured into 300 g. of water when the free sulfonic acid separated out in the form of white needles. It was recrystallized from water.

In order to determine the position of the sulfonic acid group in the ring, a portion of the acid was diazotized and the diazonium group replaced by a hydrogen atom. By the usual method the sulfonic group was converted into its sulfonamide which, after recrystallization from alcohol, melted at 86°, corresponding to the *m*-ethylsulfonamide described by Semptowski.¹⁸

The helianthine dye prepared by diazotizing this amine and coupling with dimethylaniline resembles very closely helianthine and *p*-methylhelianthine.

Anal. Calcd. for $C_8H_{11}O_2NS$: S, 15.92. Found: 16.17, 15.73.

3-5-Dibromo-4-amino-ethylbenzene.—One equivalent of *p*-ethylaniline hydrochloride dissolved in water was treated with four equivalents of bromine. The solid which separated out was crystallized from alcohol as long, silky, white, thread-like crystals melting at 85°. The corresponding reaction with chlorine yields a pasty mass which could not be purified.

Anal. Calcd. for $C_8H_9Br_2N$: Br, 56.76. Found: 56.32.

Diazo-amino-ethylbenzene.—This compound was prepared by diazotizing aniline and coupling it with *p*-ethylaniline and by the reverse process. The same compound was formed in each case. Aniline (10 g.) was dissolved in a solution of 100 g. of water and concd. hydrochloric acid corresponding to 12 g. of the free acid, and diazotized. This was treated with a solution of 13 g. (0.107 mole) of *p*-ethylaniline in the theoretical amount of acid. A saturated solution of 50 g. of sodium acetate was added with stirring and the reaction mixture allowed to stand for several hours. The compound which separated out was filtered off, pressed on a porous plate and recrystallized from petroleum ether. It crystallized in yellow needles which melted at 75°.

Anal. Calcd. for amino nitrogen: 5.96. Found: 6.16.

***o*-Amino-azo-ethylbenzene.**—We were unable to isolate this compound in the pure state since it forms an oil which cannot be distilled without decomposition and does not solidify at 20°.

***o*-Ethylphenylhydrazine.**—*o*-Ethylphenylhydrazine hydrochloride was prepared by the ordinary methods for the preparation of hydrazines. It was pressed on a porous plate and recrystallized from dilute acid. The free *o*-ethylphenylhydrazine was prepared by warming the hydrochloride with caustic soda solution. It was then extracted with ether. In the free state it is a very unstable liquid, boiling at 156° at 28 mm. and melting at 49–50°. Its hydrochloride forms hydrazones readily. When *p*-tolylaldehyde is treated with an aqueous solution of the hydrochloride, a hydrazone is formed. It decomposes rapidly in the air. After recrystallizing from alcohol, it melted at 102.5–103°.

Anal. Calcd. for $C_8H_{11}N_2.HCl$: HCl, 21.01. Found: 20.81.

***o*-Ethylphenylhydroxylamine.**—Attempts to prepare this compound by all standard

¹⁸ Semptowski, *Ber.*, 22, 2673

methods were unsuccessful. The reduction of *p*-nitro-ethylbenzene with zinc dust in neutral solution does not take place at low temperatures and at a higher temperature the azoxy derivative is formed in small quantities. Zinc dust in alcoholic solution gives a good yield of the azoxy compound. Ammonium sulfide in alcoholic solution has no effect in the cold, while at higher temperatures it gives the amine.

***p*-Ethylazoxybenzene.**—In attempting to prepare the *p*-ethylphenylhydroxylamine by the method used by Bamberger¹⁹ for *p*-methylphenylhydroxylamine, we obtained the *p*-ethylazoxybenzene. This is a striking difference between the behavior of the two nitro compounds.

A water solution of 2.4 g. of calcium chloride was added to a mixture of 28 g. of *p*-nitro-ethylbenzene dissolved in 70 g. of ethyl alcohol. The mixture was boiled under reflux for a half hour during which time 30 g. of zinc dust was added in portions. The zinc oxide was filtered off and the filtrate poured into water. The oil which separated was steam distilled to remove any volatile impurities. When cooled it solidified and was recrystallized from alcohol.

When *p*-ethylazoxybenzene was distilled from iron filings, it gave *p*-ethylazobenzene, which is described by Schultz,²⁰ m. p. 63°.

***p*-Ethylbenzaldehyde.**—We attempted to prepare the *p*-ethylbenzaldehyde from ethylbenzene and carbon monoxide by means of the Gattermann-Koch reaction, using high-speed stirring to accelerate the reaction. Only a trace of the aldehyde was formed.

Azo Dyes from Aniline, *o*- and *p*-Methylaniline and *o*- and *p*-Ethylaniline.—Aniline, *o*- and *p*-methylaniline and *o*- and *p*-ethylaniline were diazotized and coupled with Schollkopf's acid and *p*-methylaniline and *p*-ethylaniline with Neville and Winther's acid. Two per cent. dyeings were made on wool skeins, using standard methods for application.

An attempt to isolate the dye from *o*-ethylaniline and Neville and Winther's acid was a failure. The coupling was complete but the solubility of the dye was so great that it could not be salted from solution.

There is a marked change in the color of the dye in going from aniline to methylaniline and a slight deepening in the color in going from methylaniline to ethylaniline. In both the methylaniline and ethylaniline series the *para* dye was deeper in shade than the *ortho*.

The two dyes prepared from *p*-ethylaniline were obtained by recrystallization from alcohol.

Summary

1. An improvement has been made upon the procedure for the preparation of ethylbenzene from benzene and ethylene in the presence of aluminum chloride.

2. The isomeric *o*- and *p*-nitro-ethylbenzenes were separated by one distillation through a high-precision vacuum still, thus eliminating the waste of materials and time necessitated by the older method of fractional distillation.

3. The nitro compounds were reduced to the corresponding amines, and from these amines several new derivatives were prepared.

4. A series of azo dyes was prepared from aniline, *o*- and *p*-methylaniline and *o*- and *p*-ethylaniline to determine the relative effects of the methyl and ethyl groups.

PUBLISHED DECEMBER 10, 1927

Historical

The chemistry of the dimethylbenzenes has been well worked out, while the corresponding ethyl derivatives have been studied to a relatively small extent. The first work upon diethylbenzenes was done by Fittig and König,³ who prepared them from bromobenzene and ethyl chloride by the Fittig synthesis. Aschenbrandt⁴ described the preparation of *p*-diethylbenzene by the Fittig synthesis and from it made several compounds. Anschütz and Immendorf⁵ were the first to prepare the diethylbenzenes by the Friedel and Crafts reaction. They claimed that the *para* isomer was the chief product. Voswinkle⁶ was the first to isolate and critically study the three isomeric diethylbenzenes. He prepared the *meta* and *para* isomers by the Friedel and Crafts reaction. By this procedure he claimed that the *para* compound was the major product and that there was no *ortho* isomer formed.⁷ To prepare the latter he used the Fittig synthesis. He separated the *meta* and *para* isomers by the difference in solubility of the barium salts of the sulfonic acids. He prepared a series of compounds from the sulfonated and nitrated derivatives of each isomer. In the nitration of *m*-diethylbenzene, he did not attempt to separate the nitro isomers, which were undoubtedly formed, and any compound made from his nitro would be a mixture of isomers.

Fournier⁷ used the same method of preparation of the *meta* and *para*-diethylbenzenes as Voswinkle, but instead of the barium salt of the *p*-diethylbenzene sulfonic acid, he used the cadmium salt to purify this isomer, since its barium salt is difficult to crystallize.

The Present Investigation

The ethylbenzenes were prepared by the Friedel and Crafts synthesis by passing ethylene into benzene and aluminum chloride heated to 70–80°, the reaction being accelerated by high speed stirring.⁸

By this procedure there are obtained a series of ethylated benzenes,

from the mono- to the hexa-ethylbenzene, the amounts of these formed depending upon the conditions of the experiment and the amount of ethylene introduced. The present investigation was carried out upon *m*-diethylbenzene, which was obtained, along with the *para* isomer and possibly some *ortho*, by the above reaction. The fraction boiling from 180–185° was used, as the boiling points of the three diethylbenzenes as determined by Voswinkle are *ortho*, 184–184.5°; *meta*, 181–182° and *para* 182–183°. The *meta* isomer was considered to be the major constituent of the diethylbenzenes from the above method of preparation of ethylated benzenes and our experiments bear out this relation.

The *m*-diethylbenzene was separated from the isomeric mixture by partial sulfonation and fractional crystallization of the barium salt of the diethylbenzene sulfonic acids. Advantage was taken of the property of *m*-diethylbenzene of being more easily sulfonated than the other two isomers and a process was worked out by which 30% of the isomeric diethylbenzenes could be isolated as the pure *meta* compound. The boiling point of *m*-diethylbenzene was found to be 180.55° (corr).

Another method of separation was investigated but with poor results. It consisted of differential oxidation, followed by partial sulfonation and partial hydrolysis, as was applied to the xylenes by Clarke and Taylor.⁹

When this method was tried with the diethylbenzenes, it was found that, by treatment with dilute nitric acid to oxidize the *ortho* and *para* isomers, nitration instead of oxidation took place. We were unable to identify the nitro product formed but the nitration must have taken place in the side chain, as conditions were more favorable for this than for nitration in the ring.

Another method of separation of the *meta* isomer was experimented with, namely, that of complete sulfonation of the diethylbenzenes using equal volumes of the hydrocarbon and concentrated sulfuric acid, followed by fractional crystallization of the barium salt of the sulfonic acid. As there was a possibility of disulfonation and as the recrystallization of the barium salt is more difficult in the presence of the other sulfonated isomers, this method was abandoned for that of partial sulfonation, as outlined above.

When *m*-diethylbenzene is nitrated with a mixture of concentrated and fuming nitric acid at 30°, a mixture of isomeric mononitro derivatives is obtained. Under the influence of the two ethyl groups, the entering nitro group would be oriented to the 2 or 4 position, with a possibility of some going to the 5 position. Voswinkle prepared a mononitro compound but was uncertain as to the position of the nitro group. He did not attempt to separate the isomers and there is little doubt that he had a mixture of isomers from which he prepared several compounds.

⁹ Clarke and Taylor, *THIS JOURNAL*, 45, 830 (1923).

By passing the nitro product from *m*-diethylbenzene through a high-precision vacuum still¹⁰ we were successful in separating the major isomer from the one or more remaining isomers. This compound constitutes 75% of the total nitro product and is the 4-nitro-*m*-diethylbenzene. Its structure was proved by oxidizing it to the 4-nitro-isophthalic acid by alkaline potassium permanganate. This melted at 245° as given by Huisinga and Holleman.¹¹ 4-Nitro-*m*-diethylbenzene boils at 133° at 4 mm. It is easily reduced to the amine, from which several compounds were made, including a series of azo dyes. The purpose of the preparation of the dyes was to determine the effect upon the color of the ethyl groups as compared with methyl groups in similar dyes.

Experimental

Separation of *m*-Diethylbenzene

To 686 g. (5.12 moles) of the crude diethylbenzenes, boiling from 180–185°, in a two-liter balloon flask, was added 1290 g. (12.5 moles) of concentrated sulfuric acid. The mixture was mechanically stirred at such a rate as to give an emulsion of the hydrocarbon and the acid, the temperature being kept between 15 and 20°. After six hours, when the stirrer was stopped and the mixture allowed to stand for a few minutes, three distinct layers separated. The top layer consisted of the unreacted hydrocarbon; the second, an amber-colored solution, was principally the sulfonated product; and the third, the lowest layer, was almost colorless. It analyzed for approximately 80% of sulfuric acid and contained less than 1% of the sulfonated hydrocarbon. When 300 cc. of water was added, most of it went to the acid layer. After standing for two hours, about half of the lower layer was siphoned off and the remainder, with the two top layers, was transferred to a flask for steam distillation. Steam was passed into the solution and distillation continued until the temperature reached 125° (thermometer in the liquid). This insured complete separation of the unreacted hydrocarbon. There remained in the flask two distinct layers, the top, consisting of the sulfonated hydrocarbon and the lower, the sulfuric acid layer. After cooling, the lower layer was siphoned off, thus freeing the sulfonated hydrocarbon from most of the excess sulfuric acid. The sulfonated hydrocarbon layer was transferred to a three-liter beaker and diluted with 300 cc. of water. A hot, saturated solution of barium hydroxide was added until a slight alkaline reaction to litmus was obtained. It was made again slightly acid with dilute sulfuric acid and then brought to the neutral point with barium carbonate. This procedure avoided the troublesome foaming that results when the carbonate is used exclusively. The solution was diluted to about two and one half liters, boiled and the precipitate filtered off. The barium sulfate cake was washed free of the sulfonated hydrocarbons by boiling with 300–400 cc. of water and filtering. Usually three to four washings were sufficient. The several filtrates were combined and evaporated to about 1500 cc. and then cooled to room temperature. It was found best to stir the solution while it was cooling as this prevented the formation of a hard cake of crystals which, if formed, gave difficulty in filtering. The separation of the pure barium salt of *m*-diethylbenzene sulfonic acid depends upon the fact that this salt is less soluble in water than the barium salts of the other two isomers, as shown by Voswinkle.¹²

¹⁰ Peters and Baker, *Ind. Eng. Chem.*, **18**, 69 (1926).

¹¹ Huisinga and Holleman, *Rec. trav. chim.*, **27**, 260–286 (1909); *C. A.*, **3**, 420 (1909).

¹² Voswinkle, *Ber.*, **22**, 315 (1889).

The salts of other metals were tried but it was found that the barium salt is the best suited for this separation. The snow-white crystals were placed upon a large Büchner funnel and repeatedly pressed until all of the mother liquor was drawn off. This liquor contained the more soluble barium salts of the *ortho*- and *para*-diethylbenzene sulfonic acids as well as a large quantity of the *meta* isomer. The crystals were dissolved in 300 cc. of water, cooled and filtered as before. Four or five such recrystallizations separated the pure *meta* isomer, as was shown by the melting point of the amide, which was made in the usual way. A second concentration of the combined mother liquors gave a small additional yield of the *meta* isomer. If all of the crystals which came out at room temperature were filtered from the mother liquor, there remained a reddish solution which showed little tendency to crystallize. The barium salt of *m*-diethylbenzene sulfonic acid crystallizes in glistening white plates which are easily soluble in the ordinary solvents. An average run for the separation of the *meta* isomer is as follows: from the 686 g. of the isomeric diethylbenzenes initially used, 292 g. was recovered unreacted, 210 g. (30%) was isolated as the *meta* isomer and the remainder washed into the filtrate. Taking into consideration the large amount of the *meta* isomer isolated and the amount washed into the filtrate to secure the pure fraction, one would be safe in assuming the *meta* isomer to be the major constituent of the isomeric diethylbenzenes.

The amide of *m*-diethylbenzene sulfonic acid crystallizes easily from alcohol and water in long, flat, white needles, forming star-shaped clusters. It melted at 101–101.5°, as given by Voswinkle. The amide of the *ortho* isomer melts at 119° and the *para* at 85°, according to the same author.

The sulfonic acid group was easily removed from the *m*-diethylbenzene sulfonic acid by the method described by Armstrong and Miller.¹³ Equal amounts, by weight, of the barium salt of the sulfonic acid and concentrated sulfuric acid were placed in a balloon flask and steam distilled. The sulfuric acid was diluted with an equal volume of water before it was added to the barium salt. Barium sulfate was precipitated and the benzene sulfonic acid went into solution. Steam was passed into the solution and by external heating of the distillation flask the temperature was increased to 130° (thermometer in the liquid). At about this point the *m*-diethylbenzene sulfonic acid began to hydrolyze, yielding the free hydrocarbon. Then the temperature was gradually increased to 160°, the major portion of the *m*-diethylbenzene coming over between 140 and 150°. Distillation was continued until all of the *m*-diethylbenzene sulfonic acid was hydrolyzed. There was a slight coloration on the remaining acid layer, which showed some decomposition by the acid. From the wide temperature range, it can be readily seen that no narrow temperature limits can be assigned for the hydrolysis of *m*-diethylbenzene sulfonic acid by steam and sulfuric acid. The *m*-diethylbenzene was dried over calcium chloride and distilled. The purity of the compound was indicated by the fact that about 95% of it distilled at one definite temperature, which was 180.55° (corr.). Yield, from the barium salt to the hydrocarbon, 95–97%. The physical properties of *m*-diethylbenzene resemble very closely those of the xylenes, it being a colorless, very mobile liquid with a pleasant, sweetish odor; $d_4^{20} = 0.8798$; $d_{25}^{20} = 0.8597$; $n_D^{25} = 1.4926$; $n_D^{20} = 1.4955$; $n_D^{15} = 1.4778$; $n_D^{10} = 1.4998$.

4-Nitro-*m*-diethylbenzene.—To obtain the formation of only the mononitro derivative of *m*-diethylbenzene, a number of experiments were made to determine the optimum temperature and concentration of nitric acid to give approximately 50% nitration, which would minimize the formation of higher nitro products. Sulfuric acid could not be used to take up the water formed in the reaction as *m*-diethylbenzene sulfonates easily, even at low temperatures. The following method was found to be very satisfactory. A mixture of 60 g. of concd. nitric acid (sp. gr. 1.42) and 40 g. of fuming

¹³ Armstrong and Miller, *J. Chem. Soc.*, 45, 148 (1884).

nitric acid (sp. gr. 1.49–1.50) was used for each 100 g. of *m*-diethylbenzene. The acid was added slowly to the hydrocarbon while the mixture was well stirred and the temperature kept below 30°. The mixture was stirred at 30° for one and one-half hours after all of the acid was in and then diluted with 100 cc. of water. The oil layer was removed and washed with water and with a 10% sodium hydroxide solution to remove any phenols. After washing it free of the alkali, it was diluted with a small amount of ether, dried over calcium chloride and distilled. After removing the unreacted *m*-diethylbenzene, it was found that the nitro product distilled over a range of 105–138° at 5 mm. pressure, which strongly indicated a mixture of isomeric mononitro derivatives. A small residue in the distilling flask showed the formation of some of the higher nitro compounds.

In order to secure a separation of these nitro isomers, a high-precision fractional vacuum still was built as described by Peters and Baker,¹⁰ with slight changes to suit our needs. The inner column was sealed directly to the distilling flask and was one continuous piece throughout the apparatus. This column was 225 cm. long and 25 mm. in diameter. No pre-air heater was used and the distillate receiver was arranged so that the measured distillate could be removed without breaking the vacuum on the whole system. By running the mixture of isomers through this still, reading every minute the temperature of the distillate and the volume distilled, the points at which cuts should be made were clearly indicated when these data were plotted. After determining these points the isomers could be sharply separated by redistillation. The lower-boiling isomers distilled between 107 and 120° at 4 mm. pressure, there being no marked temperature break within that range. From 120° the temperature rose sharply to 133°, pressure constant, and remained at that point throughout the distillation. This isomer composed 75% of the mixture and was the 4-nitro-*m*-diethylbenzene. The structure was definitely proved by oxidizing it to 4-nitro-isophthalic acid, which melted at 245°. From the boiling point data, the low-boiling fraction seemed to consist of two possible isomers, namely, 2-nitro-*m*-diethylbenzene and 5-nitro-*m*-diethylbenzene. As there was only a small quantity of this mixture, no further study of it was made. Voswinkle gave 280–285°, with decomposition, as the boiling point of the mononitro derivative which he prepared. The nitro derivatives are amber-colored (reddening upon standing for several months), pleasant-smelling liquids. 4-Nitro-*m*-diethylbenzene boils at 133° at 4 mm.; $d_4^{25} = 1.0860$; $d_{25}^{25} = 1.0644$; $n_D^{25} = 1.5300$.

4-Amino-*m*-diethylbenzene.—The 4-nitro-*m*-diethylbenzene was easily and completely reduced to the amine by iron filings and acetic acid. The reaction was complete in about six hours when the mixture was heated on a boiling water-bath. The solution was made alkaline, the amine steam distilled, dried over calcium chloride and distilled under reduced pressure. The freshly distilled amine was almost colorless but gradually assumed a reddish color upon standing. It is insoluble in water, soluble in ether, alcohol, etc. The amine hydrochloride formed very easily and crystallized in long, clustered, anhydrous needles which are very soluble in water. Voswinkle prepared the acetyl derivative and gave 194° as its melting point. We prepared the same derivative and found that it crystallizes in long, flat, anhydrous, white needles that melt at 112–113.5°, (corr.). The benzoyl derivative crystallizes in white, anhydrous, lustrous plates which melt at 176.5° (corr.). The boiling point of the amine is 116.5° (corr.) at 12 mm. and 141° (corr.) at 30 mm. pressure; $d_4^{25} = 0.9651$; $d_{25}^{25} = 0.9545$; $n_D^{25} = 1.5395$.

Anal. Calcd. for $C_{10}H_{14}N$: N, 9.40. Found: 9.44.

4-Hydroxy-*m*-diethylbenzene.—This phenol was prepared by heating the diazo-tized amine and steam distilling the product. It was washed with 50% sulfuric acid, dried over potassium carbonate and distilled in a vacuum; yield, 78%. An attempt was made to prepare the phenol from the sodium salt of *m*-diethylbenzene sulfonic acid

but with little success. It is an amber-colored liquid, completely soluble in sodium hydroxide solution, very slightly soluble in water and soluble in ordinary organic solvents. It has a distinct phenolic odor. It gave no color with aqueous ferric chloride but with an alcohol-water solution it gave a green coloration. 4-Hydroxy-*m*-diethylbenzene boils at 124.5–125.5° (corr.); $d_4^{20} = 0.9986$; $d_{25}^{25} = 0.9794$; $n_D^{25} = 1.5218$.

Anal. Calcd. for $C_{10}H_{14}O$: C, 79.94; H, 9.40. Found: C, 79.79; H, 9.73.

4-Chloro-*m*-diethylbenzene.—This compound was prepared from the amine by the Sandmeyer reaction, using the procedure outlined by Marvel and McElvain for the preparation of the chlorotoluenes.¹⁴

The amine was diazotized and added to the freshly prepared cuprous chloride solution at 0°. After stirring for two hours, the brown addition product was decomposed by gradually heating, and the chlorine compound steam distilled. It was washed with sodium hydroxide and sulfuric acid, dried and distilled in a vacuum; yield, 50%. Istiate¹⁵ prepared the chloro derivatives of the diethylbenzenes from monochlorobenzene, ethylene and aluminum chloride, but did not attempt to separate the different chloro isomers. The 4-chloro-*m*-diethylbenzene is a colorless, pleasant-smelling liquid boiling at 94.5° (corr.) at 12 mm.; $d_4^{20} = 1.0335$; $d_{25}^{25} = 1.0119$; $n_D^{25} = 1.5149$.

Anal. Calcd. for $C_{10}H_{13}Cl$: Cl, 21.04. Found: 20.66.

4-Bromo-*m*-diethylbenzene.—The bromine derivative was prepared by the Sandmeyer reaction by adding the diazotized amine to the cuprous bromide-hydrobromic acid mixture at 0–5° and also at 105°. The yield at both of these temperatures was very poor but the low-temperature reaction gave the best yield, it being about 19%. Voswinkle prepared the monobromo derivative by direct bromination but here again he was uncertain as to the position of the bromine atom. The purification of this halide was similar to that for the chlorine compound. It is a colorless liquid boiling at 106.5° (corr.) at 12 mm.; $d_4^{20} = 1.2709$; $d_{25}^{25} = 1.2462$; $n_D^{25} = 1.5359$.

Anal. Calcd. for $C_{10}H_{13}Br$: Br, 37.52. Found: 38.55.

4-Iodo-*m*-diethylbenzene.—This compound was prepared by the usual method of adding potassium iodide to the diazotized amine. It was purified by the method given under the chloro derivative. It is a colorless liquid boiling at 131.5° (corr.) at 12 mm.; $d_4^{20} = 1.5026$; $d_{25}^{25} = 1.4740$; $n_D^{25} = 1.5729$.

Anal. Calcd. for $C_{10}H_{13}I$: I, 48.81. Found: 47.16.

***m*-Diethylbenzene Iodoso Chloride.**—This compound was prepared by treating 4-iodo-*m*-diethylbenzene, dissolved in carbon tetrachloride, with chlorine at 0°. The iodoso chloride is very soluble in this solvent and separated out in yellow crystals as the latter evaporated. This compound was quite unstable, even at low temperatures, and decomposed, giving off free chlorine. The freshly prepared crystals melted with decomposition at 51–53°. Attempts to prepare the iodoso oxide were unsuccessful.

4-Cyano-*m*-diethylbenzene.—This nitrile was prepared from the amine by the Sandmeyer reaction.¹⁶ The neutralized diazonium chloride was added to the cuprous cyanide solution at 0–5° and the diazonium complex decomposed by heating, the nitrile being purified in the usual way. It is a yellowish liquid boiling at 134° (corr.) at 12 mm.; $d_4^{20} = 0.9699$; $d_{25}^{25} = 0.9507$; $n_D^{25} = 1.5195$.

Anal. Calcd. for $C_{11}H_{13}N$: N, 8.80. Found: 8.45.

***m*-Diethylthiocarbanilide.**—This derivative was prepared by the method given by Snedker,¹⁷ which consisted of using one molal proportion of the amine to 1.25 moles of carbon bisulfide and cooling to about 10°. While the solution was being stirred a 40% solution of sodium hydroxide was added. After stirring for a few minutes, the carbon bisulfide was allowed to evaporate. The *m*-diethylthiocarbanilide crystallized in very fine, white needles which, when recrystallized from alcohol and water, melted at 144.5° (corr.); yield, 36.5%.

Comparison of Azo Dyes Prepared from Aniline, 4-Amino-*m*-Dimethylbenzene and 4-Amino-*m*-Diethylbenzene

In order to see what effect the ethyl groups of 4-amino-*m*-diethylbenzene would have upon the color of dyes prepared from it, in comparison with those obtained from 4-amino-*m*-diethylbenzene and aniline, a series of dyes was made from these amines. They were diazotized and each coupled with R-salt, chromotrope, H-acid, etc., as second components. The dyes were made and applied to the wool without isolation from solution. The procedure for the three amines and ten second components is as follows.

One-hundredth of a mole of each amine was diazotized in the usual way and the solution diluted to 100 cc. One-thousandth of a mole of each of the ten second components was placed in a beaker and to each was added 50 cc. of water and 2.5 cc. of a 10% sodium carbonate solution. After obtaining complete solution of the naphthalene salt, the solution was cooled to 5° and 10 cc. of the cold diazotized amine solution was added, with stirring. The coupling was usually very rapid and in most cases the dye was in complete solution. The dye solution was kept cold for about an hour and then allowed to come to room temperature. Each dye solution was diluted to 100 cc. and 50 cc. of this solution was used for each dyeing. The 50 cc. of dye solution taken was diluted to 200 cc. and 10 cc. of 5% sulfuric acid added. The entering of the skeins, etc., was carried out as is usual for wool dyeings. The dye-bath was heated until complete exhaustion of the dye by the wool, which required from thirty to sixty minutes. By the above procedure the amount of dye on the wool varied from one component to the other but the amount formed from the three amines with any one second component was practically the same.

Table I is a classification of the dyes from the three amines. The introduction of the methyl groups in the molecule has a very pronounced effect, giving a change in color as would be expected. In comparing the methyl and ethyl groups, there is little change in the color but the intensity of the color is increased in a majority of the comparative dyeings, namely, nos. 1, 2, 4, 6, 7 and 9, and in 5 and 10 the intensity is the same. In numbers 3 and 8, the reverse is true but this is possibly due to incomplete coupling.

¹⁷ Snedker, *J. Soc. Chem. Ind.*, **44**, 486T (1925).

Taking the series as a whole, we can definitely say that the presence of the ethyl groups in the amine molecule gives a decided effect over the methyl groups in the intensity of the color of the dye.¹⁸

TABLE I

CLASSIFICATION OF AZO DYES MADE FROM ANILINE, *m*-DIMETHYLANILINE AND *m*-DIETHYLANILINE BY COUPLING WITH NAPHTHALENE DERIVATIVES

Second component	Aniline	<i>m</i> -Dimethylaniline	<i>m</i> -Diethylaniline
1. H-acid	Bordeau	Bordeau	Deeper Bordeaux
2. Chromotrope	Red	Crimson	Deeper crimson
3. Armstrong's acid	Yellow	Dull yellow	Yellow
4. Schaeffer's salt	Orange	Scarlet	Deeper scarlet
5. R-salt	Deep orange	Red	Red
6. J-acid	Yellow-brown	Red-brown	Deeper red-brown
7. <i>p</i> -Aminobenzoyl-J-acid	Burnt orange	Red	Deeper red
8. J-acid urea	Orange	Red	Lighter red
9. <i>p</i> -Aminobenzoyl- <i>p</i> -amino-benzoyl-J-acid	Orange	Red	Deeper red
10. Neville and Winther's acid	Deep orange	Red	Red

Summary

1. *m*-Diethylbenzene has been separated from its isomers by partial sulfonation and fractional crystallization of the barium salt of the sulfonic acid.

2. 4-Nitro-*m*-diethylbenzene has been separated from its isomers and reduced to the amine, from which several derivatives were made by standard methods.

3. A series of azo dyes was made from aniline, *m*-diethylbenzene and *m*-diethylbenzene to determine the influence of the ethyl groups over the methyl groups in the color of the dyes. It was found that the colors were the same but the intensity of the color was increased.

BALTIMORE, MARYLAND

¹⁸ The authors wish to thank the Jackson Laboratory and the Technical Laboratory of E. I. du Pont de Nemours and Co. for advice in the preparation of the dyes, for furnishing the second components and for classifying the dyeings.

DICARBOXYPHENYLARSONIC ACIDS. II
3,4-DICARBOXYPHENYLARSONIC ACID AND SOME OF ITS
DERIVATIVES

BY CLIFF S. HAMILTON AND VIOLA C. JELINEK

RECEIVED SEPTEMBER 2, 1927

PUBLISHED DECEMBER 10, 1927

Previous to this time, only three dicarboxyphenylarsonic acids have been prepared. Isophthalarsonic acid, or 2,4-dicarboxyphenylarsonic acid, was prepared by Michaelis from 2,4-dimethylphenylarsonic acid by oxidation with potassium permanganate in alkaline solution.¹ According to the German patents, 4-acetyl-amino-2,5-dicarboxyphenylarsonic acid was prepared by oxidation of 4-acetyl-amino-5-carboxy-2-methylphenylarsonic acid with potassium permanganate in alkaline solution.² 2,3-Dicarboxyphenylarsonic acid, the first dicarboxyphenylarsonic acid with the carboxyl groups ortho to each other, was prepared by Hamilton and Frazier³ by first nitrating *o*-phthalic acid, then reducing the nitro compound to 3-amino-*o*-phthalic acid and finally introducing the arsonic acid group by means of Bart's reaction.⁴

As a further contribution to the study of dicarboxyphenylarsonic acids, 3,4-dicarboxyphenylarsonic acid and some of its derivatives have been prepared. This is the first dicarboxyphenylarsonic acid to be obtained by the introduction of the arsonic group into the neutral ester of an aromatic dicarboxy acid. 4-Nitro-*o*-phthalic acid was first obtained by preparing phthalimide from phthalic anhydride and urea, reducing phthalimide to phthalide, nitrating phthalide and oxidizing 5-nitrophthalide to 4-nitro-*o*-phthalic acid. On direct reduction of 4-nitro-*o*-phthalic acid with tin and hydrochloric acid, Bogert⁵ and Miller⁶ found that carbon dioxide was evolved, forming *m*-aminobenzoic acid. Thus to prepare 4-amino-*o*-phthalic acid, it was necessary to esterify 4-nitro-*o*-phthalic acid before reduction in order to protect the carboxyl groups. The dimethyl-4-nitrophthalate was then reduced with zinc dust and hydrochloric acid in the presence of alcohol.

The arsonic acid group was introduced directly into dimethyl-4-amino-phthalate following the method used by Bart to prepare 2-carboxyphenylarsonic acid.^{4b} Bart observed that substitution of the arsonic acid group did not occur when benzene diazonium chloride was treated with arsenious acid in weakly or strongly acid solution, the diazo compound

¹ Michaelis, *Ann.*, 320, 335 (1902).² Farbwerke vorm. Meister, Lucius and Bruning, Ger. pat. 203,717 (1907).³ Hamilton and Frazier, *THIS JOURNAL*, 48, 2414 (1926).⁴ (a) Bart, Ger. pat. 250,264 (1910); (b) *Ann.*, 429, 55 (1922).⁵ Bogert and Renshaw, *THIS JOURNAL*, 30, 1136 (1908).⁶ Miller, *Ber.*, 11, 992 (1878); *Ann.*, 208, 223 (1881).

behaving exactly the same as if arsenious acid were not present. The diazonium compound gave off nitrogen, gradually changing to phenol. However, when the reaction was carried out in the presence of hydroxyl ion of not too high concentration, the diazo compound reacted with the arsenious acid to form phenylarsonic acid. The failure to form the arsonic acid after treatment of the diazonium chloride with arsenious acid in the presence of hydrogen ion, led Bart to conclude that the diazonium group could not be replaced by the arsonic acid radical. Because of the favorable effect of hydroxyl ion on the formation of arsonic acids, Bart concluded that the reaction took place only after the transformation of the diazonium to the diazohydrate form, which is stable only in alkaline solution. Further investigation by Bart showed that hydroxyl ion in high concentration had a negative influence on the course of arsonic acid formation. It was not known whether this phenomenon depended on the fact that the diazotate, which is formed by increasing the hydroxyl-ion concentration, had a lower tendency to react with arsenious acid, or whether the activity of arsenious acid as a reducing agent was decreased. It was certain, according to Bart, that the best reaction took place when the hydroxyl-ion concentration was just sufficient for the formation of the *syn*-diazohydrate from the diazonium compound.

Bart also found that if the diazo compound contained a strongly negative group such as nitro or carboxyl, a good reaction with arsenious acid occurred even with a small hydroxyl-ion concentration, due to the great tendency of such diazonium compounds to form the diazohydrate. If the negative group was meta or para to the arsonic acid group, a somewhat stronger alkalinity was found to be necessary than for a compound containing the negative group in the ortho position. This was thought to be due, probably, to the further distance of the negative group from the diazonium group, a slightly higher alkalinity being required to form the *syn*-diazo compound.

Thus, in preparing the dimethyl ester of 3,4-dicarboxyphenylarsonic acid, the diazonium mixture, before being added to the sodium arsenite solution, was just neutralized with sodium hydroxide solution in order to form the *syn*-diazohydrate. This change was apparent, for just at the neutral point an orange precipitate separated from the clear diazonium solution. Because of the presence of the negative carboxyl groups, a very low hydroxyl-ion concentration was used. The diazonium solution was just neutralized with sodium hydroxide solution, but none was added to the sodium arsenite solution, a sufficient hydroxyl-ion concentration resulting from the hydrolysis of the sodium arsenate. The neutral methyl ester of 3,4-dicarboxyphenylarsonic acid was hydrolyzed with metallic sodium and alcohol, forming the sodium salt, which was converted into the silver salt. From the silver salt pure 3,4-dicarboxyphenylarsonic acid was obtained

Experimental Part

Preparation of Phthalimide.—The phthalimide used in the synthesis of 3,4-dicarboxyphenylarsonic acid was prepared according to the method of Herzog;⁷ yield 97%.

Preparation of Phthalide.—Phthalide was prepared readily by the method of Reissert.⁸ The yield from 1130 g. of phthalimide was 743 g. of phthalide (73%); m. p. 71–73°.

Nitration of Phthalide.—Hoenig nitrated phthalide with potassium nitrate and concd. nitric acid and believed that the product was 4-nitrophthalide.⁹ Teppema showed that Hoenig's product was 5-nitrophthalide instead of the 4-nitro derivative.¹⁰ 5-Nitrophthalide was prepared very satisfactorily by the method of Hoenig. From 743 g. of phthalide, 704 g. of crude 5-nitrophthalide was obtained. On recrystallization from ethyl alcohol, the nitrophthalide melted at 132–134°.

Oxidation of 5-Nitro-phthalide.—By following the method of Bogert and Boroschek,¹¹ 90% yields of 4-nitro-*o*-phthalic acid melting at 162–163° were obtained.

Preparation of the Dimethyl Ester of 4-Nitro-*o*-phthalic Acid.—Dimethyl-4-nitrophthalate was prepared by the method of Bogert and Renshaw,¹² which involved the sulfuric acid method of esterification. Four hundred g. of pure 4-nitro-*o*-phthalic acid yielded 448 g. of the ester melting at 69–71°; yield, 86%.

Reduction of Dimethyl-4-nitrophthalate to Dimethyl-4-aminophthalate.—Dimethyl-4-nitrophthalate was reduced with alcoholic hydrochloric acid and zinc dust according to the method of Bogert and Renshaw.¹³ Tan-colored, glistening plates of dimethyl-4-aminophthalate melting at 80–84° were obtained in 75% yield.

Arsonation of Dimethyl-4-aminophthalate.—The method which was used by Bart¹⁴ to prepare 2-carboxyphenylarsonic acid was modified and employed in the arsonation of dimethyl-4-aminophthalate. Sixty-two g. of dimethyl-4-aminophthalate was dissolved in a three-liter beaker containing 1200 cc. of water and 105 cc. of hydrochloric acid (sp. gr. 1.18). The beaker was surrounded by a freezing mixture and the solution was cooled below 0° by the aid of a motor-driven stirrer. With constant stirring and keeping the temperature below 0°, a solution of 24 g. of sodium nitrite in 300 cc. of water was added drop by drop by means of a separatory funnel until starch iodide paper indicated an excess of nitrous acid. After stirring for fifteen minutes, the excess hydrochloric acid was carefully neutralized with sodium hydroxide solution, care being taken to keep the temperature below 0°. At the neutral point, as indicated by Congo Red paper, an orange precipitate separated. The diazo mixture, kept at 0°, was added slowly with constant stirring to a three-gallon crock containing a solution of 1500 cc. of water, 150 g. of sodium arsenite, and 15 g. of copper sulfate. The purpose of the copper sulfate was to serve as a catalyst. After each addition of the diazo mixture, nitrogen was evolved. A red coloration, spoken of by Bart,¹⁴ when the diazo solution was first poured into the sodium arsenite solution, was not noticed. Since a good yield of the arsonated product was obtained, this indicated that the red coloration was not necessary for a good reaction. After the diazo solution had all been added, the mixture was stirred for one hour. The resulting brown material was then heated to insure com-

plete removal of nitrogen, filtered, acidified with hydrochloric acid to Congo Red paper and evaporated to dryness. The last stages of the evaporation were carried out over a water-bath and finally in an oven at 150°. The yellow residue was pulverized and extracted at room temperature with 400 cc. of absolute methyl alcohol, filtered and the residue washed with methyl alcohol. The yellow filtrate and the washings were combined and distilled to remove most of the methyl alcohol. The residue in the distilling flask was poured into an evaporating dish and heated over a water-bath. The methyl ester of 3,4-dicarboxyphenylarsonic acid remained as a sticky, yellow-brown substance. On drying overnight in an oven at 140° the sticky compound changed to a yellow, crystalline material; yield, 77–80%.

Hydrolysis of the Dimethyl Ester of 3,4-Dicarboxyphenylarsonic Acid.—Fifty g. of the crude dimethyl ester of 3,4-dicarboxyphenylarsonic acid was dissolved in 300 cc. of absolute ethyl alcohol. Alcohol which was free from water was used in order to obtain the sodium salt as a solid rather than as an oil. Some of the salt and arsenic trioxide present in the crude ester did not dissolve and were removed by filtration. When a solution of 25 g. of metallic sodium in 400 cc. of ethyl alcohol was added, the cream-colored sodium salt precipitated immediately. The mixture was refluxed for one hour. Excess sodium was used to prevent the product from darkening and becoming sticky. The sodium salt was filtered, washed with ethyl alcohol and dried overnight at 140°. The yield was quantitative.

Preparation of the Silver Salt of 3,4-Dicarboxyphenylarsonic Acid.—Fifty-nine grams of the sodium salt of 3,4-dicarboxyphenylarsonic acid was dissolved in 100 cc. of water, forming a very viscous, brown solution. The solution was slightly acidified with nitric acid and upon the addition of a solution containing 108 g. of silver nitrate in 100 cc. of water, the silver salt precipitated.

Preparation of 3,4-Dicarboxyphenylarsonic Acid.—The silver salt was filtered, washed with water and, while still wet, was suspended in 300 cc. of water. Conc'd. hydrochloric acid was added until the heavy, curdy precipitate of silver chloride was completely formed. On filtering off the silver chloride, a yellow filtrate was obtained which contained 3,4-dicarboxyphenylarsonic acid in solution. The filtrate was decolorized with charcoal and the silver salt reprecipitated on the addition of a solution of 100 g. of silver nitrate in 100 cc. of water. The white silver salt was filtered, suspended in water, acidified with hydrochloric acid and the silver chloride removed by filtration. On evaporation of the filtrate and drying in an oven at 80°, pure 3,4-dicarboxyphenylarsonic acid remained as a light yellow, crystalline mass; yield 40%, calculated on the basis of the sodium salt.

3,4-Dicarboxyphenylarsonic acid melts and effervesces at 180°. Clusters of light yellow crystals are obtained from a very concentrated solution of 3,4-dicarboxyphenylarsonic acid. It is highly soluble in hot or cold water and in methyl alcohol and insoluble in ether, benzene and chloroform.

Anal. Sample dried at 80°, subs., 0.1891: 24.50 cc. of 0.05312 *N* iodine solution. Calcd. for $C_6H_4O_7As$: As, 25.85. Found: 25.81.

Derivatives

The Anhydride.—The anhydride of 3,4-dicarboxyphenylarsonic acid was prepared by heating the free acid for three days at 160° under reduced pressure in the presence of phosphorus pentoxide. Water splits off from the carboxyl groups and the arsonic acid group, forming the following compound

The anhydride condensed with phenol and resorcinol, forming compounds similar to phenolphthalein and fluorescein.

Anal. Subs., 0.1016, 0.0904: 15.90, 14.30 cc. of 0.04986 *N* iodine solution. Calcd. for $C_8H_5O_4As$: As, 29.51. Found: 29.26, 29.58.

The Methyl Ester.—The methyl ester of 3,4-dicarboxyphenylarsonic acid is a light yellow, crystalline solid which is readily soluble in water, ether, benzene, chloroform, methyl alcohol and ethyl alcohol.

Anal. Subs., 0.5272, 0.2725: 68.00, 34.47 cc. of 0.04933 *N* iodine solution. Calcd. for $C_{10}H_{11}O_7As$: As, 23.57. Found: 23.86, 23.40.

The Ethyl Ester.—The ethyl ester of 3,4-dicarboxyphenylarsonic acid was prepared by refluxing the free acid with absolute ethyl alcohol for fourteen hours. On evaporation of the alcohol and drying in a vacuum oven at 80°, a yellow, sticky material remained which solidified on cooling. The ethyl ester of 3,4-dicarboxyphenylarsonic acid readily absorbs moisture and is soluble in water, methyl alcohol, ether and carbon tetrachloride.

Anal. Subs., 0.2703, 0.1739: 32.20, 20.75 cc. of 0.04845 *N* iodine solution. Calcd. for $C_{12}H_{13}O_7As$: As, 21.66. Found: 21.64, 21.68.

The Neutral Trisodium Salt.—The neutral trisodium salt of 3,4-dicarboxyphenylarsonic acid is a cream-colored solid very soluble in water, and insoluble in methyl alcohol, ether, benzene and chloroform.

Anal. Subs., 0.1346, 0.1122: 14.50, 12.30 cc. of 0.05312, 0.04986 *N* iodine solution. Calcd. for $C_8H_4O_7AsNa_3$: As, 21.05. Found: 21.45, 20.50.

The Tetrasodium Salt.—The tetrasodium salt of 3,4-dicarboxyphenylarsonic acid is a cream-colored solid very soluble in water and insoluble in methyl alcohol, ether, benzene and chloroform.

Anal. Subs., 0.0947, 0.1050: 9.8, 11.07 cc. of 0.04986 *N* iodine solution. Calcd. for $C_8H_3O_7AsNa_4$: As, 19.83. Found: 19.35, 19.72.

The Silver Salt.—The silver salt of 3,4-dicarboxyphenylarsonic acid is a white solid, insoluble in water, methyl alcohol, ether, benzene and chloroform.

Anal. Subs., 0.1272, 0.7251: 0.1001, 0.5671 g. of AgCl. Calcd. for $C_8H_3O_7AsAg_4$: Ag, 60.14. Found: 59.22, 58.86.

Summary

1. 3,4-Dicarboxyphenylarsonic acid has been prepared and its properties have been studied.

2. The anhydride, methyl ester, ethyl ester, trisodium salt, tetrasodium salt and the silver salt of 3,4-dicarboxyphenylarsonic acid have been prepared and their properties determined.

3. Derivatives of the anhydride are being studied.

OPTICAL ROTATION AND ATOMIC DIMENSION. VII. THE HALOGENO-HEPTA-ACETYL DERIVATIVES OF GENTIOBIOSE

By D. H. BRAUNS

RECEIVED SEPTEMBER 6, 1927

PUBLISHED DECEMBER 10, 1927

In the sixth article of this series, it was reported that the specific rotational values of the halogen hepta-acetyl derivatives of two bioses (cellobiose and glucosido-mannose) deviate from the regular relationship observed for the monose sugars and further that an agreement is obtained by excluding the values for the fluoro derivatives. This conclusion was also supported by the values for the chloro, bromo and iodo compounds of lactose measured by Hudson and Kunz¹ (the fluoro derivative being amorphous). These three bioses possess the same type of carbon attachment in their structural formulas, the two constituent monoses being attached to each other by an oxygen atom in the same way (according to the latest views the *fourth* carbon of the one monose to the *first* carbon of the second).

The preparation and the rotational values of the pure crystalline fluoro, chloro, bromo and iodo derivatives of acetylated gentiobiose are described in the present article. The synthesis of this biose by Helferich and co-workers² leaves hardly any doubt that in gentiobiose the *sixth* carbon of the one monose is attached through an oxygen atom to the *first* carbon atom of the other. Gentiobiose is, therefore, a representative of the so-called "straight chain" bioses, the others being representative of the branched chain bioses. The data for the specific rotations compiled in Tables I and II show that both kinds of bioses behave in the same

manner: by including the fluoro derivatives a deviation from the regular relationship of the monose sugars is observed, whereas by excluding the fluoro derivatives the *same ratio 17:21* is found again. The ratio 41:17:21 obtained from the specific rotational values of the halogen derivatives of the monose sugars agrees closely with the ratio derived from the calculations of de Boer and van Arkel³ for distances of the carbon atom to the halogen atoms in carbon compounds. This ratio is 41:17:22.6.

The interpretation stated and discussed in the preceding article⁴ holds also for the gentiobiose derivatives. Besides α -fluoro-, chloro-, bromo- and iodo-hepta-acetylgentiobiose impure β compounds of chloro- and iodo-hepta-acetylgentiobiose can be obtained. Starting from β -octa-acetylgentiobiose in acetic anhydride solution, which is saturated at -15° with hydrochloric acid, the β -chloro derivative is first formed and subsequently converted to the α -chloro compound. On account of this conversion, which is much enhanced by zinc chloride (see experimental part for further information) and which even takes place in a pure chloro-form solution, a mixture in which the β compound predominated is not easily obtained.⁵

³ De Boer and van Arkel, *Z. Physik*, **41**, 27 (1927). Also their value for the distance carbon-hydrogen agrees with the respective rotational differences of the salicin derivatives reported in Part V.

⁴ That as a result of the complicated structure of the molecule other atoms are situated in the neighborhood of the halogen atoms, whereby these halogen atoms are selectively influenced.

⁵ The observed facts may be studied further for the purpose of obtaining more detailed information on the mechanism of substitution. An interesting treatment of this subject is given by Hückel ["Konfigurationsänderungen bei Substitutionsreaktionen," *Z. angew. Chem.*, **39**, 842 (1926)]. The positions of α - and β -hydroxyl, acetyl and halogen in the molecule having been established and correlated, and the nomenclature having therefore been put on a sound basis [Hudson, *THIS JOURNAL*, **46**, 463 (1924); Böseken, *Ber.*, **46**, 2612 (1913); Pictet, *Helv. Chim. Act.*, **3**, 649 (1920)], the conclusion may be reached that the *Walden inversion* from β -octa-acetyl gentiobiose to

Experimental Part

General Remarks.—For all determinations of the specific rotation U. S. P. chloroform or purified chloroform was used. The volume of the solution was made up in the same flask to 24.9767 cc. at 20°, which must be multiplied by the factor 4.0038 to obtain 100 cc. The reading was made in the same 4dm. tube at 20° and is given in circular degrees.

β -Octa-acetylgentiobiose.—The preparation by Hudson and Johnson⁶ was improved, yielding a method similar to the method of Haworth and Wylam.⁷ After the method had been tested with small quantities it was found that 4 kg. of powdered gentian root could be worked up at one time. The weevils that infest the root and powder may in some cases reduce the yield to *nil*. A genuine powder yielded originally about 3% of pure octa-acetylgentiobiose, of which 1 kg. was prepared. The remaining powder was kept in tin containers. After one year only about 0.5% yield could be obtained from this powder, and a few months later none was obtained.

Four kilograms of powdered gentian root was mixed with 35 liters of water in a 16-gallon crock; 8 small cakes of bakers' yeast was added and the mixture was allowed to ferment to completion, which required two days, an additional 8 cakes of yeast having been added on the morning of the second day. The mixture was stirred occasionally with a paddle. Lead subacetate solution (1600 cc. of specific gravity 1.25) was added and the mixture was well stirred and filtered on large Büchner funnels and washed with a few liters of water. The filtrate was treated with hydrogen sulfide until all of the lead was precipitated. The excess hydrogen sulfide was blown out with a current of air. The liquid was then filtered on Büchner filters containing a layer of hot decolorizing carbon (heated in a pan with boiling water). The almost colorless filtrate was evaporated in a large distilling apparatus in a vacuum to a sirup of high density, the maximum temperature of the outside bath being 65°. When the gentian powder has undergone deterioration the filtrate is more acid and should be neutralized with sodium bicarbonate.

The sirup was digested under a reflux condenser on a steam-bath with 1200 cc. of absolute methyl alcohol with frequent, vigorous shaking. The mixture was then cooled rapidly to 20° and filtered on a large suction filter. The filtrate was concentrated at low temperature, the thick sirup being poured into two tared 6-liter flasks. One-fourth of its weight of dry sodium acetate and four times its weight of acetic anhydride were added to the sirup and the mixture was slowly heated on the steam-bath with vigorous shaking. As soon as the reaction started and the mixture boiled, it was quickly cooled in ice water to prevent foaming. When the reaction had quieted down the solution was boiled for five minutes and the contents of each flask was poured with constant stirring into about 8 liters of water. At first a dark, sticky reaction product formed which was separated by decantation and allowed to solidify under fresh water. A purer product gradually separated from the decanted solution on standing for a few days. The crude octa-acetate was recrystallized first from 50% alcohol and then from absolute methyl alcohol (with the aid of decolorizing carbon) until a pure product was obtained.

α -chloro-hepta-acetyl gentiobiose proceeds at least in two definite steps. Preliminary experiments showed that α -octa-acetylgentiobiose and β -penta-acetylglucose seem to follow the same procedure in this reaction. Schlubach [*Ber.*, 59, 840 (1926)] and Brigl and Keppler [*Ber.*, 59, 1588 (1926)] have already prepared β -chloro-acetyl glucose and similar β derivatives by other methods.

⁶ Hudson and Johnson, *THIS JOURNAL*, 39, 1274 (1917).

⁷ Haworth and Wylam, *J. Chem. Soc.*, 123, 3122 (1923).

α -Fluoro-hepta-acetylgentiobiose was prepared from **β -octa-acetylgentiobiose** in the manner previously described.⁸ It is important to finish the distillation as quickly as possible (in twenty minutes instead of half an hour). The sirup was crystallized by stirring with some methyl alcohol, the yield of impure crystals being 7 g. from 15 g. of **β -octa-acetate**. It was recrystallized several times by dissolving in boiling methyl alcohol with addition of decolorizing carbon, filtering through hardened paper with the aid of a hot-water funnel and allowing the filtrate to cool gradually. The pure product crystallizes in small needles and is stable, colorless and tasteless. It is fairly soluble in benzene, slightly soluble in petroleum ether, water and cold methyl alcohol; m. p. 168–169° (Helferich, Bäuerlein and Wiegand, 162–163°).⁹ The determination of the specific rotation in chloroform gave the following result.

Rotation. Third recrystallization. Subs., 0.6358: $\alpha = +4.325^\circ$; $[\alpha]_D^{20} = +42.48^\circ$. Fourth recrystallization. Subs., 0.6015: $\alpha = +4.142^\circ$; $[\alpha]_D^{20} = +42.99^\circ$. Fifth recrystallization. Subs., 0.6303: $\alpha = +4.384^\circ$; $[\alpha]_D^{20} = +43.43^\circ$. Sixth recrystallization. Subs., 0.6251: $\alpha = +4.384^\circ$; $[\alpha]_D^{20} = +43.79^\circ$. Seventh recrystallization. Subs., 0.6142: $\alpha = +4.280^\circ$; $[\alpha]_D^{20} = +43.51^\circ$.

Therefore, $+43.80^\circ$ is taken as the specific rotation of the pure substance, since another preparation gave as the final rotation $+43.85^\circ$.

Found: C, 48.76; H, 5.44; F, 2.81; 62.10 cc. of 0.1 *N* NaOH ; mol. wt., 554, 651.

α -Chloro-hepta-acetylgentiobiose.—Many experiments were made before suitable conditions were found to obtain this derivative. The use of zinc chloride in the reaction is especially essential. Besides the two reactions mentioned in the introduction, another reaction is noticeable in which probably a dichloro compound is formed. This dichloro compound is not easily separated from the monochloro compound, the best means found being recrystallization from methyl alcohol. In order to prevent its formation as far as possible, it is necessary to follow exactly the description of the preparation as to time and temperature.

A tube 25 cm. long and 5 cm. in diameter was closed at one end and sealed at the other end to a tube 1 cm. in diameter and 7 cm. long. This tube was used as a container for saturating with hydrochloric acid a suspension of 10 g. of dry **β -octa-acetylgentiobiose** in a solution of 3 g. of zinc chloride in 100 cc. of pure acetic anhydride. The hydrochloric acid was washed by passage through sulfuric acid and then through acetic anhydride, after which it was passed through a glass spiral tube provided with a bulb pocket at the lower end for condensing acetic anhydride vapor (by cooling the spiral in an ice-and-salt mixture). A slow stream of hydrogen chloride thus prepared was passed through the described solution of gentiobiose octa-acetate, the container being cooled in ice and salt. Saturation was completed in about three hours. The tube was sealed and kept for twenty-two hours at 3 to 5°. It was opened after cooling in ice and salt. The solution, after being concentrated by means of a current of dry air under a bell jar for one hour, was poured into a separatory funnel containing ice water, crushed ice and chloroform and was shaken out 4 times with water. The chloroform solution was dried with calcium chloride and concentrated at low temperature to a sirup which crystallized readily when stirred with ether. The crystals were separated on a suction filter. Recrystallization was first performed by adding ether to a concentrated

⁸ Brauns, *THIS JOURNAL*, 45, 834 (1923).

⁹ Ref. 2 a, p. 36.

chloroform solution. Repeated recrystallizations did not remove all impurities, as the chlorine content was always found to be too high. Good results were obtained by making a concentrated solution in hot methyl alcohol, adding some decolorizing carbon, filtering through hardened paper with the aid of a hot-water funnel and cooling the solution in ice and afterwards in ice and salt.

The crystals were separated on a suction filter and dried in a vacuum desiccator; *m. p.* 148°. The determination of the specific rotation in chloroform gave the following results.

Rotation. First recrystallization. Subs., 0.4434: $\alpha = +5.684^\circ$; $[\alpha]_D^{20} +80.04^\circ$. Second recrystallization. Subs., 0.4642: $\alpha = +5.961^\circ$; $[\alpha]_D^{20} +80.18^\circ$. Third recrystallization. Subs., 0.6431: $\alpha = +8.276^\circ$; $[\alpha]_D^{20} +80.36^\circ$. Fourth recrystallization. Subs., 0.6476: $\alpha = +8.370^\circ$; $[\alpha]_D^{20} +80.70^\circ$. Fifth recrystallization. Subs., 0.6289: $\alpha = +8.117^\circ$; $[\alpha]_D^{20} +80.59^\circ$. Sixth recrystallization. Subs., 0.6491: $\alpha = +8.370^\circ$; $[\alpha]_D^{20} +80.51^\circ$; 0.6185: $\alpha = +7.978^\circ$; $[\alpha]_D^{20} +80.54^\circ$; 0.6495: $\alpha = +8.373^\circ$; $[\alpha]_D^{20} +80.50^\circ$.

The average of the last crystallization, $+80.52^\circ$, is taken as the specific rotation of the pure substance. The pure solution crystallizes in needles and is tasteless, colorless and stable. It is readily soluble in ordinary solvents except water, petroleum ether and ether.

Anal. Subs., 0.2377: CO_2 , 0.4172; H_2O , 0.1134. Subs., 0.2477, 0.2501: AgCl , 0.0535, 0.0523. Subs., 0.5000: 310.53 cc. of 0.1 *N* NaOH ; 249.25 cc. 0.1 *N* H_2SO_4 . Subs., 1.3392, 2.5513: C_6H_6 , 100 g., Δf , 0.114°, 0.202°. Calcd. for $\text{C}_{28}\text{H}_{48}\text{O}_{17}\text{Cl}$: C, 47.65; H, 5.39; Cl, 5.41; 61.10 cc. of 0.1 *N* NaOH ; mol. wt., 655. Found: C, 47.50; H, 5.33; Cl, 5.34; 5.17; 61.28 cc. of 0.1 *N* NaOH ; mol. wt., 588, 631.

α -Bromo-hepta-acetylgentiobiose.—Thirty grams of octa-acetylgentiobiose was dissolved in 300 cc. of purified chloroform and cooled to about 0° in an ice-and-salt mixture, 75 cc. of a saturated solution of hydrogen bromide in acetic acid (also cooled to 0°) being added. The mixture was kept in a stoppered Erlenmeyer flask in ice water for one and one-half hours, then was poured into a separatory funnel containing ice water and cracked ice and shaken out 4 times with ice water. The chloroform extract was dried with calcium chloride, filtered and evaporated to a sirup at low temperature. Dry ether was added and by evaporating and stirring, the sirup was brought to crystallization. The crystals were filtered by suction and recrystallized by dissolving in a small amount of purified chloroform and gradually adding ether to the filtered solution. The first separation contained most of the impurities. The recrystallization was repeated until a constant rotation was obtained; *m. p.* 144°. The solutions for the rotations were prepared with purified chloroform.

Rotation. First recrystallization. Subs., 0.6049: $\alpha = +9.770^\circ$; $[\alpha]_D^{20} +100.85^\circ$. Second recrystallization. Subs., 0.6061: $\alpha = +9.808^\circ$; $[\alpha]_D^{20} +101.04^\circ$. Third recrystallization. Subs., 0.6113: $\alpha = +9.895^\circ$; $[\alpha]_D^{20} +101.06^\circ$; 0.6343: $\alpha = +10.269^\circ$; $[\alpha]_D^{20} +101.08^\circ$. Fourth recrystallization. Subs., 0.6301: $\alpha = +10.206^\circ$; $[\alpha]_D^{20} +101.14^\circ$; 0.6383: $\alpha = +10.328^\circ$; $[\alpha]_D^{20} +101.03^\circ$.

Therefore, $+101.08^\circ$ is taken as the specific rotation of the pure substance. It is not stable but can be kept in a desiccator over sodium hydroxide in an ice box. It crystallizes in colorless needles and is tasteless. It is soluble in ordinary solvents except water, petroleum ether and ether. Zemplén,¹⁰ who first described crystalline bromo-hepta-acetylgentiobiose, found *m. p.* 132–133.5° and $[\alpha]_D^{19} +111.8^\circ$. Probably Zemplén's preparation contained some dibromo derivative, as is also indicated by the bromine determination (found 12.06% Br).

¹⁰ Zemplén, *Ber.*, 57, 702 (1924).

Anal. Subs., 0.2757: CO_2 , 0.4530; H_2O , 0.1207. Subs., 0.3146, 0.3126: AgBr , 0.0864, 0.0859. Subs., 0.5000: 306.44 cc. of 0.1 *N* NaOH ; 249.25 cc. of 0.1 *N* H_2SO_4 . Subs., 1.0431, 1.7316: C_6H_6 , 100 g., Δ_f , 0.082°, 0.135°. Calcd. for $\text{C}_{28}\text{H}_{40}\text{O}_{17}\text{Br}$: C, 44.62; H, 5.05; Br, 11.43; 57.20 cc. of 0.1 *N* NaOH ; mol. wt., 699. Found: C, 44.81; H, 4.90; Br, 11.68, 11.69; 57.19 cc. of 0.1 *N* NaOH ; mol. wt., 636, 641.

α -Iodo-hepta-acetylgentiobiose.—Five grams of gentiobiose octa-acetate was dissolved in 10 cc. of methylene chloride in a Pyrex test-tube and a minute amount of zinc iodide was added. The solution was cooled in an ice-and-salt bath. Hydriodic acid (which was first passed through asbestos mixed with red phosphorus, then through a calcium chloride tower, then through a phosphorus pentoxide tube and finally through a spiral tube cooled in ice and salt) was passed in a slow stream through the gentiobiose octa-acetate solution for ten to fifteen minutes. The solution was poured into a dish and evaporated with a dry current of air under a bell jar. The residue was stirred with petroleum ether, the solution was poured off and this process repeated until crystallization started. The crystals were mixed with dry ether, filtered by suction and washed with small amounts of ether. Recrystallization was produced by dissolving in a small amount of purified chloroform and gradually adding ether. The first separation contains most of the colored impurities. The recrystallization was repeated until a constant rotating substance was obtained.

The pure compound decomposes at 134° forming a dark brown liquid. The determination of the specific rotation in chloroform gave the following results.

Rotation. First recrystallization. Subs., 0.4524: $\alpha = +9.080^\circ$; $[\alpha]_D^{20} +125.32^\circ$. Second recrystallization. Subs., 0.5555: $\alpha = +11.212^\circ$; $[\alpha]_D^{20} +126.02^\circ$. Third recrystallization. Subs., 0.5270: $\alpha = +10.640^\circ$; $[\alpha]_D^{20} +126.06^\circ$.

Therefore, +126.10° is taken as the specific rotation of the pure substance. The pure compound crystallizes in long needles and is tasteless and colorless. It is not stable but can be kept in a pure condition for many months in a desiccator over sodium hydroxide in an ice box. It is readily soluble in the ordinary solvents except water, petroleum ether and ether.

Anal. Subs., 0.2477: CO_2 , 0.3788; H_2O , 0.1092. Subs., 0.2157: AgI , 0.0688. Calcd. for $\text{C}_{28}\text{H}_{40}\text{H}_{17}\text{I}$: C, 41.82; H, 4.73; I, 17.02. Found: 41.71; H, 4.94; I, 17.24.

α - and β -Chloro-hepta-acetylgentiobiose.—Two grams of β -octa-acetylgentiobiose was dissolved in 20 cc. of acetic anhydride and saturated in an ice-and-salt bath with hydrochloric acid in the manner described for the preparation of the α -chloro derivative, except that no zinc chloride was added. The tube was sealed and kept for three hours at 15°; then it was cooled in an ice-and-salt bath and opened, the solution being poured into an evaporating dish and evaporated for half an hour with a current of dry air. The remaining solution was diluted with purified chloroform and poured into a separatory funnel containing ice water and cracked ice. The chloroform solution was quickly shaken out 3 times with ice water, dried with calcium chloride and evaporated with a rapid dry current of air to a sirup which was stirred with ether and soon solidified to a crystalline mass which was then thinned with ether, the crystals were filtered on a suction filter and dried in a vacuum desiccator. The determination of the specific rotation of 0.4651 g. of substance in purified chloroform gave the results shown in Table III. The tabulation shows a change from a negative to a positive rotation. A Carius determination gave the following result. Subs., 0.2458: AgCl , 0.0597; calcd. for a monochloro-derivative, $\text{C}_{28}\text{H}_{40}\text{O}_{17}\text{Cl}$, 5.42% Cl. Found: 6.0% Cl. A small amount of dichloro-derivative is therefore present in the reaction product. Calculated according to Hudson's method [Hudson, THIS JOURNAL, 46, 462, 476, 2600 (1924)] taking the specific rotation of α -chloro-hepta-acetylgentiobiose (mol. wt. 655, $[\alpha]_D = +80.5$) and Hudson's coefficient $B_{\text{gentiobiose}} = +15,900$ as a basis, the specific rotation of

TABLE III
 SPECIFIC ROTATION

Time after solution	α	$[\alpha]_D^{20}$
10 min.	-0.520	- 7.0°
30 min.	-0.450	- 6.0
1 hr.	-0.398	- 5.3
2 hr.	-0.312	- 4.2
5 hr.	-0.03	- 0.5
45 hr.	+1.473	+19.8

β -chloro-hepta-acetylgentiobiose should be $(B_{\text{gentiobiose}} - A_1)/655 = 15,900 - [(80.5(655) - 15,900)]/655 = -32$, from which it is concluded that at least three-fourths of the reaction product is β -chloro-hepta-acetylgentiobiose. This indicates that the β -chloro derivative is formed first and is then converted into the α -chloro derivative. A preliminary experiment was made for the purpose of converting the impure β -chloro-hepta-acetylgentiobiose with silver carbonate and methyl alcohol into the α -methyl derivative. A colorless sirup which could not be brought to crystallization was obtained.

α - and β -Iodo-hepta-acetylgentiobiose.—Eight grams of β -gentiobiose octa-acetate was dissolved in 16 cc. of methylene chloride and the solution was saturated in an ice-and-salt bath with hydriodic acid in the manner described for the preparation of the α -iodo derivative, no zinc chloride being added. The light brown solution was quickly evaporated in a current of dry air. On stirring with petroleum ether the residue solidified to a mass of needles which was dissolved in a small quantity of purified chloroform. Ether was added until crystallization started. The crystals which separated were washed with ether on a suction filter. They were sticky and contained iodine. Probably the recrystallization had partly converted the α - into the β -iodo derivative. The determination of the specific rotation of 0.1674 g. of substance in purified chloroform gave the following result.

Time after solution	α	$[\alpha]_D^{20}$
6 min.	-0.381	-14.2°
10 min.	-0.268	-10.3
20 min.	-0.208	- 7.7
30 min.	-0.173	- 6.5
1 hr.	-0.035	- 1.3
24 hr.	+2.045	+76.3
48 hr.	+2.530	+94.4
72 hr.	+2.634	+98.3

After twenty-four hours the solution gradually turned brown. Calculated according to Hudson's method, taking the specific rotation of α -iodo-hepta-acetylgentiobiose (mol. wt. 746, $[\alpha]_D = +126.1$) and Hudson's coefficient $B_{\text{gentiobiose}} = +15,900$ as a basis, the specific rotation of β -iodo-hepta-acetylgentiobiose should be $(B_{\text{gentiobiose}} - A_1)/746 = (15,900 - [(126.1)(746) - 15,900])/746 = -83$, from which it is concluded that at least 67% of the reaction product is β -iodo-hepta-acetylgentiobiose. This supports the conclusion reached in the case of the chloro derivative that in this reaction the β halogen derivative is formed first and is subsequently converted into the α -halogen derivative.

Summary

The α -fluoro-, chloro-, bromo- and iodo-hepta-acetyl derivatives of gentiobiose have been prepared and described. A comparison of the

specific rotational values of these halogen derivatives shows that these straight chain biose derivatives behave the same as the branched chain biose derivatives investigated in the previous article, as agreement with the regular relationship observed for the corresponding derivatives of the monose sugars is obtained only by excluding the values for the fluoro derivatives.

Besides the pure α -halogen derivatives of gentiobiose, impure β -chloro and iodo compounds were obtained.

The Walden inversion from β -octa-acetylgentiobiose to α -chloro- and iodo-hepta-acetyl gentiobiose by the action of hydrochloric and hydriodic acids proceeds at least in *two* definite steps, β -chloro- or iodo-hepta-acetyl-gentiobiose being intermediately formed.

ACYL *ISO*-UREAS

BY S. BASTERFIELD AND MYRON S. WHELEN

RECEIVED SEPTEMBER 13, 1927

PUBLISHED DECEMBER 10, 1927

The chemistry of methyl- and ethyl-*iso*-ureas (oxygen ethers of urea) and their acyl derivatives has been studied mainly by Stieglitz and his collaborators,^{1,2,3} and by Wheeler and Johnson.⁴

More recently E. A. Werner⁵ has made important contributions to this field of study.

In an investigation of the pharmacological properties of acyl *iso*-ureas, it was observed by one of us⁶ that carbethoxy-ethyl-*iso*-urea was mildly depressing to the central nervous system and caused a large and rapid fall of body temperature. Later it was shown that dicarbethoxy-ethyl-*iso*-urea possessed similar properties but in greater degree⁷ while carbo-*n*-butoxy-ethyl-*iso*-urea had only slight physiological action.⁸

In view of these results, the preparation of a greater variety of acyl *iso*-ureas was undertaken. Since only methyl- and ethyl-*iso*-ureas and their derivatives have been prepared up to the present, a study of the possibility of obtaining propyl-, butyl-, phenyl-, benzyl- and phenylethyl-*iso*-ureas was commenced, preliminary results of which are reported in this

⁸ Basterfield, Woods and Wright, *ibid.*, **48**, 2371 (1926).

paper. A considerable number of new acyl derivatives of methyl- and ethyl-*iso*-ureas are also described.

The *iso*-urea hydrochlorides were prepared by the method of Stieglitz and Bruce² which consists in the addition of anhydrous alcohols to cyanamide in the presence of dry hydrogen chloride. The acyl derivatives were obtained by treating the *iso*-urea hydrochlorides in ether suspension with the required amount of acyl halide, the whole being shaken with concentrated aqueous potassium or sodium hydroxide. Details of purification are given in the experimental part of the paper.

The addition of *n*-propyl and *n*-butyl alcohols to cyanamide was found to take place much less readily than that of methyl and ethyl alcohols. The hydrochlorides of *n*-propyl and *n*-butyl-*iso*-ureas were obtained but could not be satisfactorily purified. A fairly pure sample of *n*-propyl-*iso*-urea was obtained as an oil and acyl derivatives of both *iso*-ureas were prepared in pure condition. Work on benzyl- and phenylethyl-*iso*-ureas is in progress.

Experimental Part

I. Derivatives of Methyl-*iso*-urea

Data on yields, melting points and analyses are given in Table I.

Phenylacetylmethyl-*iso*-urea, $C_6H_5CH_2CONHC(OCH_3)NH$.—This was obtained as an oil which was decomposed somewhat by distillation under reduced pressure. The oil was dissolved in anhydrous ether and the solution treated with dry hydrogen chloride. The precipitated hydrochloride was analyzed for chlorine by titration with a standard solution of silver nitrate.

Chloro-acetylmethyl-*iso*-urea, $CH_2ClCONHC(OCH_3)NH$.—This was obtained as an oil which was converted into the hydrochloride and analyzed for displaceable chlorine. The salt was purified by recrystallization from ethyl alcohol.

Carbo-*n*-propoxymethyl-*iso*-urea, $C_3H_7OCONHC(OCH_3)NH$.—This compound, prepared from methyl-*iso*-urea and *n*-propyl chlorocarbonate, was obtained as an oil which rapidly solidified in a desiccator. It was recrystallized from ligroin.

An attempt to prepare the hydrochloride yielded only *n*-propyl-allophanic ester; m. p. 167°. The salt is evidently unstable and loses methyl chloride even at room temperature. The allophanic ester was further identified by analysis.

II. Derivatives of Ethyl-*iso*-urea.

See Table II for further data on these derivatives.

Phenylacetylethyl-*iso*-urea, C₆H₅CH₂CONHC(OC₂H₅)NH.—This compound was an oil which was purified by distillation under reduced pressure.

***p*-Nitrobenzoylethyl-*iso*-urea**, NO₂C₆H₄CONHC(OC₂H₅)NH.—Slightly yellow crystals from ether.

α -Bromopropionylethyl-*iso*-urea, CH₃CHBrCONHC(OC₂H₅)NH.—This was obtained as an oil which was decomposed by distillation under reduced pressure. After standing for several months, the oil had deposited a quantity of white crystals. The solid was insoluble in ether but was soluble in warm alcohol. It was at first thought that the substance might be 2-ethoxy-4-methylhydantoin but analysis showed the required nitrogen content for α -bromopropionylethyl-*iso*-urea. The insolubility in ether, however, suggests that the solid is a polymer, the original oil being the unpolymerized compound.

Chloro-acetylethyl-*iso*-urea, CH₂ClCONHC(OC₂H₅)NH.—The base, a viscid oil, was converted into the hydrochloride.

Carbo-*n*-propoxy-ethyl-*iso*-urea, C₃H₇OCONHC(OC₂H₅)NH.—The clear oil first obtained solidified in a freezing mixture. Analysis showed it to be quite pure.

Carbo-*iso*-amoxy-ethyl-*iso*-urea, C₆H₁₁OCONHC(OC₂H₅)NH.—The oil first obtained was found to be quite pure.

Benzenesulfonylethyl-*iso*-urea, C₆H₅SO₂NHC(OC₂H₅)NH.—This compound was obtained as a solid, crystallizing from alcohol in large, rhombic prisms. The first sample melted at 86°. After standing for a few weeks the crystals were yellowish and moist. The substance was recrystallized, m. p. 76°. In the course of a few days the melting point had risen to 101°. Repeated recrystallizations gave fractions with different melting points, the highest being 110°. All fractions melted at 101° after standing for a few days. The material melting at 101° had exactly the same nitrogen content as the original substance. The phenomenon is probably due to di- or polymorphism.

III. *n*-Propyl-*iso*-urea, NH₂C(OC₃H₇)NH

Five g. of cyanamide was dissolved in 250 cc. of *n*-propyl alcohol and the calculated amount of dry hydrogen chloride passed into the solution cooled in ice. After standing

for three days, the liquid gave no reaction for cyanamide. The alcohol was removed by distillation under reduced pressure. A viscous, semi-solid mass was left which became almost completely solid after prolonged standing in a vacuum desiccator. Recrystallization from alcohol even at low temperatures was unsuccessful. Concentrated alcoholic solutions poured into ether or ligroin at -20° gave only semi-solid products. The nearly solid mass obtained after long standing in a desiccator was very hygroscopic and became sirupy in a few minutes after exposure to the air.

From a sample of this impure hydrochloride, the free base was liberated by treatment with a large excess of powdered potassium hydroxide in ether suspension. The ether solution on evaporation yielded a slightly yellow oil of very obnoxious and penetrating odor. It was dried in a vacuum and analyzed without further purification.

Anal. Calcd. for $C_6H_{10}N_2O$: N, 27.27. Found: 27.27, 27.40.

Benzoyl-*n*-propyl-*iso*-urea, $C_6H_5CONHC(OC_3H_7)NH$.—The impure propyl-*iso*-urea hydrochloride from 5 g. of cyanamide was converted into the benzoyl derivative by the usual method. The product was an oil which was appreciably contaminated with propyl alcohol. It was taken up in ether and treated with dry hydrogen chloride. The precipitated hydrochloride was recrystallized from alcohol. It melted at 97° with evolution of *n*-propyl chloride. The yield was good but a portion was accidentally lost and the exact yield was not determined.

Anal. Calcd. for $C_{11}H_{14}N_2O_2 \cdot HCl$: Cl, 14.73. Found: 14.92, 14.85.

IV. *n*-Butyl-*iso*-urea Hydrochloride, $NH_2C(OC_4H_9)NH \cdot HCl$

When hydrogen chloride was passed into a butyl alcohol solution of cyanamide (5 g. in 250 cc.) a fine, white, crystalline precipitate was rapidly formed. This was found to be the dihydrochloride of cyanamide, the latter acting in the di-imide form as a diacid base. To minimize the separation of this compound, 200–300 cc. more alcohol was used and an excess of hydrogen chloride carefully avoided. The reaction mixture stood for a month before the reaction for cyanamide had disappeared. The liquid had meanwhile assumed a reddish-brown color. When the alcohol had been removed by distillation in a vacuum, a red, semi-solid mass was obtained. Attempts to purify this were fruitless, but the presence of *n*-butyl-*iso*-urea was proved by the preparation from the impure product of the *p*-nitrobenzoyl derivative.

***p*-Nitrobenzoyl-*n*-butyl-*iso*-urea**, $NO_2C_6H_4CONHC(OC_4H_9)NH$.—The impure butyl-*iso*-urea hydrochloride was suspended in ether and treated with the required quantity of *p*-nitrobenzoyl chloride in the presence of aqueous potassium hydroxide. The ether phase yielded on evaporation a pale yellow solid. Recrystallized from ether it melted at 118° .

Anal. Calcd. for $C_{12}H_{16}N_2O_4$: N, 15.84. Found: 15.76, 15.80.

Summary

1. A number of new acyl derivatives of methyl- and ethyl-*iso*-ureas have been prepared.

2. The addition of *n*-propyl and *n*-butyl alcohols to cyanamide has been studied and the impure hydrochlorides of *n*-propyl and *n*-butyl-*iso*-ureas have been obtained. *n*-Propyl-*iso*-urea has been obtained as an oil sufficiently pure for analysis, and its benzoyl derivative prepared and analyzed as the hydrochloride. *n*-Butyl-*iso*-urea has been characterized by the preparation and analysis of its *p*-nitrobenzoyl derivative.

AN APPARATUS FOR DETERMINING BOTH THE QUANTITY OF GAS EVOLVED AND THE AMOUNT OF REAGENT CONSUMED IN REACTIONS WITH METHYL MAGNESIUM IODIDE

BY E. P. KOHLER, J. F. STONE, JR., AND R. C. FUSON

RECEIVED SEPTEMBER 20, 1927

PUBLISHED DECEMBER 10, 1927

Methyl magnesium iodide has long been used as a valuable and, in most cases, a reliable reagent for ascertaining the number of active hydrogen atoms in an organic compound.¹ This is accomplished by measuring the methane evolved when a known weight of substance reacts with excess of the reagent in an apparatus devised by Zerewitinoff² which admirably serves this purpose.

A number of Grignard reactions—notably those involving oxidation and reduction—are accompanied by evolution of gas which is not due to the presence of active hydrogen. In order to follow the course of these reactions it is necessary to know the quantity of reagent consumed as well as the amount of gas evolved. The apparatus herein described was designed for the study of such reactions. Once at hand it has been employed for getting information on the structure of a great variety of organic compounds, and has proved so useful that it seemed advisable to make it available to others with similar problems.

The Apparatus³

The apparatus is shown in Fig. 1. *A* is a 500cc. cylindrical reservoir used for storing the solution of the reagent. It is attached to the apparatus by a ground-glass joint and contains a glass tube *a* which connects it to the buret *B* through the by-pass in the special stopcock *C*. At the top the reservoir is connected by a glass tube *b* to the stopcock *c*. Stopcocks *c* and *d* are 120° three-way stopcocks whose use will be described below, *B* is a 10cc. buret graduated in twentieths of a cc. *D* is a 5cc. buret graduated in tenths of a cc. The special stopcock *C*⁴ carries, in addition to the by-pass, an ordinary three-way stopcock arrangement for con-

² Zerewitinoff, *Ber.*, 40, 2026 (1907).

³ An apparatus essentially like this was first designed by J. F. Stone, Jr., for the investigation of nitro compounds. After several years' experience it was redesigned and simplified by R. C. Fuson. The quantitative results published herewith were obtained with the new apparatus.

⁴ Instead of this special stopcock the original apparatus had a rubber stopper with four holes through which passed inlet and outlet tubes, and the ends of the two burets. In that form the apparatus can be constructed from materials generally available. It gives satisfactory results with substances that react rapidly but when long heating is necessary the rubber stopper consumes reagent and evolves gas.

necting *B* and *D* in turn with the reaction chamber *E*. The reaction chamber consists of a 40cc. flat-bottomed flask attached by a ground-

Fig. 1.

glass joint to the shoulder *i*. In the present work four such flasks were made, each being ground to fit *i*; this was done to allow for breakage and to avoid delays due to cleaning. *E* is immersed in a bath *F* which serves as a temperature regulator. From the shoulder *i* a tube for gas leads to a U-tube *G* packed with glass beads and phosphorus pentoxide. In order that its temperature may not undergo any sudden change, *G* is kept in a beaker of water at room temperature. The U-tube is connected to a gas buret *H*. This buret is an ordinary 50cc. gas buret graduated in tenths of a cc. and equipped with a special capillary stopcock *I* which serves not only to connect the buret in turn with the capillary arms *m* and *n* but has in addition a special vent *l* which serves to connect *m* with the air. The buret is filled with mercury and has at its base a 20cc. overflow bulb which is connected with a leveling bulb. It is enclosed in a Victor Meyer jacket filled with water and carrying a thermometer. The tube *g* serves ordinarily to connect to the air through *d* but during the process of filling it is attached to the system *J-K-L* which will be described later. *A*, *B*, *C*, *D* and *E* are made of Pyrex glass.

The Preparation of the Reagent

The Grignard reagent used is a solution of methyl magnesium iodide in *iso*-amyl ether containing approximately 0.8 mole of active reagent per liter. In preparing it pure dry materials are used and the operations are carried out as far as possible in an atmosphere of pure dry nitrogen.⁵

The following procedure is used. One hundred g. of *iso*-amyl ether and 8 g. of magnesium are placed in a 500cc. round-bottom wetted-neck flask equipped with a stirrer, dropping funnel and a tube for introducing dry nitrogen. Forty g. of methyl iodide is dropped in during the course of an hour, the reaction flask being continually swept by a current of dry nitrogen and maintained at a temperature between 0 and 20°. The reagent is then diluted by the addition of 175 g. of *iso*-amyl ether. The flask is immersed in an oil-bath and heated for one and one-half hours at about 100°. After being allowed to stand overnight it is transferred to the apparatus.

Filling the Apparatus

For introducing the reagent solution into the reservoir *A* a special apparatus is attached to tube *g* as shown in Fig. 1. The flask *J* is the original vessel in which the

⁵ PURIFICATION OF THE NITROGEN.—Pure dry nitrogen was obtained by passing tank nitrogen successively through Fieser's solution, saturated lead acetate solution, concd. sulfuric acid and phosphorus pentoxide. The purification train consisted of the following ten parts connected in the order named: mercury trap (for pressure regulation), safety bottle, two wash bottles containing Fieser's solution,⁶ safety bottle, wash bottle containing lead acetate solution, safety bottle, two sulfuric acid drying towers, a Liebig duck partially filled with phosphorus pentoxide.

⁶ Fieser, THIS JOURNAL, 46, 2639 (1924).

reagent was made and is transferred to the position shown in Fig. 1 in such a way as to admit as little air as possible. *K* is a glass tube packed with glass wool for filtering the reagent. It leads into the settling tower *L* which carries the tube *g* leading to the apparatus.

Before *J* is placed in position the entire apparatus is cleaned, dried and filled with dry nitrogen. This is accomplished by washing successively with water, alcohol, ether and absolute ether. A rapid current of dry nitrogen is then passed through the apparatus for several hours. For this purpose *J* is replaced by an empty flask *J'* of the same size and stopcocks *c*, *d*, *C* and *o* are turned so that the nitrogen passes through the various parts of the apparatus in the following order: *J-K-L-g-B-a-A-b-h*. Stopcock *o* is turned so as to allow the nitrogen to escape into the air. In order to sweep the tube *e*, stopcocks *c* and *d* are turned so as to lead the gas directly from *g* to *h* through *e*. From time to time *o* is closed and *h* is opened so as to allow the gas to escape through the shoulder, the flask *E* being removed.

When the sweeping is complete *o*, *c*, *d* and *h* are closed and *J'* is replaced by *J* (containing the reagent). The reagent is then filtered through *K* into *L* by allowing nitrogen under suitable pressure to flow in at *p* and by opening *r* to the air. The reagent is allowed to settle in *L* and when clear or nearly so it is driven into the reservoir *A* by closing *r*, opening *o* to the air and turning *c* and *d* so that the solution flows from *g* into *B* and thence through the by-pass in *C* to the reservoir.

After the solution has been driven into *A*, stopcocks *c*, *d* and *C* are closed. *J*, *K* and *L* are then removed and *g* and *B* are cleaned by blowing successively dilute acid, water, alcohol and ether through the circuit *g-B-s* established by properly adjusting *d* and *C*. This circuit is then swept with dry nitrogen and the apparatus is ready for use.

Standardization of the Reagent Solution

Before the reagent solution can be used it must be standardized, that is, its strength in moles of active methyl magnesium iodide per liter must be determined. This is done in the following manner.

The reaction flask *E*, after being carefully cleaned, is heated in a free flame and allowed to cool in a vacuum desiccator. It is then placed in position, the ground-glass joint being lubricated with a small amount of good stopcock grease. If the grinding has been properly done, there will be little tendency for the flask to drop off and in case this seems likely the flask can be conveniently supported by a block placed in *F*. The bath *F* is now placed in the position shown in Fig. 1 such that *E* is almost entirely immersed. *C* is then turned so as to connect *D* and *s*, *h* is opened and nitrogen admitted at *o*. With *I* turned so as to connect *II* with *m*, the mercury level in *II* is raised until it stands a little above *I* in *m*. *I* is then closed. After the nitrogen has been passed through *D* and *E* for about twenty minutes *C* is turned so as to disconnect *s* and *D* and to connect *A* and *B* through the by-pass. *I* is now turned to connect *m* with the air through the vent *l*. The small amount of mercury in *m* is driven out and the circuit *G-m* is swept for a minute or two. *I* is then turned to connect *m* with *H* and *h* is closed after enough nitrogen has been allowed to flow into *H* to bring the mercury level down to the scale of the buret.

The Grignard reagent is now introduced. Stopcocks *o* and *c* are turned so as to admit nitrogen under pressure to *A*. *B* is then connected to *g* through *d*. The pressure of the nitrogen causes the solution to flow into *B*. When sufficient solution has been introduced into *B* the by-pass is closed by giving *C* an eighth of a turn in a clockwise direction; *c* and *d* are then closed. The level of the solution in *B* is now read as accurately as possible, by estimating to hundredths of a cc. With *d* still closed *C* is given a quarter turn in a clockwise direction. This brings the stopcock just beyond the posi-

tion for connecting *B* to *s* and must be done quickly. With *h* connected to *B* through *c*, *C* is turned back (in a counter-clockwise direction) far enough to allow the solution to run into *E*. In this way the desired volume of solution is introduced into *E*, and *C* is closed by a slight clockwise turn. It is well to keep the mercury level in *H* so adjusted that the pressure in *E* is always less than atmospheric. After a minute or two the level of the solution is read as before; the difference between this and the initial reading gives the volume of solution used. A measured volume of water is now introduced from *D* by turning *C* (clockwise direction) to connect *s* and *D*. To complete the reaction *F* is replaced by a beaker of water kept boiling by a small flame and the reaction flask is heated at 100° for at least five minutes. *F* is now replaced and brought to its initial temperature. After allowing at least fifteen minutes for the system to reach equilibrium the level in *H* is again read. The difference between this and the initial reading gives the total increase in volume of the system. To get the volume of gas produced by the reaction it is necessary to subtract from this the volume of reagent solution and of water introduced. We now have the total volume of gas obtained from a measured volume of Grignard reagent; from this the strength of the latter can be calculated. This may be conveniently expressed in terms of the amount of gas obtained per cc. of solution used. Thus a solution made up according to the directions given above will have a strength of about 16 cc. of gas per cc. of solution.

After a determination has been made *E* is removed and *D* is connected to *s*. Dilute acid, water, alcohol and ether are poured successively into *D* and allowed to run out through *s*. To clean the shoulder *i* it is sufficient to spray it with suitable solvents, usually alcohol followed by ether.

Use of the Apparatus

The apparatus is designed for the purpose of determining simultaneously two things—the amount of gas given off and the amount of Grignard reagent consumed by a given reaction. These ends are accomplished by the following procedure.

A weighed sample, usually about 0.2 g. of the compound to be studied, is placed in the reaction flask *E* which is then put in place and swept with nitrogen as described above. A measured volume of the Grignard reagent solution is now introduced, care being taken to use an amount in considerable excess of that required by theory. The reaction chamber is heated until the reaction ceases and the increase in volume is measured and the volume of evolved gas calculated in the manner previously described.

To find the amount of reagent consumed it is necessary only to determine the amount remaining unchanged at the end of the reaction and to subtract this from the total amount used. This is done by introducing a measured volume of water from *D* and determining the amount of Grignard reagent remaining by the procedure used in standardizing the solution. Thus in the case of acetanilide, for example, a sample weighing 0.2648 g. (0.00196 mole) was treated with 4.01 cc. of methyl magnesium iodide solution containing 0.7143 mole per liter or 0.00286 mole of Grignard reagent. The volume of evolved gas corrected to 0° and 760 mm. was 44.2 cc. or 0.00198 mole. By treating the excess Grignard reagent with

water 20.8 cc. or 0.00093 mole of gas was obtained. The amount of reagent consumed in the reaction is, therefore, $0.00286 - 0.00093 = 0.00193$ mole.

TABLE OF RESULTS
ALL QUANTITIES ARE EXPRESSED IN THOUSANDTHS OF A MOLE

Compound	Amt. of compd.	Amt. of reagent used	Gas from reaction	Gas from excess of reagent	Amt. of reagent consumed

The first two compounds contain only active hydrogen, the following two only carbonyl groups. The values obtained with these four substances indicate that under favorable conditions the apparatus makes it possible to determine both the gas evolved and the reagent consumed with an accuracy of about 3%. Benzoin and dibenzoylmethane, representing substances which contain both hydroxyl and carbonyl groups, give almost equally good results. In all these cases the reaction, including the escape of most of the gas from the solution, is rapid—most of the gas being collected within a few minutes.

The values obtained for the succeeding two compounds show that solutions of methyl- and bromodibenzoylmethane contain little if any enolic modification. Neither of these substances gives a copper compound when its ethereal solution is shaken with copper acetate, but the former is capable of forming a sodium compound while the latter apparently is not.⁷ The sodium compound of the methyl derivative may be formed as a result of progressive enolization but the ratios between the quantities of reagent consumed and gas evolved show that in these cases addition to carbonyl is far more rapid than enolization. It seems quite as probable therefore that the sodium compound is formed by addition of sodium alcoholate and elimination of alcohol.

Acetanilide and benzyl benzamide behave exactly like benzhydrol and diphenylamine; the liberated gas is equivalent to the reagent consumed.

⁷ Wislicenus, *Ann.*, 308, 247 (1899).

The resulting magnesium compounds are, doubtless, derived from the enolic modifications.

The last four substances constitute an interesting series. Acetophenone, however carefully dried and purified, always gives at least ten times as much gas as is normally obtained from substances which contain no active hydrogen, but the total amount of reagent consumed is one mole per mole of ketone. Phenyl acetophenone and diphenyl acetophenone also yield an excessive quantity of gas, the former three times, the latter five times the normal amount. In acetomesitylene, finally, the liberated gas is equivalent to the reagent consumed: one mole per mole of ketone.

The explanation of these peculiar results is as follows. In acetomesitylene the hindrance to addition of the Grignard reagent to the di-ortho substituted carbonyl group is prohibitive; the sole products of the reaction are, therefore, methane and the magnesium derivative $(\text{CH}_3)_2\text{C}_6\text{H}_2\text{C}(\text{OMgI})\text{:CH}_2$. In acetophenone the hindrance is comparatively small but the amount of enolization is still appreciable. The substitution of phenyl for hydrogen in the methyl group of acetophenone has a twofold effect: it increases the hindrance to addition and thereby favors the formation of the metallic derivative, but it also, like the introduction of methyl into dibenzoylmethane, diminishes the tendency to enolize. The result of these opposing influences appears to be a slight diminution in the amount of enolization. The work of Grignard and others⁸ shows that in the reactions between ketones and organic magnesium compounds addition to carbonyl and enolization occur as competing processes far more frequently than we are aware. Grignard and Savard in a recent paper⁹ have described the action of 22 Grignard reagents on pulegone. They obtained the most extensive enolization when the alkyl group was secondary or tertiary and contained 3 or 4 carbon atoms. The series under consideration presents another factor of importance. Here the hindrance to addition is not due to the complexity of the magnesium compounds; it lies in the structure of the ketone and in acetomesitylene it is so great that even the simplest Grignard reagent leads to complete enolization.

Use and Limitations

The foregoing list of compounds was selected from more than a hundred that have been examined, because they are well known, present no complications, and show both the nature of the results and the accuracy attainable. It is evident that the reaction with methyl magnesium iodide can be used for learning much more about the structure and properties of an organic compound than merely the number of active hydrogen atoms it

contains. For this reason an examination of its behavior in the new apparatus has in this Laboratory become a part of the systematic investigation of almost every new compound. Such an examination consumes but little time, once the apparatus is set up and charged, because a single charge of reagent serves for more than a hundred determinations. Analyses of the reagent immediately after its preparation and after it had remained in its receptacle, exposed to light for months, show that its composition is invariable. When the apparatus is thus permanently set up it can be used with advantage in all cases in which it is possible to determine active hydrogen by the Zerewitinoff method; but since it is more complicated and more liable to injury than that devised by Zerewitinoff, and also requires more experience for its successful operation, it would not be worth while to construct it merely for the purpose of an occasional determination of active hydrogen.

We have found that while an examination of the behavior of a substance toward methyl magnesium iodide is helpful in many—perhaps most—cases, there are others in which it is quite unprofitable. In some of these the substance is not sufficiently soluble in the reagent, a difficulty which can usually be overcome by first dissolving it in some indifferent solvent. We have used dry xylene which was added to the substance after it had been weighed into the flask. The values marked with an asterisk were obtained in this manner.

A much more frequent complication is due to the formation of insoluble intermediate addition products. These rarely interfere with the determination of active hydrogen, and sometimes disappear on prolonged heating, but not infrequently make it impossible to complete the reaction.

A third difficulty arises from the occurrence of successive reactions. These appear most frequently in cases involving oxidation and reduction, and reveal themselves by a slowly diminishing evolution of gas. In these cases it is impossible to determine when the reaction is complete.

Summary

This paper contains:

1. A description of an apparatus for determining the gas evolved and the reagent consumed in reactions between methyl magnesium iodide and organic compounds.
2. A list of values showing the degree of accuracy obtainable.
3. A discussion intended to indicate the use of the apparatus.

ADDITIONS AND CORRECTIONS

1926, VOLUME 48

Reduction Equilibria of Zinc Oxide and Carbon Monoxide, by Charles G. Maier and Oliver C. Ralston.

P. 364. The authors of this paper write as follows: "Dr. Charles Rosenblum of the University of Rochester has kindly called our attention to an error in our paper on 'Reduction Equilibria of Zinc Oxide and Carbon Monoxide' appearing in the JOURNAL, Vol. 48, p. 364, 1926. The value of the T^2 coefficient for ΔC_p in Table III, p. 370, is incorrect because of an algebraic error in the summation and should be -14.73×10^{-7} instead of $+22.47 \times 10^{-7}$. This produces a small change in the value of I , which now becomes -60.305 ± 0.091 , and the standard free energy equation on this basis is $\Delta F^\circ T = +47,390 + 4.467 \ln T - 1.56 \times 10^{-3} T^2 + 2.455 \times 10^{-7} T^3 - 60.305 T$. The free energy of formation of zinc oxide at 298°K. is $-75,720$. Other values depending upon these figures will in consequence be subject to a small correction which, however, in general will be less than the experimental error of the determinations, and well within the figure of 300 calories probable error which we estimated in this work."

1927, VOLUME 49

The Preparation of Crystalline *d*-Talonic Acid, by Oscar F. Hedenburg and Leonard H. Cretcher.

P. 479. In line 7 instead of "gulconic" read "gulonic."

Structure of a Protective Coating of Iron Oxides, by Richard M. Bozorth.

P. 975. The last line of Table V should read, "Thickness of Fe_2O_3 layer, 2×10^{-4} cm.; thickness of Fe_3O_4 layer, 2×10^{-4} cm."

Reciprocal Solubility of the Normal Propyl Ethers of 1,2-Propylene Glycol and Water, by Henry L. Cox, William L. Nelson and Leonard H. Cretcher.

P. 1080. In line 8 instead of "low" read "high."

Fluorescein and Some of its Derivatives, by W. R. Orndorff and A. J. Hemmer.

P. 1277. Table I. In the first line of data, Col. 3, instead of " $\text{F} + 2\text{CH}_3\text{OH}$," read " $\text{F} + \text{CH}_3\text{OH}$."

In the seventh line of data, Col. 3, instead of " $\text{F} + 2\text{CH}_3\text{CO}$," read " $\text{F} + \text{CH}_3\text{COOH}$," Cols. 7 and 8, instead of " CH_3CO ," read " CH_3COOH ."

In the eighth line of data, Col. 3, instead of " $1\text{CH}_3\text{CO}$," read " CH_3COOH ."

In the sixteenth line of data, Col. 3, instead of " $\text{F} + 2\text{C}_6\text{H}_5\text{NO}_2$," read " $\text{F} + \text{C}_6\text{H}_5\text{NO}_2$."

P. 1278. Table II. In the third line of note *b*, instead of "This carbonate . . .," read "This carbamate . . ."

The Composition of Corn Wax, by R. L. Shriner, F. P. Nabenhauer and R. J. Anderson.

P. 1291. Last paragraph. "CORRECTION.—The credit for supplying the acids used for comparison by Dr. R. L. Shriner should be given to others. The behenic acid was prepared by Dr. R. R. McGregor and the *n*-eicosanoic acid was a synthetic product prepared by Dr. J. R. Johnson.

CARL R. NOLLER."

Researches on Thiazoles. II. The Nitration and Reduction of 2-Mercapto-benzothiazole and its Substituted Derivatives, by Jan Teppema and L. B. Sebrell.

P. 1779. Third paragraph, second line, instead of "6-phenyl-2-mercaptobenzo-thiazole," read "6-nitro-2-phenylbenzothiazole."

Action of the Grignard Reagent on Alkylbarbituric Acids, by Arthur W. Dox.

P. 2275. Addendum supplied by the author as follows:

In a recent paper of the above title¹ the writer showed that 5,5-dialkylbarbituric acids react with the Grignard reagent to form stable crystalline products. In the case of diethylbarbituric acid and ethylmagnesium bromide a complete analysis of the product gave the empirical formula $C_{12}H_{22}O_2N_2$. With barbituric acids or Grignard reagent containing other alkyls the nitrogen determinations indicated analogous products. The formula represents a product which would result from a reaction between one mole of the barbituric acid and two moles of Grignard reagent with loss of one molecule of water. On the assumption that two carbonyls had reacted and that the water could be split out in either of two ways, two structural formulas were tentatively proposed:

A third possibility occurred to the writer at the time but was not mentioned because it seemed less in conformity to the usual Grignard reactions. This consists in the reaction between a single carbonyl and two molecules of Grignard reagent with loss of one molecule of water, giving a product (III) with the same empirical formula:

It now appears that precedent is to be found for reaction products of Type III, since anhydrides and lactones react in this manner. Bauer² obtained dialkylphthalides (IV) and Houben³ dialkylchromenes (V) by reaction between a single carbonyl and two molecules of Grignard reagent.

In the case of 1,3-diphenyl-5,5-dipropylbarbituric acid, where three Grignard reagent molecules reacted and one molecule of water was split off, the product, if represented by Type III, would be

The constitution of these substances still remains to be determined, but in the light of Bauer's and Houben's work Type III affords a fairly satisfactory explanation of the reaction except that hydrolysis would be expected to yield an amine instead of the ketone actually obtained.

ARTHUR W. DOX

Magnesium Diethyl and its Reaction with Acetyl Chloride, by Henry Gilman and F. Schulze.

P. 2329. In lines 9 and 18-19 instead of "dimethylethylcarbinol" read "methyl-diethylcarbinol."

NEW BOOKS

A System of Qualitative Analysis for the Rare Elements. By ARTHUR A. NOYES and WILLIAM C. BRAY. The Macmillan Company, New York City, 1927. 536 pp. 22 × 14.5 cm. Price, \$5.00.

Widespread use, to say nothing of imitations more or less shameless, has attested, for thirty years, the value of A. A. Noyes' *Qualitative Chemical Analysis*. From time to time outlines of a more comprehensive system have appeared in various periodicals and as communications to various societies. Now we have a finished masterpiece which insures to its authors long-continued preëminence in the qualitative field, as well as considerable influence upon the quantitative procedure of the future. The contributions of twenty-nine collaborators, distributed over the long period of development of the book, are duly acknowledged.

"Qualitative Analysis for the Metallic Elements" might describe the contents more exactly, as practically all are included—even hafnium separated from zirconium. The rare earth group is to a large extent resolved, and the balance of the fractionations indicated by references. The fact that whole pleiads are detected along with thallium, lead, thorium, bismuth and uranium should be emphasized. Acid radicals are not included, except some containing metallic elements. Incidentally it appears that a comprehensive system for detection of acid radicals constitutes a new world for conquest.

The "Confirmatory Experiments," two hundred pages crammed with experiments and references, afford reading of absorbing interest, and form in many respects the most valuable feature of the book. As the authors remark, this material, if presented in the discursive manner customary in periodicals, would fill a bulky volume. Lastly come "Reactions of the Elements" in tabular form, the first really satisfactory summary of the kind that the reviewer has seen.

The authors tend to diverge sharply from traditional procedures and to introduce striking novelties, such as ethyl acetate as extracting agent or solvent, or the free use of concentrated perchloric acid alone or with hydrobromic, formic or other acids. As reagents for the alkali group we find the unfamiliar sequence: magnesium uranyl acetate, sodium bismuthinitrite, antimony trichloride, sodium hydrotartrate or 6-chloro-5-nitrotoluenemetasulfonate, and silicotungstic acid. Only a study of the confirmatory experiments can show how great are the economies of time and effort, as well as the safeguards against error, gained by the analyst who will restock his reagent shelves.

A modern introductory chemical course consisting mainly of diluted physical chemistry, followed by the usual half year of "qualitative" will afford very scanty preparation for the task set by Noyes and Bray. While we cannot return to the days when the majority of chemists had a really

minute knowledge of inorganic properties and reactions, it is a pity to see the breed so nearly extinct as it is at present. Who knows but that its partial regeneration may be one of the good effects of this remarkable book?

G. S. FORBES

Outlines of Theoretical Chemistry. BY FREDERICK H. GETMAN, Ph.D., formerly Associate Professor of Chemistry in Bryn Mawr College. Fourth edition, revised and partly rewritten. John Wiley and Sons, Inc., New York City, 1927. xii + 728 pp. 179 figs. 22 × 14.5 cm. Price \$3.75.

In the preface of the first edition, the author stated: "The book is designed to meet the requirements of classes beginning the study of theoretical or physical chemistry. A working knowledge of elementary chemistry and physics has been presupposed in the presentation of the subject. . . . With the exception of a few paragraphs in which the application of the calculus is unavoidable, no use is made of higher mathematics, so that the book should be intelligible to the student of very moderate mathematical attainments. . . . In selecting material for this book, the author has been guided in a large measure by his own experience in teaching theoretical chemistry to beginners and to advanced students. . . . While the treatment of each topic is brief, effort has been made to avoid the sacrifice of clearness to brevity."

The latest edition of "Outlines of Theoretical Chemistry" is about 250 pages larger than the first edition, which appeared in 1913, and 100 pages larger than the preceding edition. The book underwent a drastic revision and extensive remodeling in the second edition (1918); and was again brought up to date in 1922, when much new material, including the results of recent work on atomic structure, was included. In the latest edition, "Outlines of Theoretical Chemistry" has once more been revised and extended, but in order to prevent it from becoming too voluminous, certain sections have been deleted or greatly abbreviated.

The arrangement of the book is that of many introductory works on this subject. The chapter headings are: Fundamental Principles; Gases; Liquids; Solids; Relation between Physical Properties and Molecular Constitution; Elementary Principles of Thermodynamics; Solutions; Dilute Solutions and Osmotic Pressure; Solutions of Electrolytes; Colloids; Thermochemistry; Homogeneous Equilibrium; Heterogeneous Equilibrium; Chemical Kinetics; Electrical Conductance; Electrolytic Equilibrium and Hydrolysis; Electromotive Force; Electrolysis and Polarization; Photochemistry; Electrical Theory of Matter; Radioactivity; Atomic Structure. The chapters on chemical kinetics, colloids and photosynthesis are particularly good, and the chapter on thermodynamics has been much improved.

"Outlines of Theoretical Chemistry" has steadily improved with each edition. It is carefully and well written and Dr. Getman is to be commended for the clear, concise and simple manner in which he introduces the beginner to the theoretical side of chemistry. An admirable feature is the numerous and well-selected problems which are placed at the end of most of the chapters for the purpose of testing the student's mastery of the subject matter of the chapter. In the opinion of the reviewer, this book is one of the outstanding introductory texts on the subject.

Necessarily, some of the topics are treated very briefly and therefore superficially—a fault which it would be difficult to avoid in a book of the scope of "Outlines of Theoretical Chemistry." Perhaps, however, half a loaf is better than no bread, especially as the student is enabled to round out and to expand the topics presented by means of the numerous references to original papers, and the list of authoritative books given at the end of each chapter.

The reviewer feels that the section on the activity concept is too meager in view of the large amount of investigation that has been carried out in this field during the past decade, and that Debye and Hückel's theory of solutions of strong electrolytes might have been presented somewhat more fully. In the opinion of the reviewer, it is unfortunate that, like so many writers, the author is not consistent in the use of prefixes, and that he employs the hybridism "unitrivalent." Being human, the author has allowed a few misprints to remain in the text, but most of these are obvious. There are, however, a few cross references to pages in the preceding edition of the book. From experience, the reviewer appreciates the difficulty of preventing this. These, however, are but minor defects in a book which contains a wealth of excellent, thoroughly serviceable, well-arranged and well-selected material.

Dr. Getman is to be congratulated on the continued success of his "Outlines of Theoretical Chemistry." The improved new edition is certain of a cordial welcome from its many old friends. To them it requires no recommendation; to others it can be warmly commended as an introduction to the study of theoretical chemistry.

The mechanical execution of the book is excellent.

H. JERMAIN CREIGHTON

Müller-Pouillet's Lehrbuch der Physik. 11. Auflage, Dritter Band, Zweite Hälfte. Kinetische Theorie der Wärme. By KARL F. HERZFELD, München, unter Mitwirkung von H. G. Grimm, Würzburg. Friedr. Vieweg und Sohn Akt.-Ges., Braunschweig, 1925. 436 pp. 52 figs. 25.5 × 17 cm.

The present volume is not an older edition circumspectly patched and sprinkled with recent references. It is, for the most part, a brand new production aiming to develop the applications of the kinetic theory

and to enlarge the circle of those who can use it with facility. The author, recently transplanted from Munich to Baltimore, emphasizes his desire to make clear the physical content of every statistical formula, as well as that of the corresponding thermodynamical formula, without presupposing unusual mathematical ability upon the part of his readers.

Starting with elementary and familiar considerations, theorems and equations in their first approximations are developed—"learning put lightly, like powder in jam." Next come "Verfeinerung der Betrachtung," "Exkurs," "genauere Diskussion," also footnotes and paragraphs in fine print to tempt the reader further. Through the references, only, would the limits of modern speculation be reached. The author with all his erudition is now primarily a teacher, again almost a propagandist, but a pedant never. In such fashion he treats kinetic theory of gases (elementary presentation), general statistical mechanics (postponing, however, Liouville's theorem and the ergodic hypothesis), gases, liquids, solids, solutions, disperse systems, quantum theory, advanced statistical discussion. Only at the very end come the numerical values, and this is the only feature at which the chemist might cavil.

Such a work is peculiarly helpful to those who cannot "take a course" and so have to dig things out for themselves; to the doctoral candidate in those last desperate hours before his "oral;" or—publish it not—to the lecturer on physical chemistry in the last moments before he meets his class. The trend of modern chemistry in many of its aspects is so obviously toward the kinetic and the statistical, that Herzfeld's book, supplemented perhaps by Tolman's Statistical Mechanics, will be welcomed by all those who read aright the signs of the times.

G. S. FORBES

Optische Methoden der Chemie. (Methods of Photochemistry.) By FRITZ WEIGERT, Professor at the University, Leipzig. Akademische Verlagsgesellschaft m. b. H., Leipzig, 1927. xvi + 632 pp. 341 figs. 24 × 16 cm. Price, unbound, M. 36; bound, M. 38.

For nearly a quarter of a century Weigert has been an indefatigable contributor to the periodical literature of photochemistry. Now the sum total of his experience, backed by intimate knowledge of the work of his contemporaries, has been applied to the production of a book certain to prove of great value to all who contend with the difficulties and exasperations peculiar to the subject.

All the important topics, with numerous ramifications, are included: optical instruments, light sources, ray filters, photographic operations, spectroscopy, photometry, spectrophotometry, colorimetry, nephelometry, measurement of color, radiometry, photochemical measurements (in the special sense), refraction, polarized light, scattered light, luminescence.

The author's sound and practical discussion is more frequently concerned with general principles than with the details of special procedures. He succeeds in giving, throughout, distinctly more than orientation and introduction, and much of the material included could scarcely be found elsewhere. The quantitative point of view predominates. A thousand references, more or less, direct the reader further without adding unreasonably to the thickness and price of the book. These references are commendably up to date, and include a great deal of non-German research. In the reviewer's opinion a considerable expansion of the list would be justified; eight brief citations, for instance, scarcely do justice to the achievements of Coblenz.

Those who have the will to turn out research of permanent value can go far with the help of this book. The semi-quantitative photochemist—may his tribe decrease—will find here both the incentive and the path to reform.

G. S. FORBES

Phosphoric Acid, Phosphates, and Phosphatic Fertilizers. By WM. H. WAGGAMAN, Scientist in Fertilizer Investigations, Bureau of Soils, U. S. Department of Agriculture, assisted by Henry W. Easterwood, formerly Chemist, Bureau of Soils, U. S. Department of Agriculture American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., 419 Fourth Avenue, at 29th Street, New York City, 1927. 370 pp. 58 figs. 15.5 X 23.5 cm. Price \$7.50.

This monograph brings together in convenient form a great deal of information—chemical, economic and technologic—with reference to phosphoric acid, phosphates and phosphatic fertilizers. The introductory chapter is a long one, including a variety of topics such as a brief review of the elementary chemistry of phosphorus; the role of phosphorus in life processes; the phosphorus requirement of soils; naturally occurring phosphates, etc. Chapter 2 deals with phosphate deposits in the United States, and Chapter 3 with phosphate deposits in foreign countries. Chapter 4 deals with so-called available phosphates, while those which are water-soluble are discussed in Chapter 5. Chapter 6 is devoted to a discussion of the sulfuric acid method of preparing phosphoric acid, while Chapter 7 is concerned with the volatilization process of preparing phosphorus and phosphoric acid. Chapter 8 deals with phosphate baking acids and powders; Chapter 9 with the use of phosphates as water softeners, and Chapter 10—the final chapter—with miscellaneous uses of phosphoric acid. Forty-three pages at the end of the book are devoted to a digest of the United States patents covering processes for the production of soluble and available phosphates by various methods.

A monograph of this sort should be judged as a whole and from this standpoint we believe that the authors have produced a book of considerable merit. Criticism of the book can be made only in a limited number of

specific instances which do not detract from its value as a whole. To the present reviewer there seems to be a lack of balance in certain of the parts and certain instances of poor judgment in choosing illustrations. For example, we may point out that the Liljenroth Process is dismissed with less than half a page, whereas a considerable number of pages are devoted to describing and discussing the experimental unit which was set up and operated at Arlington Farms. With regard to illustrations, we suggest that those on pages 64, 111, and particularly the one on page 243, might well be omitted.

While not up to the standard of some of the monographs in the American Chemical Society Series, we believe that the present one falls well within the average and that the authors are to be congratulated on its production.

HARRY A. CURTIS

Contemporary Developments in Chemistry. Lectures by Eminent Chemists. Columbia University Press, New York, 1927. 464 pp. Illustrated. 23.5 × 16 cm. Price \$11.00.

This is a collection of twenty-five lectures delivered at Columbia University in a special course given during the Summer Session of 1926, on the occasion of the opening of the Chandler Laboratories. The subjects of the lectures and the names of the lecturers are as follows:

Synthetic Organic Chemistry in the Study of Odorous Compounds, by Marston T. Bogert; Chemical Reactivity, by James F. Norris; Chemical Relationships of Sugars, Optically Active Amino Acids, Hydroxy Acids and Halogen Acids, by Phoebus A. Levene; Reversible Oxidation-Reduction Reactions in Organic Systems, by W. Mansfield Clark; Crystal Structure in its Relation to Chemical Problems, by Ralph W. G. Wyckoff; Catalysis and the Mechanism of Chemical Reactions, by Hugh S. Taylor; Carbohydrates, by Sir James Colquhoun Irvine; Oxidative Catalysis in the Body, by Edward C. Kendall; Immunology as a Branch of Chemistry, by H. Gideon Wells; Rare Gases of the Atmosphere, by Richard B. Moore; Synthetic Organic Chemistry, by E. Emmet Reid; Permeability and Electric Phenomena in Membranes, by Leonor Michaelis; Radicals as Chemical Individuals, by Charles A. Kraus; The Influence of Pressure upon Chemical Transformations, by Ernst Cohen; A Development in the Chemistry of Sanitation, by John Arthur Wilson; The Direct Measurement of Osmotic Pressure, by J. C. W. Frazer; Chemistry of Bacteria, by Treat B. Johnson; Contact Catalysis, by Wilder D. Bancroft; Water-Soluble Vitamins, by Elmer V. McCollum; Quantitative Research in the Chemistry of Nutrition, by Henry C. Sherman; Theory of Velocity of Ionic Reactions, by J. N. Brönsted; Physico-Chemical Principles in Electro-Metallurgical Research, by Colin G. Fink; Reactions in Liquid Ammonia, by E. C. Franklin; Agricultural Chemistry,

by Charles A. Browne; Completing the Periodic Table, by B. S. Hopkins.

The lectures, as a rule, are summaries of recent work in their respective fields in which the lecturer himself usually has been a productive investigator. Though presented in this way by specialists, they are nevertheless directed to the general chemical reader rather than to fellow specialists in the field. Such summaries are most useful and are all too rare. This collection is therefore a valuable addition to our chemical literature.

ARTHUR B. LAMB

Elementary Organic Chemistry. By LOUIS A. OLNEY, Sc.D., Professor of Chemistry and Dyeing, Lowell Textile School. Howes Publishing Company, 90 William Street, New York City, 1927. 191 pp. 4 figs. 14.5 × 20.5 cm. Price \$3.00.

"The author has found the publication of this book on Elementary Organic Chemistry necessary because up to the present time no other book has been published which fulfills the requirement of certain classes of students in the Lowell Textile School."

"Between the ten to twenty pages treating the subject of carbon compounds, which is inserted in most modern text-books on General Chemistry, and the three to five hundred page book on the subject, there appears to be no published text which gives the fundamental principles of Organic Chemistry, and a general discussion of the subject, in a space that would correspond to from fifteen to twenty lectures."

A careful reading of the text convinces the reviewer that it is unfortunate for a scientist to be forced in this way to write a text-book on a subject with which he is apparently not directly familiar. This is all the more serious since the users of short texts of this kind will usually not be specialists who are capable of correcting the mistakes.

In addition to many minor mistakes some of the more serious are the constant treatment of esterification as the "exact" equivalent of neutralization, the confusion of hydrolysis and dissociation and the discussion of the basic character of the hydroxyl group in the carboxyl group. A large number of errors in important formulas are apparently typographical but none the less dangerous. Among these are those of propylene, acetylene, diazonium salts and magenta.

No mention is made of such important and simple subjects as synthetic methanol, oxyacetylene cutting of steel and the air-oxidation of naphthalene.

The use of a bulb condenser in fractional distillation, as shown on p. 179, is hardly to be recommended.

In conclusion the reviewer would urge the recognition of a place for a short organic text to fill the needs of students who require only the barest smattering of the subject.

FRANK C. WHITMORE

Handbuch der biologischen Arbeitsmethoden. (Handbook of Biological Procedure.)
Abt. III, Physikalisch-chemische Methoden, Teil B, Heft 3. Edited by Prof. DR.
EMIL ABDERHALDEN. Urban and Schwarzenberg, Berlin N 24, Friedrichstrasse
105 B, 1926. Pp. 385-594. 65 figs. 25.5 × 17.5 cm. Price, M. 9.30.

This is the first "Lieferung" of the volume of Abderhalden's handbook which deals with the methods of colloid research. It contains five articles as follows: Coagulation of Sols and Determination of the Isoelectric Point, by E. Bloch; Methods of Determining Adsorption, by H. Fodor; Methods of Biological Dispersoid Analysis, by V. von Hahn; Determination of the Structure of the Colloidal Micelle, by R. Riwlín; and Ultrafiltration and Electro-ultrafiltration, by H. Bechhold. The article on coagulation of sols deals for the most part with the action of electrolytes on sols, mutual precipitation of sols and the methods of determining the degree of coagulation. The methods described for determining the so-called isoelectric point are; cataphoresis, coagulation, measurement of the displacement of P_H by the addition of an acid or base, osmotic pressure, swelling and viscosity. The section on adsorption gives numerous examples of adsorption of gases and adsorption from solutions both dilute and quite concentrated, chiefly with carbon as adsorbent. The significance of $1/n$ in the Freundlich adsorption equation is discussed and a section is devoted to negative adsorption. The methods of dispersoid analysis discussed by von Hahn are filtration, diffusion, sedimentation, optical methods, coagulation and special methods. The chapter on the composition of the micelle gives chiefly the views of Pauli and Fodor on hydrous ferric oxide and albumin and of McBain on the soaps. Bechhold's chapter naturally deals primarily with his own work on ultrafiltration.

The articles in this volume give what appears to be a fairly comprehensive survey of the investigations of Europeans, especially the Germans, in the subject under discussion. Almost no attention is paid to American work. The important question of ionic antagonism in biological systems is passed over in a sentence, page 396, and in all the discussion of adsorption by charcoal there is no reference to the work of Coolidge or of Bartell and Miller on ash-free charcoals. Thirty pages (547-577) are devoted to the physical chemistry of the proteins but there is no reference to Loeb although his investigations doubtless furnished the inspiration for much of the work reported in this section.

Subject Index to Volume XLIX, 1927¹

ABIETIC ACID, purification of, from rosin and prepn. of some of its derivs...	2898
Absorption, gasometric detn. of NO, with special reference to, by FeCl ₂	979
Absorption (of rays), infra-red, by the N-H bond—in aniline and alkylanilines, 347; study of the mol. constitution of certain org. compds. by.....	847
Acetals, affinity, reactivity and structure in acetal formation, 2517; odor and structure of certain cyclic.....	3116
Acetanilide, system, -propionanilide.....	2296
Acetic acid, action of benzylamine on glucose in, soln., 1759; use of the chloranil electrode in glacial, and the strength of certain weak bases, 3047; chem. investigation of the H-ion activity of, solns.....	3062
Acetyl chloride, MgF ₂ and its reaction with, 2328, (correction).....	3190
Acetylchloroaminobenzene, photochem. rearrangement of.....	2145
Acetylenic acids, unsatn. phenomena of, and esters, 2258; unsatn. phenomena of, and esters—reaction between (AcO) ₂ Hg and some, and esters.....	2264
Acid azides, rearrangement of, and hydroxamic acids of geometrical isomers.....	2528
Acid chlorides, SiCl ₄ as a reagent for the prepn. of.....	2114
Acidity, of the waters of some Puget Sound bogs.....	2981
Acids, non-volatile, of the pear, quince, apple, loganberry, blueberry, cranberry, lemon and pomegranate, 1300; non-inversion of sucrose by adsorbed, and its significance for theories of adsorption and catalysis, 1686; effect of inorg. salts on the adsorption of inorg., 1698; cond. of, in liquid NH ₃ , 2162; unsatn. phenomena of acetylenic, 2258, 2264; theory of acid and basic catalysis, 2554; activity of weak, in aq. sulfate solns.....	2678
Acridine, synthesis of certain compds.....	810
Actinometry, self-integrating chem., for ultraviolet dosage or other sp. purposes..	3081
Activation, of mol. H by electron impact.....	58
Activity, revision of, in water-alc. mixts., 217; change in, of molten PbCl ₂ upon diln. with KCl, 722; potential of a proposed standard form of Cu and the, of CuSO ₄ , 2423; of weak acids in aq. sulfate solns.....	2678
Activity coefficients, of formic acid in neutral salt solns., 1; of the ions in certain phosphate solns., 173; of electrolytes—the limiting law for a tri-trivalent salt, 363; of electrolytes—unsymmetric valence-type effect in highly dil. solns., 410; of aq. Ba(NO ₃) ₂ , Na ₂ SO ₄ and H ₂ SO ₄ , 647; of HCl in aq. solns. with Ba and La chlorides at 25°, 1435; of H ₂ SO ₄ in aq. solns. with Na ₂ SO ₄ at 25°, 1445; of electrolytes—bi-bivalent salt and the ion attraction theory..	2372
Acyldiurethans, and their reactions with NH ₃ and amines.....	2942
Acyloisoureas.....	3177
Adsorption, decompn. of EtOH at the surface of thoria—on the thoria catalyst, 116; of water vapor by charcoal, 708; from soln. by ash-free adsorbent charcoal—non-inversion of sucrose by adsorbed acids and its significance for theory of, 1686; effect of inorg. salts on the, of inorg. acids and bases, 1698; of Hg vapor by charcoal, 1949; of H and C ₂ H ₄ on a Cu catalyst poisoned with CO, 2136; exptl. test of the Gibbs theorem, 2230; Theorie der, von Gasen (Jaquet, book review), 2667; catalytic activity and adsorptive power of supported Fe, Co, Ni, Cu and Ag, 2783; Handbuch der biologischen Arbeitsmethoden—[methods of detn. of] (Abderhalden, book review).....	3198
Affinity, in acetal formation.....	2517
Air, activity of various metals and metal oxide catalysts in promoting the oxidation of methane by.....	1454
Alcohols, action of aromatic, on aromatic compds. in the presence of AlCl ₃ —condensation of some secondary, with phenol, 1365; relative reactivities of the hydroxyl-H atoms in certain.....	2640
Aldehydes, synthesis of 2-aryl-6-dimethylaminobenzothiazoles from 2-amino-5-dimethylaniline thiosulfuric acid and aromatic.....	1373
Alizarin, prepn. of, from phthalic anhydride and o-dichlorobenzene.....	473, 2335
Alkalies, detn. of excess of, in hypochlorite solns., 791; conductance of dil. aq. solns. of, at 25°.....	1486

¹ This index was prepared in the Editorial Offices of *Chemical Abstracts* through the courtesy of Dr. E. J. Crane and under his direction.

Alkali metal carbonates, equil. in solns. of	1235
Alkali metals, conduction process in glass—replacement of the Na by, 447; differential cleavage of the C to C linkage by	2599
Alkoxyethyl-diethylmethylammonium hydroxides, decompn. of	1718
Alkylanilines, infra-red absorption by the N-H bond in	347
Alkylation, of hydroxynaphthoquinone, 857; of benzene, toluene and naphthalene	3142
Alkylbarbituric acids, action of the Grignard reagent on, 2275, (addendum)	3189
Alkylnitroguanidines	2303
Allene bases, use of Grignard reagents in attempted syntheses of asymmetric	546
Allylthiourea, addn. compds. of, with Ag halides	1814
Alumina, high-temp. equil. between C and	2753
"Aluminon," reaction of, with hydroxides of Sc, Ga, In, Tl and Ge	216
Aluminum, confirmatory test for, 1991; reaction of, with the NH_4 salt of aurintricarboxylic acid and its application to the colorimetric detn. of, in H_2O	2395
Aluminum alloys, Al amalgam as an agent for the reduction of phenylsulfone chlorides to thiophenols	1386
Aluminum chloride, reaction of lactones and of furfuran derivs. with aromatic hydrocarbons and, 562; action of anhyd., on cresyl benzoates, 1028; action of aromatic alcs. on aromatic compds. in the presence of	1365
Aluminum compounds, crystal structure of CuAl_2	3110
Amalgams, Al, as an agent for the reduction of phenylsulfone chlorides to thiophenols, 1386; reduction of benzophenone by Mg amalgam, 2666; vapor pressures of potassium, 3003; vapor pressure of Na and Cs	3011
American Chemical Society, additions and corrections for the Golden Jubilee no.	3199
Amines, reaction between dichloroacetic acid and aromatic, 1091; reduction of aromatic nitro compds. to, with H and Pt-oxide Pt black as a catalyst, 1093; substituted <i>o</i> -alkylhydroxylamines chemically related to medicinally valuable, 1527; infra-red absorption spectra of org. derivs. of NH_2 —primary, secondary and tertiary alkyl, 1837; halogenated tertiary, 2299; prepn. and base strengths of some, 2908; acyldiurethans and their reactions with	2942
Amino acids, catalytic and sp. dynamic actions of certain	805
Amino bases, addn. to nitrostyrene	1598
<i>p</i> -Aminobenzoic acid, cyclic alkamine esters of, 1303; piperidyl and substituted piperidyl alkyl esters, 1307; substituted piperidine-alkyl esters of, 2835; 1-cyclohexyl- and 1-phenyl-ethyl-3-carbethoxy-4-piperidyl derivs. of	2862
2-Amino-5-bromo- <i>p</i> -cymene, new dyes derived from	2819
Aminocinnamic acid, menthyl esters of	452
2-Amino- <i>p</i> -cymene, new dyes derived from, 2819; nitration of	2832
2-Amino-5-dimethylaniline thiosulfuric acid, synthesis of 2-aryl-6-dimethylamino-benzothiazoles from, and aromatic aldehydes	1373
Amino group, oxidation of compds. possessing the primary	1742
2-Amino-7-hydroxynaphthalene, acetylbenzoyl derivs. of	559
α -Amino- β -hydroxyvaleric acid, synthesis of	538
γ -Amino- β -hydroxyvaleric acid, synthesis of	538
2-Amino-6-nitro- <i>p</i> -cymene	494
Amino nitrogen, rate of hydrolysis of solns. of proteins in acids as measured by the formation of	275
<i>o</i> -Aminophenol, acyl derivs. of	3129
2- <i>m</i> -Aminophenyl-6-methylbenzothiazoles, synthesis of	3135
2- <i>o</i> -Aminophenyl-6-methylbenzothiazoles, synthesis of	3135
Ammonia, equil. pressures of, mixed with N, 1146; effect of added gases on the decompn. of, sensitized by optically excited Hg vapor, 1478; infra-red absorption spectra of org. derivs. of, 1837; heat of formation of NH_4 carbamate from CO_2 and, 1909; cond. of acids and salts in liquid, 2162; d. of solns. of Na in liquid, 2206; photochem. decompn. of, by relatively short wave lengths, 2495; soly. of non-radiated cholesterol in liquid, 2526; Ag ion catalysis of persulfate oxidations—salt effect on the velocity of oxidation of, 2689; fluorescence in mixts. of Hg vapor and, 2699; reaction of chloroacetic acid with, 2889; acyldiurethans and their reactions with	2042
Ammoniates, ionic sizes and their relationship to crystal structure type, solid soln. and double salt formation and the stability	201
Ammonium, conduction process in glass—replacement of the Na by	447
Ammonium azido-dithiocarbonate	2129

Ammonium carbamate, heat of formation of, from NH_3 and CO_2	1909
Ammonium compounds, substituted, decompn. of quaternary ammonium hydroxides—alkoxymethyldiethylmethyammonium hydroxides, 1718; tetramethylammonium azido-dithiocarbonate—tetramethylammonium thiocyanate	2129
Ammonium cupric chloride, crystal structure of, dihydrate.	2149
Ammonium hydroxide, equil. between cryst. $\text{Zn}(\text{OH})_2$ and aq. solns. of.	1419
Ammonium monometaphosphate.	123
Ammonium phosphates, dissocn. pressures of.	1904
Ammono-aldehydes, hydrobenzamide and benzyldeneimine as.	1558
Amylase, establishment of the optimal H-ion activities for the enzymic hydrolysis of starch by pancreatic and malt, under varied conditions of time and temp., 2000; influence of Na acetate, Na borate, Na citrate and Na phosphate upon the activity of pancreatic.	2596
Amylenes, polymerization of the.	873
"Amyl"-phenylhydrazines, <i>p</i> -"active"	1043
Analysis, Atlas de Spectres d'Arc: Tableaux d'Analyse pour les Recherches Spectrochimiques (Bardet, book review), 302; Die elektrometrische (potentiometrische) Massanalyse (Müller, book review), 581; Elektroanalytische Schnellmethoden (Fischer, Schleicher, book review), 1611; Handbook of Org. (Clarke, Collic, book review), 2125; of Org. Compds. (Coleman, Arnall, book review), 2126; Quant. (Mahin, book review), 2949; Anleitung für das Praktikum in der Gewichtsanalyse (Weinland, book review), 2951; Indicators: Their Use in Quant. (Koltzoff, book review), 2952; Neue Methoden der Organisch-Chem. (Ter Meulen, Heslinga, book review), 2953; System of Qual., for the Rare Elements (Noyes, Bray, book review)	3191
Aniline, infra-red absorption by the N-H bond in.	347
Antimony, solid soly of, in Pb, 1667; azo dyes contg.	2869
Antimony alloys, solid soly. of Sb in Pb as detd. by cond. measurements on cold-worked alloys.	1667
Antimony compounds, Org. (Christiansen, book review)	1122
Apple, non-volatile acids of.	1300
Aquo-ammonocarbonic acids, new reactions of the mixed.	509
Argon, computation of the free energy and fugacity in gaseous mixts. of C_2H_4 and.	2172
Aromatic compounds, action of aromatic alcs. on, in the presence of AlCl_3 , 1365; nitration of, with metallic nitrates, 1522; positive halogen attached to C in	1796, 1801, 1806, 1810
Arsenic, hitherto unsuspected source of, in human environment.	1410
Arsenic pentoxide, detn. as $\text{MgNH}_4\text{AsO}_4$	1451
Arseno compounds, aliphatic-aromatic.	998
Arylarsenoacetic acids.	998
2-Aryl-6-dimethylaminobenzothiazoles, synthesis from 2-amino-5-dimethylaniline thiosulfuric acid and aromatic aldehydes.	1373
Arylsulfuranilides.	2270
Arylsulfurchlorides.	2270
Atomic form (Price, book review)	1609
Atomic weights, 33rd ann. rept. of the Comm. on.	583
Atoms, Die Welt der (Haas, book review), 1850; Der Bau der, und das periodische System (Koppel, book review), 1851; Magnetism and At. Structure (Stoner, book review), 2119; Die seltenen Erden vom Standpunkte des Atombaues (Hevesy, book review), 2121; reactivity of, and groups in org. compds.; 2640; optical rotation and at. dimension	3170
Auric oxide. See <i>Gold oxide</i>	
Aurin, absorption spectra of.	1545
Aurintricarboxylic acid, reaction of Al with the NH_4 salt of, and its application to the colorimetric detn. of Al in H_2O	2395
Azides, rearrangement of acid, and hydroxamic acids of geometrical isomers.	2528
Azido-carbondisulfide, behavior toward Cl, Br and I.	2759
Azido-dithiocarbonic acid, 917; and derivs.	2129
Azomethane, decompn. of, 912; thermal decompn. of, over a large range of pressure.	1495
BACILLUS LEPRÆ , various ω -cyclohexylalkylalkylacetic acids and their action toward, 2934; certain Δ^2 -cyclopentenylalkylacetic acids and their action toward.	2940

- Bacteria, occurrence of Ca citrate crystals in cultures of butyric acid forming 2884
Bacterium pruni, identification of some products formed by, in milk 1556
 Barbituric acid, action of the Grignard reagent on alkyl, 2275 derivs (addendum) 3189
 Barium *n*-butyrate, soly of 2859
 Barium chloride, activity coeff of HCl in aq solns with 1435
 Barium chromate, fractional pptn of Ra chromate and 738
 Barium nitrate, variation of the cell const with concn and the molal conductance of aq, at 0°, 636, f p and activity coeff of aq 647
 Bases, effect of inorg salts on the adsorption of inorg, 1698, th ory of acid and basic catalysis, 2554, strength of certain weak 3047
 Beckmann rearrangement, of salicylhydroxamic acid derivs, 2545, 7 nitro phenanthridone by, of 2 nitrofluorenone oxime 2618
 Benzaurin, absorption spectra of 1545
 Benzene, elec moments of substituted, mols and the structure of the benzene ring, 1030, equal between H cyclohexane and, 1157 elec moments of certain org mols in, soln, 1676, shift in a near infra red absorption band of some, derivs, 2034, as a solvent for certain solid substances, 2416 comparison of heterocyclic systems with, 2604 alkylation of 3142
 Benzene ring, structure of 1030
 Benzil, reduction of, by the binary system, Mg + MgI₂ (or MgBr₂) 2584
 Benzoic acid, action of anhyd AlCl₃ on cresyl ester of, 1028 vapor pressure curve of, 1280, substituted piperidine alkyl esters of 2835
 Benzophenone, reduction by Mg amalgam 2666
 Benzoselenazoles, synthesis of 2011
 Benzylamine, action on glucose in AcOH soln 1759
 Benzyl chlorides, reaction of *p* substituted, with NaHS 2549
 Benzylideneimine, as ammono aldehyde 1558
 Beryllium halides, organo 2904
 Biochemistry, Practical (Plimmer, book review) 2127, Textbook of Biol Chemistry (Sumner, book review) 2670
 Biology, Handbuch der biologischen Arbeitsmethoden (Abderhalden book review). 3198
 "Bios," control of, testing and the concn of a 227
 Bismuth, Gmelins Handbuch der anorg Chemie (Meyer, book review) 1387
 Bismuth thioglycolamide, prepn of 1017
 Blood, biochemistry of S—identity of ergothionine from ergot of rye with sympectothion and thiasine from pigs 575
 Blueberry, non volatile acids of 1300
 Boa constrictor, fat 2046
 Bogs, acidity of the waters of some Puget Sound 2981
 Bond, infra red absorption by the N—H, 347, differential cleavage of the C to C linkage by alkali metals, 2599, polarity of the C-halogen bond 2849, 2853
 Books, new (reviews), Atlas de Spectres d'Arc Tableaux d'Analyse pour les Recherches Spectrochimiques (Bardet), 302 Tabelle der Hauptlinien der Linienspektren aller Elemente nach Wellenlänge Geordnet (Kayser), 302, Phys Chemistry for Colleges (Millard), 303, The New Heat Theorem—Its Foundations in Theory and Expt (Nernst), 303, Gmelins Handbuch der anorg Chemie (Meyer), 304, 1387, 1607, 2337, Manual of Radioactivity (Hevesy), 305, Die elektrometrische (potentiometrische) Massanalyse (Muller), 581, Introductory College Chemistry (Gordon), 581, Chem Calcns (Jaffe), 582, Principles of General Chemistry (Brinkley), 582, Donnees Numériques D'Électricité, Magnétisme et Électrochimie (Buffat, *et al*), 887, A Handbook of Elementary Chemistry for Students of Medicine, Dentistry and Pharmacy (Attix), 887, Tables Annuelles de Constantes et Données Numériques de Chimie, de Physique et de Technologie (Cohen, *et al*), 887, Art de L'Ingénieur et Metallurgie (Descroix), 888 Eine neue Form des Periodischen Systems der Elemente (Antropoff), 888, Photosynthesis (Spoehr), 889, Beiträge zur Chemie der Platinmetalle (Claus), 890, Muller-Pouillet's Lehrbuch der Physik—Lehre von der strahlenden Energie (Lummer, *et al*), 1120, Muller-Pouillet's Lehrbuch der Physik—Physikal, chem und tech Thermodynamik, einschl Wärmeleitung (Eucken, *et al*), 1121, Comprehensive Treatise on Inorg and Theoretical Chemistry Vol VII Ti, Zr, Hf, Th, Ge, Sn, Pb, Inert Gases (Mellor), 1122, Org Derivs of Sb (Christiansen), 1122, Applied X-Rays (Clark), 1388, Lehrbuch der Min-

- eralogie (II) Spezielle Mineralogie (Niggli, Weber), 1389; Practical Colloid Chemistry (Ostwald, Wolski, Kuhn), 1390; Über die Natur und Bildungsweise der marinen Eisensilikate insbesondere der chamositischen Substanzen (Berz), 1390; C Compds.—Textbook of Org. Chemistry (Porter), 1391; Kolloidchemische Technologie (Liesegang), 1391; Die Katalyse in der org. Chemie (Sabatier), 1392; General Chemistry (Cady), 1605; Equilibria in Satd. Salt Solns. (Blasdale), 1606; Thermodynamics for Students of Chemistry (Hinshelwood), 1608; At. Form with Special Reference to the Configuration of the C Atom (Price), 1609; Thermodynamics and Chemistry MacDougall), 1610; Elektroanalytische Schnellmethoden (Fischer, Schleicher), 1611; Pyrosol—Das Kolloide Phänomen in der Glühend Flüssigen Materie und seine Erstarrungs-Zustände unter Berücksichtigung des Latenten Photographischen Bildes (Lorenz, Eitel), 1612; Surface Equilibria of Biol. and Org. Colloids (Nöuy, *et al.*), 1613; Katalyse mit Kolloiden Metallen (Hückel), 1614; Chemistry of Dyeing (Wood), 1615; Gesammelte Abhandlungen von Dr. F. Kehrman (Kehrman, Sandoz), 1615; Lead Poisoning (Aub, *et al.*), 1615; Old Chemistries (Smith), 1847; Recent Advances in Phys. and Inorg. Chemistry (Stewart), 1848; Anorganische Chemie (Schwarz), 1849; Physico-Chem. Metamorphosis and Some Problems in Piezochemistry (Cohen), 1849; Die Welt der Atome (Haas), 1850; Der Bau der Atome und das periodische System (Koppel), 1851; Colloids: A Textbook (Kruyt), 1852; Einführung in die Chemie der Polymeren Kohlenhydrate: Ein Grundriss der Chemie, der Stärke, des Glykogens, der Zellulose und anderer Polysaccharide (Karrer), 1852; Problems in Org. Chemistry (Underwood), 1853; A Text-Book of Org. Chemistry—Historical, Structural and Economic (Read), 1854; Magnetism and At. Structure (Stoner), 2119; Handbuch der Anorg. Chemie (Abegg), 2120; Die seltenen Erden vom Standpunkte des Atombaus (Hevesy), 2121; Evolution and Development of the Quantum Theory (Bligh), 2122; Radioaktivität (Meyer, Schweidler), 2122; Die Verwendung der Röntgenstrahlen in Chemie und Technik (Mark), 2123; Forschungen zur Kristallkunde: (I) Trachten der Kristalle (Tertsch), 2124; Die Herstellung kolloider Lösungen anorg. Stoffe (Reitstötter), 2125; Handbook of Org. Analysis (Clarke, Collic), 2125; Organische Molekülverbindungen (Pfeiffer), 2126; Prepn. and Analysis of Org. Compds. (Coleman, Arnall), 2126; Practical Org. and Bio-Chemistry (Plimmer), 2127; Lehrbuch der Enzyme (Oppenheimer, Kuhn), 2128; General Inorg. Chemistry (Sneed), 2335, Properties of Inorg. Substances (Segerblom), 2336; Physico-Chem. Geology (Rastall), 2338; Problem of Physico-Chem. Periodicity (Hedges, Myers), 2338, Titanium (Thornton), 2339; Colloid Chemistry, Theoretical and Applied (Alexander), 2340; Enzymes: Properties, Distribution, Methods and Applications (Waksman, Davison), 2341; Periodic Table (Deming), 2667; Theorie der Adsorption von Gasen (Jaquet), 2667; Text-Book of Org. Chemistry (Schmidt), 2668; Textbook of Biol. Chemistry (Sumner), 2670; General Chemistry—Theoretical and Descriptive (McCutcheon, Seltz), 2948; Quant. Analysis (Mahin), 2949; Anleitung für das Praktikum in der Gewichtsanalyse (Weinland), 2951; Selenium (Doty), 2951; Abridged Scientific Publications from the Kodak Research Labs., 2952; Indicators: Their Use in Quant. Analysis and in the Colorimetric Detn. of H-Ion Concn. (Kolthoff), 2952; Neue Methoden der Organisch-Chem. Analyse (Ter Meulen, Heslinga), 2953; Principles of Org. Chemistry (Worrall), 2953; System of Qual. Analysis for the Rare Elements (Noyes, Bray), 3191; Outlines of Theoretical Chemistry (Getman), 3192; Müller-Pouillet's Lehrbuch der Physik (Herzfeld), 3193; Optische Methoden der Chemie (Weigert), 3194; Phosphoric Acid, Phosphates, and Phosphatic Fertilizers (Waggaman, Easterwood), 3195; Contemporary Developments in Chemistry, 3196; Elementary Org. Chemistry (Olney), 3197; Handbuch der biologische Arbeitsmethoden (Abderhalden)..... 3198
- Boron, Gmelins Handbuch der anorg. Chemie (Meyer, book review)..... 304
- Bromination, of *p*-cymylene-2,6-diamine, 572; of naphthazarin..... 2825
- Bromine, reaction with chloride ion in HCl, 142; thermal dissoc. of, 656; "satn." of the petroleum lubricant hydrocarbons as shown by their reaction with, 1116; suggested mechanism of the splitting of cyclopropane ring by, 2066; behavior of azidocarbonylsulfide toward, 2759; rate of reaction between, and unsatd. fatty acids as evidence of stereo-isomerism..... 2808

Bromine monochloride.....	142
Buffer action, theory of.....	173
<i>tert.</i> -Butyldiphenylcarbinol, structure of $C_{17}H_{18}$ obtained by the dehydration of ..	2914
<i>tert.</i> -Butyl hypochlorite, addn. to cinnamic acid.....	2071
Butyltrichloromethylcarbinol.....	1068
Butyric acid, soly. of Ba salt of, 2859; occurrence of Ca citrate crystals in cultures of, -forming bacteria.....	2884
CALCIUM CITRATE , occurrence of, crystals in cultures of butyric acid-forming bacteria and the H_2O of crystn. of.....	2884
Calcium nitrate, temp.-compn. relations of the binary system, $-H_2O$, 1958; vapor pressure-temp. relations of the binary system, $-H_2O$	1963
Calculations, of partial molal quantities of binary solns., 2255; Chem. (Jaffe, book review).....	582
Calibration, fixed point for the, of pressure gages.....	1174
Calorimeter, new type of rotating adiabatic.....	1940
Carbamazides, structure of.....	266
Carbamic acid, heat of formation of NH_4 salt of, from NH_3 and CO_2	1909
3-Carbethoxy-4-piperidones, prepn. and reduction of certain phenyl substituted..	2862
Carbohydrates, Einführung in die Chemie der Polymeren (Karrer, book review).....	1852
Carbon, At. Form with Special Reference to the Configuration of the, Atom (Price, book review), 1609; positive halogens attached to, in the aromatic series, 1796, 1801, 1806, 1810; differential cleavage of the, to, linkage by alkali metals, 2599; high-temp. equil. between ThO_2 and, 2744; high-temp. equil. between Al_2O_3 and, 2753; polarity of the, -halogen bond	2849, 2853
Carbon dioxide, equation of state for gaseous, 1130; vapor pressure of liquid, at 0° , 1174; equation of state for fluids—application to, 1665; reaction between cinnamyl chloride, Mg and, 1825; heat of formation of NH_4 carbamate from NH_3 and, 1909; surface tension of liquid, 2704; ds. of coexisting liquid and gaseous, and the soly. of H_2O in liquid, 2729; formation of triphenylmethyl peroxide from, and phenylmagnesium bromide.....	2843
Carbon monoxide, catalytic prepn. of unsatd. hydrocarbons from H and, 796; adsorption of H and C_2H_4 on a Cu catalyst poisoned with, 2136; reduction equilibria of ZnO and, (correction).....	3189
Carbon monoxide-hemoglobin, application of the oil turbine type of ultracentrifuge to the study of the stability region of.....	2920
Carbon tetrachloride, elec. moments of certain org. mols. in, soln.....	2408
Carbonyl compounds, apparent reduction potential of unsatd.....	1083
Catalysis, attempts to activate Cu for hydrogenation by oxidation and reduction, 25; decompn. of EtOH at the surface of thoria, 104, 116; in prepn. of unsatd. hydrocarbons from CO and H, 796; action of certain amino acids, 805; oxidation effects that resemble the sp. dynamic effect, 987; reduction of aromatic nitro compds. to amines with H and Pt-oxide Pt black as a catalyst, 1093; reduction of di- and triphenylamines with H and Pt-oxide Pt black, 1099; Die, in der org. Chemie (Sabatier, book review), 1392; chain-reaction theory of negative, 1460; mit Kolloiden Metallen (Hückel, book review), 1614; promoter action in homogeneous, 1630; non-inversion of sucrose by adsorbed acids and its significance for theory of, 1686; in oxidations in aq. solns., 2005; selective reduction of furfuralcrolein by means of Pt-oxide Pt black and H, 2101; synthesis of water vapor in contact with metallic Au, 2426; combination of C_2H_4 and H in the presence of metallic Cu, 2503; theory of acid and basic, 2554; Ag ion, of persulfate oxidations, 2689; activity of supported Fe, Co, Ni, Cu and Ag.....	2783
Catalysts, effect of accidental, on rate in the thermal decompn. of ozone, 1202; activity of various metals and metal oxide, in promoting the oxidation of methane by air, 1454; adsorption of H and C_2H_4 on a Cu, poisoned with CO, 2136; heats of adsorption on poisoned and heat-treated, 2200; methanol....	2468
Cellobiose, production from cellobiose octa-acetate.....	2822
Cellobiose octa-acetate, production of cellobiose from.....	2822
Cells, electrolytic, variation of the cell const. with concn. and the molal conductance of aq. $Ba(NO_3)_2$, Na_2SO_4 and H_2SO_4 at 0°	636
Cells, voltaic, electrode equil. in the Weston standard, 78; of the standard cell type with low e.m.f.'s.....	2222

- Cellulose, Einführung in die Chemie der Polymeren Kohlenhydrate (Karrer, book review) 1852
- Centrifugal force, influence on rate of evapn 135
- Centrifuge, application of the oil turbine type of ultra, to the study of the stability region of CO-hemoglobin 2920
- Cesium amalgam, vapor pressure of 3011
- Cesium azido-dithiocarbonate 917
- Chamositic substances, Über die Natur und Bildungsweise der marinen Eisen-silikate insbesondere der (Berz, book review) 1390
- Charcoal, heats of adsorption of several gases and vapors on, 156 adsorption of water vapor by, 708, adsorption from soln by ash-free adsorbent, 1686, adsorption of Hg vapor by 1949
- Chaulmoogra oil, chem investigation of 1119
- Chaulmoogric acid, synthesis of compds similar to, 517, *dl* 1070
- Chemical compounds, crystal structures of 2 intermetallic compds 3107
- Chemical constitution, study of the, of certain org compds by the absorption of light, 847, connection between, and tinctorial properties in the thioflavine and chloramine yellow groups, 1315, Gesammelte Abhandlungen von Dr F Kehrman (Kehrman, Sandor, book review) 1615
- Chemical industry, Kolloidchemische Technologie—Ein Handbuch kolloid chem Betrachtungsweise in der (Liesegang, book review) 1391
- Chemistry, Introductory College (Gordon, book review), 581, Chem Calcns (Jaffe, book review), 582, Principles of General (Brinkley, book review), 582 A Handbook of Elementary, for Students of Medicine, Dentistry and Pharmacy (Attix, book review), 887, Tables Annuelles de Constantes et Donnees Numériques de (Cohen, *et al*, book review), 887, Comprehensive Treatise on Inorg and Theoretical (Mellor, book review), 1122, General (Cady, book review), 1605, Thermodynamics and (MacDougall, book review), 1610 Old Chemistries (Smith, book review), 1847, Physico Chem Metamorphosis and Some Problems in Piezochemistry (Cohen, book review), 1849 Die Welt der Atome (Haas, book review), 1850, Die Verwendung der Röntgenstrahlen in (Mark, book review), 2123, General—Theoretical and Descriptive (McCutcheon, Seltz, book review), 2948, Outlines of Theoretical (Getman, book review), 3192 Contemporary Developments in (book review) 3195
- Chloramine yellow group, connection between chem constitution and tinctorial properties in 1315
- Chloranil, use of the, electrode in glacial AcOH and the strength of certain weak bases 3047
- Chloride ion, reaction with Br in HCl 142
- Chlorides, SiCl_4 as a reagent for the prepn of acid 2114
- Chlorination, of β, β dichloroethyl sulfide 3119, 3125
- Chlorine, action of light on, 2184, behavior of azido carbon disulfide toward 2759
- Chloroacetic acids, infra red absorption spectra of, 50 reaction with NH_3 2889
- Chloromethylacetophenones 1846
- 6 Chloro 5 nitro *m* toluenesulfonic acid, prepn of the Na salt of 298
- Chlorovanillin, prepn of, and some of its derivs 535
- Cholesterol, soly of non radiated, in liquid NH_3 2526
- Cinchophen analogs, synthesis of some new and intermediate products 2650
- Cinnamic acid, sulfonation of—action of NaHSO_3 upon derivs of, 258 addn of Et and tertiary butyl hypochlorites to 2071
- Cinnamyl chloride, reaction between Mg, CO_2 and 1825
- Citric acid, influence of Na salt of, upon the activity of pancreatic amylase, 2596, occurrence of Ca citrate crystals in cultures of butyric acid forming bacteria and the H_2O of crystn of Ca citrate 2884
- Coating, structure of a protective, of Fe oxides, 969, (correction) 3189
- Cobalt, catalytic activity and adsorptive power of supported 2783
- Coconut oil, lower fatty acids of 2829
- Coffee nut tree seed oil, Kentucky 2061
- Colloid chemistry, Practical (Ostwald, Wolski, Kuhn, book review), 1390, Kolloidchemische Technologie—Ein Handbuch kolloidchemischer Betrachtungsweise in der chem Industrie und Technik (Liesegang, book review), 1391, Theoretical and Applied (Alexander, book review) 2340
- Colloids, vol changes attending the formation of rubber sols, 620, prepn and

- properties of colloidal and monoclinic S in org liquids, 630, phenomena in dye solns, 790, prepn of a stable colloidal soln of Pb, 1382, Pyrosole—Das Kolloide Phänomen in der Glühend Flüssigen Materie und seine Erstarrungs Zustände unter Berücksichtigung des Latenten Photographischen Bildes (Lorenz, Eitel, book review), 1612 Surface Equilibria of Biol and Org (Nouy, *et al*, book review), 1613, Katalyse mit Kolloiden Metallen (Huckel, book review), 1614, A Textbook (Kruyt, book review), 1852, Die Herstellung kolloider Lösungen anorg Stoffe (Reitstötter, book review), 2125, Handbuch der biologischen Arbeitsmethoden (Abderhalden, book review) 3198
- Color, Gesammelte Abhandlungen von Dr F Kehrman (Kehrman, Sandoz, book review) 1615
- Compressibility, isotherms of H, N and mixts of these gases, 687, 1955, of Te 1892
- Condition equation, for gaseous CO, 1130 for fluids—application to gaseous Et₂O and CO₂ 1665
- Conduction, electrical, in glass 447
- Conduction, thermal, Muller Pouillet's Lehrbuch der Physik (Eucken, *et al*, book review) 1121
- Conductivity, electrical, variation of the cell const with concn and the molal, of aq Ba(NO₃)₂, Na₂SO₄ and H₂SO₄ at 0°, 636 of dil aq solns of the alkali hydroxides at 25°, 1486 solid soly of Sb in Pb as detd by measurements on cold worked alloys, 1667, of acids and salts in liquid NH₃, 2162 source of error in, measurements, 2167 effect of Fe and O on the, of Cu 2711
- Constantan, Cu-, thermocouples and the H thermometer compared from 15° to 283° abs, 2343, H gas thermometer compared with the O and H vapor pressure thermometers by means of a Cu, thermocouple 2367
- Constants, Données Numériques D'Électricité, Magnétisme et Électrochimie (Buffat, *et al*, book review), 887, Tables Annuelles de, et Données Numériques de Chimie, de Physique et de Technologie (Cohen, *et al*, book review) 887
- Copper, attempts to activate, for catalytic hydrogenation by oxidation and reduction, 25 adsorption of H and C₂H₄ on a, catalyst poisoned with CO 2136 constantan thermocouples and the H thermometer compared from 15° to 283° abs, 2343 H gas thermometer compared with the O and H vapor pressure thermometers by means of a, -constantan thermocouple, 2367 potential of a proposed standard form of, and the activity of CuSO₄, 2423 catalytic combination of C₂H₄ and H in the presence of metallic 2503 effect of Fe and O on the elec cond of, 2711, catalytic activity and adsorptive power of supported 2783
- Copper ammonium chloride, crystal structure of, dihydrate 2149
- Copper compounds, crystal structures of Cu₂Mg and CuAl 3107
- Copper oxide, reduction of mixed ZnO and Cu₂O 1432
- Copper potassium chloride crystal structure of dihydrate 2149
- Copper rubidium chloride, crystal structure of dihydrate 2149
- Copper sulfate potential of a proposed standard form of Cu and the activity of 2423
- Corn cobs, lignin from 2037
- Corn starch, properties of—removal of combined fatty acids 1584
- Corn wax compn of, 1290, (correction) 3189
- Cranberry, non volatile acids of 1300
- p*-Cresol, sepn from its isomers and a study of the h p, 839 h p of *o*-Cresolbenzen, and some of its derivs, 992 absorption spectra of 1588
- Cresyl benzoates, action of anhyd AlCl₃ on 1028
- Crystals, sizes of ions and the structure of ionic, 765, Forschungen zur Kristallkunde (I) Trachten der Kristalle (Tertsch, book review) 2124
- Crystal structure, ionic sizes and their relationship to, type, 201, of NH₄, K and Rb cupric chloride dihydrates, 2149, of HgI₂ and HgI, 2357, of 2 intermetallic compds 3107
- Cyclohexane, equil between benzene, H and 1157
- Cyclohexene, ultraviolet absorption spectrum of 1335, 2106, 3137
- ω -Cyclohexylalkylacetic acids, various, and their action toward *B leprae* 2934
- 1-Cyclohexyl 3-carbethoxy-4 piperidyl *p* aminobenzoate 2862
- Cyclohexylphenols 2098
- Δ^2 -Cyclopentenylalkylacetic acids, certain, and their action toward *B leprae* 2940
- Cyclopropane ring, suggested mechanism of the splitting of, by Br 2066
- p* Cymene, studies 494, 572, 2819, 2832

- p*-Cymylene 2,5 diamine 2819
p-Cymylene-2,6-diamine, bromination of 572
 Cystine, decompn of free and combined, with special reference to certain effects produced by heating fish flesh 2540
- DEHYDROTHIO *p* TOLUIDINE**, synthesis of new isomers of, and of some related compds 1315, 3135
 Density, micro method for the detn of 2988
 Dentistry, A Handbook of Elementary Chemistry for Students of (Attix, book review) 887
 Diacetone alcohol, ethers of, 530, decompn of, in alkali hydroxide solns 2955
 α, β Diacylstyrenes, synthesis of, and their reaction with HBr 2110
 Dibenzoarsenole, derivs of 482
 Dibenzoylethylene mode of addn of halogen to 1106
 Dicarboxyphenylarsonic acids, and derivs 3165
 Dichloroacetic acid, reaction with aromatic amines 1091
 1,2 Dichloroanthraquinone, formation from *o* dichlorobenzene 2334
 2,3 Dichloroanthraquinone, formation from *o* dichlorobenzene 2334
o Dichlorobenzene, prepn of alizarin from phthalic anhydride and, 473, 2335
 formation of 1,2 dichloroanthraquinone and 2,3 dichloroanthraquinone from 2334
 β, β Dichloroethyl sulfide, chlorination of 3319, 3125
 Dielectric constants, of binary mixts 1676 2408, 2416
m Diethylbenzene, and some of its derivs 3157
 Diffusion, of O through Ag, 312, app for measuring the, of gases and vapors through membranes, 427, potential measurements applied to HCl gelatin systems 1921, 1934
dl 1,2 Dihydroxybutyric acids, prepn of the two 2309
 1,4 Diketones, unsatd 1106
 Diphenylamine, catalytic reduction of, with H and Pt oxide Pt black, 1099 as a qual reagent for Zn 2214
 Diphenylbenzidine, as an internal indicator for the titration of Zn with $K_4Fe(CN)_6$ 356
 Diphenylcarbinol, absorption spectra of 1541
 Diphenylmethane, absorption spectra of, and its carbinol 1541
 Diphenylmethylamine 1742
 Dissociation, pressures of KH_2PO_4 and NaH_2PO_4 and of $K_2H_2P_2O_7$ and $Na_2H_2P_2O_7$ 375
 Dissociation constant, of nitramide 193
 Distillation, high vacuum 2118
 Dithionic acid, decompn and oxidation of 703
 Dixanthyl 9,9' dicarboxylic acid 2080
 Dixanthyls, dissociate into free radicals of substituted 2080
 Double salt, ionic sizes and their relationship to formation of 201
 Drugs, effect of polarized light on the pharmacol properties of some 2017
 Dyeing, Chemistry of (Wood, book review) 1615
 Dyes, 2 amino 6 nitro *p* cymene and certain new azo 494 colloidal phenomena in solns of, 790 thiazoles—connection between chem constitution and tinctorial properties in the thioflavine and chloramine yellow groups, 1315 constitution of erythrosin and related, 1594 new, derived from 2 amino and 2 amino 5-bromo *p* cymene, 2819, azo, contg Sb 2869
- ELECTRIC DISCHARGE**, chem action in the elec spark discharge—ignition of methane 396
 Electric field, luminescence of Grignard compds, in 1858
 Electricity, Données Numériques D'Électricité (Buffat, *et al*, book review) 887
 Electric moments, of substituted benzene mols and the structure of the benzene ring, 1030, of certain org mols in benzene soln, 1676 of certain org mols in CCl_4 soln 2408
 Electric resistors, new variable 451
 Electro analysis, Elektroanalytische Schnellmethoden (Fischer, Schleicher, book review) 1611
 Electrochemistry, Données Numériques de (Buffat, *et al*, book review) 887
 Electrodes, equil in the Weston standard cell, 78 attempt to measure the potential of the Au Au_2O_3 , 1271, potential of the Au Au_2O_3 , 1855 free energy of Au_2O_3 as detd from measurements of the Au- Au_2O_3 , 1989, use of the chloranil, in glacial AcOH and the strength of certain weak bases 3047

- Electrolysis, of Grignard solns. 1295
- Electrolytes, activity coeffs. of, 363, 410; effect on the photochem. decompn. of $K_2S_2O_8$, 960; Equilibria in Satd. Salt Solns.—Summary of the Heterogeneous Equilibria Which Exist in Aq. Solns. of (Blasdale, book review), 1606; activity coeffs. of—bi-bivalent salt and the ion attraction theory 2372
- Electrons, activation of mol. H by impact of, 58; electron-sharing ability of org. radicals 1786
- Electro-ultrafiltration, *Handbuch der biologischen Arbeitsmethoden* (Abderhalden, book review) 3198
- Enargite, as a possible source of Ge 3028
- Energy, free, of reduction of quinones referred to the gaseous state, 293; *Lehre von der strahlenden* (Lummer, *et al.*, book review), 1120; free, of formation of phosphine, 1901; free, of Au_2O_3 , 1989; computation of the free, in gaseous mixts. of C_2H_4 and A 2172
- Engineer, Art de (Descroix, book review) 888
- Enzymes, effect of C_2H_4 on the, of pineapples, 1117; *Lehrbuch der* (Oppenheimer, Kuhn, book review), 2128; Properties, Distribution, Methods and Applications (Waksman, Davison, book review) 2341
- Equation of state, for gaseous CO_2 , 1130; for fluids—application to gaseous Et_4O and CO_2 1665
- Equilibrium, electrode, in the Weston standard cell, 78; action of light on the ferrous-ferric: I-iodide, 976; pressures of a gas in a mixt., especially of NH_3 , mixed with N, 1146; between benzene, H and cyclohexane, 1157; in solns. of alkali carbonates, 1235; chem., in non-ideal gases whose isometrics are linear, 1393; between cryst. $Zn(OH)_2$ and aq. solns. of NH_4OH and of $NaOH$, 1419; in Satd. Salt Solns. (Blasdale, book review), 1606; Surface, of Biol. and Org. Colloids (Noüy, *et al.*, book review), 1613; high-temp., between ThO_2 and C, 2744; high-temp., between Al_2O_3 and C, 2753; reduction, of ZnO and CO (correction) 3189
- Ergot, identity of ergothioneine from, of rye with sympectothion and thiasine from pigs' blood 575
- Ergothioneine, identity of, from ergot of rye with sympectothion and thiasine from pigs' blood 575
- Erythrosin, constitution of, and related dyes 1594
- Esters, unsatn. phenomena of acetylenic acids and 2258, 2264
- Ethyl acetate, coeff. of sapon. of, by $NaOH$, 2216; sapon. of 2257
- Ethyl alcohol, decompn. at the surface of thoria, 104, 116; revision of some activities in water-, mixts., 217; reaction between K_2CO_3 and S in alc. soln. 3114
- Ethylbenzene, some derivs. of 3150
- Ethylene, effect on the enzymes of pineapples, 1117; action on pure starch, 2116; adsorption on a Cu catalyst poisoned with CO, 2136; computation of the free energy and fugacity in gaseous mixts. of A and, 2172; catalytic combination of, and H in the presence of metallic Cu, 2503; reaction with H in the presence of excited Hg atoms 3131
- Ethylene chlorohydrin, ultraviolet absorption spectrum of 1335, 2106, 3137
- Ethyl ether, pressure-vol.-temp. relation for gaseous, 1123; ultraviolet absorption spectrum of, 1335, 2106, 3137; equation of state for fluids—application to gaseous, 1665; reactions of anesthetic, with KOH and with Hg and the test for foreign odors 2655
- Ethyl hypochlorite, addn. to cinnamic acid 2071
- Evaporation, influence of centrifugal force on rate of 135
- FATS, *boa constrictor* 2046
- Fatty acids, removal of combined, from corn starch, 1584; some pseudo-thiohydantoin and α -mercapto acids from higher, 2064; rate of reaction between Br and unsatd., as evidence of stereo-isomerism, 2808; lower, of coconut oil 2829
- Fermentation tube, new 2118
- Ferric salts, etc. See *Iron salts*.
- Ferrous salts, etc. See *Iron salts*.
- Fertilizers, Phosphatic (Waggaman, Easterwood, book review) 3195
- Films, plastic, and the drop-wt. method of interfacial tension measurement 1991
- Fish, decompn. of free and combined cystine with special reference to certain effects produced by heating, flesh 2540

Flames, mechanism of the uniform movement in the propagation of.....	386
Flowing junction, simple type of.....	2787
Fluorescein, and some of its derivs., 1272, (correction).....	3189
Fluorescence, in mixts. of NH_3 and Hg vapor.....	2699

- Helium group (Mellor, book review)** 1122
- Hexaarsenoacetic acid** 998
- Hexanoic acid, some Br derivs of** 1828
- History, Old Chemistries (Smith, book review), 1847, Text Book of Org Chemistry (Read, book review)** 1854
- Hydantoins, various effects produced by the action of light upon the isomeric modifications of certain polypeptide-** 2877
- Hydrates, ionic sizes and their relationship to crystal structure type, solid soln and double salt formation and the stability of** 201
- Hydration, $NaPO_3$ and its acid, 1878, of $NaPO_3$ in alk soln at 75°** 2180
- Hydrazines, mol rearrangement of some new unsymmetrical, 286 prcpn of optically active** 1043
- Hydrazino bases, addn to nitrostyrene** 1598
- Hydrazoic acid, volumetric detn of** 2133
- Hydrobenzamide, as ammono aldehyde** 1558
- Hydrobromic acid, reaction with α, β -diacylstyrenes** 2110
- Hydrocarbons, reaction of lactones and of furfuran derivs with aromatic, and $AlCl_3$, 562, deviations from Raoult's law for mixts of, 750 catalytic prepn of unsatd, from CO and H , 796 "satn" of the petroleum lubricant, as shown by their reaction with Br , 1116, structure of $C_{17}H_{18}$ obtained by the dehydration of *tert*-butyldiphenylcarbinol** 2914
- Hydrochloric acid, partial molal heat capacity of the constituents and the sp heat of aq solns of $NaCl$ and, 93, reaction between Br and chloride ion in, 142 diffusion-potential measurements applied to, -gelatin systems, 1921, diffusion-potential measurements applied to, -gelatin systems—components of, -gelatin solns, 1934, f ps of aq solns of** 2795
- Hydrogen, activation of mol, by electron impact, 58 concn of water vapor in compressed N and a mixt of these gases in the presence of condensed water, 65, infra-red absorption by the N -, bond, 347 compressibility isotherms of N and, and mixts of these gases, 687, 1955, catalytic prepn of unsatd hydrocarbons from CO and, 796, reduction of aromatic nitro compds to amines with, and Pt -oxide Pt black as a catalyst, 1093, reduction of di- and triphenylamines with, and Pt -oxide Pt black, 1099, equil between benzene, cyclohexane and, 1157, influence of water on the combination of the halogens with, 1416, selective reduction of furfuralacrolein by means of Pt -oxide Pt black and, 2101, adsorption on a Cu catalyst poisoned with CO , 2136, Cu constantan thermocouples and the, thermometer compared from 15 to 283° abs, 2343, gas thermometer compared with the O and H vapor-pressure thermometers by means of a Cu -constantan thermocouple, 2367, catalytic combination of C_2H_4 and, in the presence of metallic Cu , 2503, relative reactivities of the hydroxyl-, atoms in certain alcs, 2640, interference of nitro and nitroso groups**

- on the Zerewitnoff method for estg active, 2815, reaction with ethylene in the presence of excited Hg atoms 3131
- Hydrogenation, attempts to activate Cu for catalytic, by oxidation and reduction 25
- Hydrogen-ion, establishment of the optimal, activities for the enzymic hydrolysis of starch by pancreatic and malt amylases under varied conditions of time and temp, 2000, chem investigation of the, activity of AcOH solns 3062
- Hydrogen ion concentration, Indicators Their Use in the Colorimetric Detn of (Kolthoff, book review) 2952
- Hydrogen peroxide, action of alk, soln on tetramethyl-*d*-glucose, 1512, decomposition by $K_2Cr_2O_7$, accelerated by Mn salts, 1630, formation photosensitized by Hg vapor 2763
- Hydrolysis, detn of relative rates for the acid, of positive halogens, 2849, kinetics of the acid, of halogen phenols and halogen naphthols 2853
- Hydroquinones, sublimation pressures of substituted 100
- Hydroxamic acids, rearrangement of acid azides and, of geometrical isomers 2528
- Hydroxyanthraquinones, poly 486
- Hydroxyanthrarufin, structure and synthesis of 486
- 4-Hydroxy 3 isopropyl 6-methylbenzophenone, and derivs 818
- Hydroxylamines, substituted *o* alkyl, chemically related to medicinally valuable amines 1527
- Hydroxylaminovaleric acids, synthesis of two 538
- Hydroxyl group, relative reactivities of the hydroxyl H atoms in certain alcs 2640
- Hydroxymethylanthraquinones 2043
- Hydroxynaphthoquinone, alkylation of, 857, studies 2825
- Hydroxysearic acids, synthesis of 9-, 10-, 11-, 12- and 13- 522
- Hydroxyureas, structure of 266
- Hypochlorites, detn of excess of alkali in solns of 791
- IGNITION, of methane by the elec spark discharge, 396, of natural gas air mixts by heated metal bars 2479
- Imidazole ring, reduction potentials of quinones contg the 2604
- Indicators, diphenylbenzidine as an internal, for the titration of Zn with $K_4Fe(CN)_6$, 356 use of methoxytriphenylcarbinols as one-color, 1218, Their Use in Quant Analysis and in the Colorimetric Detn of H Ion Concn (Kolthoff, book review) 2952
- Indigo, synthesis of substitution derivs of 499
- Indium, potentiometric detn of 2739
- Indium hydroxide, reaction of "aluminon" with 216
- Inorganic chemistry, Gmelins Handbuch der (Meyer, book review), 304, 1387, 1607, 2337, comprehensive Treatise on (Mellor, book review), 1122, Recent Advances in (Stewart, book review), 1848, (Schwarz, book review), 1849, Handbuch der (Abegg, book review), 2120, General (Sneed, book review), 2335 Properties of Inorg Substances (Segerblom book review) 2336
- Interfacial tension, plastic films and the drop wt method of, measurement 1991
- Invertase, Clerget-, hydrolysis consts of sucrose and raffinose 1019
- Iodides, action of light on the ferrous ferric I, equil 976
- Iodine, thermal dissocn of, 656 action of light on the ferrous-ferric -iodide equil, 976 behavior of azidocarbonyl disulfide toward 2759
- 2-Iodomethylfuran 1061
- Ions, electrolytic, sizes of, and their relationship to crystal structure type, solid soln and double salt formation and the stabilities of hydrates and ammoniates, 201, sizes of, and the structure of ionic crystals, 765, bi-bivalent salt and the, attraction theory 2372
- Iron, structure of protective coating of Fe oxides, 969, (correction), 3189, detn of ferrous, in silicates, 1472, thioglycolic acid as a color test for, 1916, effect on the elec cond of Cu, 2711, catalytic activity and adsorptive power of supported 2783
- Iron chloride, gasometric detn of NO, with special reference to absorption by $FeCl_2$ 979
- Iron oxides, structure of a protective coating of, 969, (correction) 3189
- Iron salts, action of light on the ferrous-ferric I-iodide equil 976
- Iron silicates, Über die Natur und Bildungsweise der marinen (Berz, book review) 1390
- Isomerism See *Stereoisomerism*

Isomers, rearrangement of acid azides and hydroxamic acids of geometrical, 2528, various effects produced by the action of light upon the isomeric modifications of certain polypeptide-hydantoins	2877
Isometrics, chem equilibria in non-ideal gases whose, are linear, 1393, of gaseous methane	1403
Isomro compounds, mechanism of the change of, to nitro compds	1765
Isopropylcarbinol	1068
Isopropylethylene, rearrangement to trimethylethylene	2624
Isotherms, compressibility, of H, N and mixts of these gases	687, 1955
Isotopes, attempts to sep the, of Hg by chem means	1500
Isoureas, acyl-	3177
Isoxazoline oxides	219
JELLIES , detn of tensile strengths of gelatin	2994
KETONES , reducing action of a mixt of MgI_2 or $MgBr_2$ and Mg on aromatic, 236, NCI_3 and unsatd	2593
δ Ketonic esters, Br derivs of some	566
δ Ketonic nitriles, some reactions of	1112
2 Keto 11 undecylic acid, constitution of	2258
Kinetic salt effects, of formic acid in neutral salt solns	1
Kinetic theory, Muller Pouille's Lehrbuch der Physik —Kinetische Theorie der Wärme (Herzfeld, book review)	3193
Kodak Research Laboratories, Abridged Scientific Publications from the (book review)	2952
LACTONES , reaction with aromatic hydrocarbons and $AlCl_3$	562
Lanthanum chloride, activity coeff of HCl in aq solns with	1435
Lapachol, synthesis of	857
Laws, activity coeffs of electrolytes—limiting, for a tri trivalent salt, 363 deviations from Raoult's, for hydrocarbon mixts, 750 paramagnetism and the 3rd law of thermodynamics	1870
Lead (Mellor, book review), 1122, prepn of a stable colloidal soln of, 1382, solid soly of Sb in	1667
Lead alloys, x ray study of, with Tl, 666, solid soly of Sb in Pb as dctd by cond measurements on cold worked alloys	1667
Lead chloride, change in activity of molten, upon diln with KCl	722
Lead poisoning (Aub, <i>et al</i> , book review)	1615
Lead tetraethyl, some reactions of	830
Lead tetraphenyl, prepn of	2315
Lemon, non volatile acids of	1300
Light, decompn of $K_2S_2O_8$ by, 16 photolysis of KNO_3 , 326, decompn of $K_2S_2O_8$ by, 338 study of the mol constitution of certain org compds by the absorption of, 847 decompn of $K_2S_2O_8$ by—effect of added electrolytes, 960 action on the ferrous-ferric I-iodide equil, 976 effect of polarized, on the phar macol properties of some drugs, 2017, action on Cl , 2184 decompn of NH_3 by relatively short wave lengths, 2495, source for continuous spectrum, 2510, various effects produced by the action of, upon the isomeric modifications of certain polypeptide-hydantoins	2877
Light, infra red, absorption by the N—H bond—in aniline and alkylanilines ...	347
Light, ultraviolet, self integrating chem actinometry for ultraviolet dosage	3081
Lignin, chemistry of, —, from corn cobs	2037
Lipoids, relation of the protein, ratio to the quality of wheats	467
Liquids, application of the phase rule to the calcul of liquid and vapor compns in binary systems	750
Lithium azido-dithiocarbonate	917
Lithium <i>N</i> -butyl, mechanism of the reaction between, and various org halogen compds	2323
Lithium chlorate, properties of the system water—	1226
Lithium iodide, direct oxidation of	701
Litmus, reaction of $NaCl$ if added to a soln of, and $HgCl$	2355
Loganberry, non-volatile acids of	1300
Lophine, metallic salts of	1995

Lubricants, "satn" of the petroleum lubricant hydrocarbons as shown by their reaction with Br	1116
Luminescence, of Grignard compds in elec and magnetic fields, and related elec phenomena	1858
MAGNESIUM , reducing action of a mixt of MgI_2 or $MgBr_2$ and, on aromatic ketones, 236, relation of the, in the ash to the quality of wheats, 457, reaction between cinnamyl chloride, CO_2 and, 1825, reduction of benzil by the binary system MgI_2 (or $MgBr_2$) +	2584
Magnesium amalgam, reduction of benzophenone by	2666
Magnesium bromide, reducing action of a mixt of, and Mg on aromatic ketones, 236, reduction of benzil by the binary system, Mg +	2584
Magnesium compounds, crystal structures of Cu_2Mg	3107
Magnesium diethyl, and its reaction with acetyl chloride, 2328, (correction)	3190
Magnesium iodide, reducing action of a mixt of, and Mg on aromatic ketones, 236, reduction of benzil by the binary system, Mg +	2584
Magnesium subbromide	236
Magnesium subiodide	236
Magnesium sulfate, system, - H_2O from 68 to 240°	2772
Magnetic effects, thermodynamic treatment of certain	1864
Magnetic field, luminescence of Grignard compds in	1858
Magnetic susceptibility, interpretation of the low-temp, of gadolinium sulfate, 1870, of the positive ions of V	2456
Magnetism, Données Numériques de (Buffat, <i>et al</i> , book review), 887, para, and the 3rd law of thermodynamics - interpretation of the low-temp magnetic susceptibility of gadolinium sulfate, 1870, and At Structure (Stoner, book review)	2119
Malachite green, photosynthesis with	1819
Malt, establishment of the optimal H-ion activities for the enzymic hydrolysis of starch by, amylase under varied conditions of time and temp	2000
Maltase, catn from yeast	1723
Manganese salts, decompn of H_2O_2 by $K_2Cr_2O_7$ accelerated by	1630
Manometers, fixed point for the calibration of, 1174, new abs, for low pressures	1953
Medicine, A Handbook of Elementary Chemistry for Students of (Attix, book review)	887
Membranes, app for measuring the diffusion of gases and vapors through	427
Menthol, studies—menthyl esters of the nitro and aminocinnamic acids	452
α Mercapto acids, from higher fatty acids	2064
2 Mercaptothiazole, nitration and reduction of, and its substituted derivs, 1779, (correction)	3189
Mercaptothiazoles	1748
Mercuration, of <i>o</i> -nitrophenol	2840
Mercuric chloride, reaction of NaCl if added to a soln of litmus and	2355
Mercury, effect of added gases on the decompn of NH_3 sensitized by optically excited, vapor, 1478, attempts to sep the isotopes of, by chem means, 1500 adsorption of, vapor by charcoal, 1949, reaction of anesthetic ethers with, 2655, fluorescence in mixts of NH_3 and, vapor, 2699, H_2O_2 formation photo-sensitized by, vapor, 2763, photochem reaction between O and, vapor at relatively low pressures, 3100, H-ethylene reaction in the presence of excited, atoms,	3131
Mercury acetate, reaction between $(AcO) \cdot Hg$ and some acetylenic acids and esters,	2264
Mercury compounds, salicylsulfonphthalein derivs	3139
Mercury iodides, crystal structures of	2357
Mesitylene, derivs of	1801
Métallurgie, Art de L'Ingénieur et (Descroix, book review)	888
Metals, relation between pseudo binary lines and solid solns in ternary systems of, 39, heat capacities of liquid, 1162, activity of various, in promoting the oxidation of methane by air, 1454, Katalyse mit Kolloiden (Huckel, book review), 1614, ignition of natural gas-air mixts by heated bars of, 2479, crystal structures of 2 intermetallic compds	3107
Methane, ignition of, in the elec spark discharge, 396, isometrics of gaseous, 1403, activity of various metals and metal oxide catalysts in promoting the oxidation of, by air	1454
Methanol, catalysts	2468
Methoxytriphenylcarbinols, use as one-color indicators	1218

Methylacridines, synthesis of 1(9)- and 3(7)-	1049
Methyl- <i>n</i> -amyl ether, ultraviolet absorption spectrum of	1335, 2106, 3137
Methyl magnesium iodide, app for detg both the quantity of gas evolved and the amt. of reagent consumed in reactions with	3181
Methylphenylstannanes	1368
Micelle, Handbuch der biologischen Arbeitsmethoden [detn of the structure of colloidal] (Abderhalden, book review)	3198
Milk, identification of some products formed by <i>Bacterium pruni</i> in	1556
Mineralogy, Lehrbuch der (Niggli, Weber, book review)	1389
Minerals, occurrence of Ge in certain Sn	3028
Mixtures, dilec consts of binary	1676, 2408, 2416
Molecular aggregation, adequacy of the assumption of, in accounting for certain of the phys properties of gaseous N	896
Molecular weights, osmometric method of detg the, of proteins	2524
Molecules, primary decompn of, in photochem reactions	2671
NAPHTHALENE , alkylation of	3142
Naphthalenedisulfonic acids, rate of conversion of the 2,7 acid to the isomeric 2,6 acid at 160° in the presence of H ₂ SO ₄	844
Naphtha/rim, bromination of	2825
Naphthols, vapor pressure of the, 1012, kinetics of the acid hydrolysis of halogen.	2853
Nernst heat theorem, The New (Nernst, book review)	303
Nickel, catalytic activity and adsorptive power of supported	2783
Nitramide, dissociation const of	193
Nitrates, nitration of aromatic compds with metallic	1522
Nitration, of aromatic compds with metallic nitrates, 1522, of 2-mercaptobenzothiazole and its substituted derivs, 1779, (correction), 3189 use of N ₂ O ₄ in place of HNO ₃ in org, 2536 of 2 amino <i>p</i> cymene	2832
Nitroacridines, synthesis of 1(9)- and 3(7)-	1049
<i>p</i> -Nitroaniline, derivs of	1801
<i>o</i> -Nitrobenzaldehyde, constitution of	815
Nitrocinnamic acid, menthyl esters of	452
Nitro compounds, reduction of aromatic, to amines with H and Pt oxide Pt black as a catalyst 1093, mechanism of the change of isonitro compds to	1765
2 Nitrofluorene, reduction of	2318
2-Nitrofluorenone oxime, 7-nitrophenanthridone by Beckmann rearrangement of	2618
Nitrogen, concn of water vapor in compressed H and, and a mixt of these gases in the presence of condensed water, 65, rate of hydrolysis of solns of proteins in acids as measured by the formation of amino, 275, infra red absorption by the H, bond, 347 coexisting liquid and vapor phases of solns of O and, 591 vapor pressure of liquid, 610, compressibility isotherms of H and, and mixts of these gases, 687, 1955 adequacy of the assumption of mol aggregation in accounting for certain of the phys properties of gaseous, 896, equil pressures of NH ₃ mixed with	1146
Nitrogen oxides, sp heat of gaseous N ₂ O ₄ , 28, gasometric detn of NO, with special reference to absorption by FeCl ₂ , 979, decompn of N ₂ O ₄ in presence of foreign gases, 1257, use of NO ₂ in place of HNO ₃ in org nitrations	2536
Nitrogen trichloride, and unsatd ketones	2593
Nitro group, interference of, on the Zerewitinoff method for estg active H	2815
Nitroguanidines, alkyl-	2303
α -Nitronaphthalene, alk oxidation of	1831
7-Nitrophenanthridone, by Beckmann rearrangement of 2 nitrofluorenone oxime	2618
Nitrophenanthridones	1324
<i>o</i> Nitrophenol, mercuriation of	2840
Nitrosoben/ene, reaction with phenylmagnesium bromide	1052
Nitroso group, interference of, on the Zerewitinoff method for estg active H	2815
Nitrostyrene, addn of amino and hydrazine bases to	1598
Nitrotrimethylgallylacetic acid, Et ester of, and related compds	499
Nomenclature, of pectin	Proc 37
ODORS , reactions of anesthetic ethers with KOH and with Hg and the test for foreign, 2655, and structure of certain cyclic acetals	3116
Oils, of Kentucky coffee nut tree seed, 2061, essential, in desert plants	2895
Oleic acid, phenylstearic acid from	1103

- Optical rotation, mutarotation of glucose, 2554, and at dimension 3170
- Organic chemistry, Textbook of (Porter, book review), 1391, (Schmidt, book review), 2668, *Die Katalyse in der* (Sabatier, book review), 1392, Problems in (Underwood, book review), 1853, Text Book of,—Historical, Structural and Economic (Read, book review), 1854, Practical (Plimmer, book review), 2127, Principles of (Worrall, book review) 2953, Elementary (Olney book review) 3197
- Organic compounds (See also *Aromatic compounds*) Study of the mol constitution of certain, by the absorption of light, 847 irreversible reduction of, 1083, *Gesammelte Abhandlungen von Dr F Kchrmann* (Kchrmann, Sandoz, book review), 1615, dielec consts of binary mixts—elec moments of certain org mols in benzene soln, 1676, *Organische Molekilverbindungen* (Pfeiffer, book review), 2126, Prepn and Analysis of (Coleman, Arnall, book, review) 2126 estn of Se in, 2330, elec moments of certain org mols in CCl₄ soln, 2408 reactivity of atoms and groups in 2640

- 2-Phenylbenzoselenazole, synthesis of 2011

2-Phenylbenzoselenazole-4'-arsonic acid, synthesis of	2011
<i>m</i> -Phenylenediamine, I derivs. of	1796
<i>p</i> -Phenylenediamine, derivs. of	1801
1-Phenylethyl-3-carbethoxy-4-piperidyl- <i>p</i> -aminobenzoate	2862
Phenylethylmalonic acid, prepn. of Me ester of	541
Phenylgermanium derivatives	457
Phenylhydrazines, <i>p</i> -"active-amyl"	1043
Phenylmagnesium bromide, reaction with nitrosobenzene, 1052; formation of triphenylmethyl peroxide from CO ₂ and	2843
Phenylstearic acid, from oleic acid	1103
Phenylsulfone chlorides, Al amalgam as an agent for the reduction of, to thio-phenols	1386
Phosphates, 123, 2180; activity coeffs. of the ions in certain solns. of, 173; and Phosphatic Fertilizers (Waggaman, Easterwood, book review)	3195
Phosphine, free energy of formation of	1901
Phosphoric acid (Waggaman, Easterwood, book review)	3195
Phosphorus, reaction between elementary, and KIO ₃ and its utilization in the volumetric detn. of	9
Phosphorus iodides, prepn. and m. ps. of pure PI ₂ and PI ₃	307
Phosphorus pentafluoride, new method of prepg.	1270
Phosphorus pentoxide, detn. as MgNH ₄ PO ₄	891
Photochemistry, photochem. rearrangement of acetylchloroaminobenzene, 2145; decompn. of NH ₃ by relatively short wave lengths, 2495; primary decompn. of mols. in photochem. reactions, 2671; photochem. reaction between O and Hg vapor at relatively low pressures, 3100; Optische Methoden der Chemie (Weigert, book review)	3194
Photographic latent image, Pyrosol—Das Kolloide Phänomen in der Glühend Flüssigen Materie und seine Erstarrungs-Zustände unter Berücksichtigung des (Lorenz, Eitel, book review)	1612
Photography, Abridged Scientific Publications from the Kodak Research Labs. (book review)	2952
Photosensitization, 2438; H ₂ O ₂ formation photosensitized by Hg vapor	2763
Photosynthesis (Spoehr, book review), 889; with malachite green	1819
<i>o</i> -Phthalaldehydic acids, structure of the condensation products of, with phenols and phenol ethers	2279
Phthalic anhydride, prepn. of alizarin from <i>o</i> -dichlorobenzene and	473, 2335
Physical chemistry, for Colleges (Millard, book review), 303; Comprehensive Treatise on Inorg. and Theoretical Chemistry. Vol. VII (Mellor, book review), 1122; Recent Advances in (Stewart, book review), 1848; Physico-Chem. Metamorphosis and Some Problems in Piezochemistry (Cohen, book review), 1849; Physico-Chem. Geology (Rastall, book review), 2338; Problem of Physico-Chem. Periodicity (Hedges, Myers, book review), 2338; Outlines of Theoretical Chemistry (Getman, book review)	3192
Physics, Tables Annuelles de Constantes et Données Numériques de (Cohen, <i>et al.</i> book review), 887; Müller-Pouillet's Lehrbuch der (book review), 1120, 1121, book review)	3193
Piezochemistry, Physico-Chem. Metamorphosis and Some Problems in (Cohen, book review)	1849
Pineapples, effect of ethylene on the enzymes of	1117
Pinene, rate of racemization of	43
Piperidine, derivs.—substituted, -alkyl benzoates and <i>p</i> -aminobenzoates, 2835; derivs.	2862
Piperidyl <i>p</i> -aminobenzoate	1307
Plants, essential oils in desert	2895
Plastic films, and the drop-wt. method of interfacial tension measurement	1991
Platinum, reduction of aromatic nitro compds. to amines with H and Pt-oxide, black as a catalyst, 1093; catalytic reduction of di- and triphenylamines with H and Pt-oxide, black, 1099; selective reduction of furfuralcrolein by means of Pt-oxide, black and H	2101
Platinum metals, Beiträge zur Chemie der (Claus, book review)	890
Platinum oxide, reduction of aromatic nitro compds. to amines with H and, Pt black as a catalyst, 1093; catalytic reduction of di- and triphenylamines with H and, Pt black, 1099; selective reduction of furfuralcrolein by means of, Pt black and H	2101
Polarity, of the C-halogen bond	2849, 2853

Polymerization, of the amylenes	873
Polymerphism, Physico-Chem Metamorphosis and Some Problems in Piezochemistry (Cohen, book review)	1849
Polypeptide, various effects produced by the action of light upon the isomeric modifications of certain, -hydantoins	2877
Polysaccharides, Einführung in die Chemie der Polymeren Kohlenhydrate (Karrer, book review)	1852
Polysulfides, aliphatic	491
Pomegranate, non-volatile acids of	1300
Potassium amalgams, vapor pressures of	3003
Potassium carbonates, system $\text{Na}_2\text{CO}_3\text{--K}_2\text{CO}_3\text{--H}_2\text{O}$, 669, 2734, systems $\text{K}_2\text{CO}_3\text{--KHCO}_3\text{--H}_2\text{O}$, 967, reaction between, and S in alc soln	3114
Potassium chloride, change in activity of molten PbCl_2 upon diln with, 722, transference nos of Na and K in mixed chloride soln	1493
Potassium cupric chloride, crystal structure of, dihydrate	2149
Potassium dichromate, decompn of H_2O_2 by, accelerated by Mn salts	1630
Potassium ferrocyanide, diphenylbenzidine as an internal indicator for the titration of Zn with	356
Potassium hydroxide, reaction of anesthetic ethers with	2655
Potassium iodate, reaction between elementary P and, and its utilization in the volumetric detn of P	9
Potassium ion, transference nos of Na and K in mixed chloride soln	1493
Potassium nitrate, photolysis of	326
Potassium persulfate, photochem decompn of	16, 338, 960
Potassium phosphate, dissocn pressure of KH_2PO_4 , 375, $\text{KH}_2\text{P}_2\text{O}_4$	1511
Potassium pyrophosphate, dissocn pressure of $\text{K}_2\text{H}_2\text{P}_2\text{O}_7$	375
Potential, electric, reduction, of quinones, 293, apparent reduction, of unsatd carbonyl compds, 1083, attempt to measure the, of the Au-Au ₂ O electrode, 1271, of the Au-Au ₂ O electrode, 1855, diffusion, measurements applied to HCl-gelatin systems, 1921, 1934, of a proposed standard form of Cu and the activity of CuSO_4 , 2423, reduction, of quinones contg the pyridine, imidazole, triazole and thiophene rings, 2604, simple type of flowing junction	2787
Pressure gages See <i>Manometers</i>	
Pressure, equal, of a gas in a mixt, especially of NH_3 mixed with N, 1146, dependence of rate of thermal decompn of ozone on, 1183, Physico-Chem Metamorphosis and Some Problems in Piezochemistry (Cohen, book review)	1849
Promoter action, in homogeneous catalysis—decompn of H_2O_2 by $\text{K}_2\text{Cr}_2\text{O}_7$ accelerated by Mn salts	1630
Propionanilide, system acetanilide—	2296
1,2-Propylene glycol, reciprocal soly of the normal propyl ethers of, and water, 1080, (correction)	3189
Propyl ethers, reciprocal soly of the normal, of 1,2 propylene glycol and H_2O , 1080, (correction)	3189
Proteins, rate of hydrolysis of solns of, in acids as measured by the formation of amino N, 275, relation of the lipid, ratio to the quality of wheats, 467, osmometric method of detg the mol wts of	2524
Pseudo thiohydantoins, some, from higher fatty acids	2604
Pyridine ring, reduction potentials of quinones contg the	2604
Pyrogallolbenzene, and derivs	1284
Pyro-sols (Lorenz, Eitel, book review)	1612
QUANTUM THEORY, Evolution and Development of the (Bligh, book review)	2122
Quinazolines	2650
Quince, non-volatile acids of	1300
Quinoline, synthesis of certain, compds	810
Quinones, sublimation pressures of substituted, 100, reduction potentials of, - free energy of reduction referred to the gaseous state, 293, reduction potentials of, contg the pyridine, imidazole, triazole and thiophene rings	2604
Quinone sulfurimines	1361
RACEMIZATION, rate of, of pinene	43
Radiation, influence on thermal unimol reactions	3033
Radicals, electron-sharing ability of org, 1786, dissocn into free, of substituted dioxanthyis	2080

Radioactivity, Manual of (Hevesy, book review), 305; (Meyer, Schweidler, book review).....	2122

- Tetrazole, metallic salts of 1995
- Thallium alloys, x-ray study of, with Pb. 666
- Thallium hydroxide, reaction of "aluminon" with 216
- Thermochemistry, standardization of Richards' thermochem. data 2476
- Thermocouple, Cu-constantan, and the H thermometer compared from 15° to 283° abs., 2343; H gas thermometer compared with the O and H vapor-pressure

- thermometers by means of a Cu-constantan . 2367
 Thermodynamics, of non isothermal systems, 792, 794, Muller-Pouillet's Lehrbuch der Physik (Eucken, *et al*, book review), 1121, for Students of Chemistry (Hinshelwood, book review), 1608, and Chemistry (MacDougall, book review), 1610, treatment of certain magnetic effects, 1864, paramagnetism and the 3rd law of 1870
 Thermometer, Cu-constantan thermocouples and the H, compared from 15 to 283° abs, 2343, H gas, compared with the O and H vapor pressure, by means of a Cu-constantan thermocouple 2367
 Thermoregulators, 985, automatic low-temp thermostat, 360, purification of toluene for, 1994, convenient thermostat heater 2255
 Thiasine, identity of ergothioneine from ergot of rye with sympectothion and, from pigs' blood 575
 Thiazoles 1315, 1373, 1779, 3135, 3189
 2-Thienylbenzoselenazole, synthesis of 2011
 Thioflavine group, connection between chem constitution and tinctorial properties in 1315
 Thioglycolic acid, as a color test for Fe 1916
 Thiophene ring, reduction potentials of quinones contg the 2604
 Thiophenols, Al amalgam as an agent for the reduction of phenylsulfone chlorides to 1386
 Thorium (Mellor, book review) 1122
 Thorium oxide, decompn of EtOH at the surface of, 104 decompn of EtOH at the surface of,—adsorption on the, catalyst, 116, high temp equil between C and 2744
 Thymolbenzoin, and derivs 818
 Thymoltetrachlorophthalein, and some of its derivs 826
 Tin (Mellor, book review) 1122
 Tin iodide, soly relations of SnI₄ 729
 Tin minerals, occurrence of Ge in certain 3028
 Tissues, colorimetric estn of Si in, by Isaacs' method 429
 Titanium (Mellor, book review), 1122, (Thornton, book review) 2339
 Toluene, purification of, for thermo regulators, 1994 alkylation of 3142
o-Toluidine, sulfonation of 298
 Toluidines, vapor pressure of the 1007
 Transference numbers, of Na and K in mixed chloride soln, 1493, moving boundary method for detg 1710
 1,2,4-Triazole, metallic salts of 1995
 Triazole ring, reduction potentials of quinones contg the 2604
 Trimethylethylaniline, resolution of 1039
dl-p Trimethylethylbenzoyl chloride, prepn of 1039
 Trimethylethylene, rearrangement of isopropyl ethylene to, and the pyrogenic decomn of pentene 2 and 2624
 Triphenylamine, catalytic reduction of, with H and Pt oxide Pt black 1099
 Triphenylcarbinols, methoxy-substituted, and their salts, 1346, absorption spectra of 1541
 β -Triphenylethylamine, prepn of 1735
 Triphenylmethane, absorption spectra of, and its carbinol 1541
 Triphenylmethyl chloride, absorption spectra of 1541
 Triphenylmethyl peroxide, formation from CO₂ and phenylmagnesium bromide 2843
 β -Triphenylpropionhydroxamic acid, rearrangement of 1735
 Tungsten compounds, seleno 3076

 ULTRACENTRIFUGE, application of the oil turbine type of, to the study of the stability region of CO-hemoglobin 2920
 Ultrafiltration, Handbuch der biologischen Arbeitsmethoden (Abderhalden, book review) 3198
 Urethans 2942

 VACUUM OVEN 985
 Valence, activity coeffs of electrolytes—the unsymmetric valence-type effect in highly dil solns 410
 Vanadium, iodimetric detn of 1138
 Vanadium ions, magnetic susceptibilities of the positive 2456
 Vanillin, new monobromo derivs of, 1077, new derivs of, and some of their reactions 1571

- Vapor pressure, of liquid O and N, 610, studies in,—the toluidines, 1007, studies in,—the naphthols, 1012, of liquid CO_2 at 0° , 1174, curve of BzOH , 1280, -temp relations of the binary system $\text{Ca}(\text{NO}_3)_2\text{--H}_2\text{O}$, 1963, of the satd aq solns of certain salts, 1974, H-gas thermometer compared with the O and H, thermometers by means of a Cu-constantan thermocouple, 2367, of K amalgams, 3003, of Na and Cs amalgams 3011
- Vapors, heats of adsorption of several gases and, on charcoal, 156, app for measuring the diffusion of, through membranes, 427, application of the phase rule to the calcul of liquid and vapor comps in binary systems 750
- Vinyl chloride, some phys properties of 2801
- WATER**, concn of water vapor in compressed H, N and a mixt of these gases in the presence of condensed, 65, system $\text{K}_2\text{CO}_3\text{--Na}_2\text{CO}_3$, 669, 2734 system $\text{KHCO}_3\text{--K}_2\text{CO}_3$, 967, reciprocal soly of the normal propyl ethers of 1,2-propylene glycol and, 1080, (correction), 3189, properties of the system Li--ClO_3 , 1226, influence on the combination of the halogens with H, 1416, temp compn relations of the binary system $\text{Ca}(\text{NO}_3)_2$, 1958, vapor pressure temp relations of the binary system $\text{Ca}(\text{NO}_3)_2$, 1963, colorimetric detn of Al in, 2395, system $\text{Na}_2\text{CO}_3\text{--NaHCO}_3$, 2487, soly in liquid CO_2 , 2729, system MgSO_4 , from 68 to 240° , 2772, acidity of the, of some Puget Sound bogs, 2981, app for the removal of dissolved gases from 2991
- Water of crystallization, of Ca citrate 2884
- Water vapor, concn of, in compressed H, N and a mixt of these gases in the presence of condensed water, 65, adsorption by charcoal, 708, catalytic synthesis of, in contact with metallic Au 2426
- Wax, compn of corn, 1290, (correction) 3189
- Wheat, relation of the Mg in the ash and the lipid protein ratio to the quality of 467
- Wurtz-Fittig reaction, mechanism of 2089
- X-RAYS** See *Rays, Rontgen*
- YEAST**, extn of maltase from 1728
- ZEREWITINOFF METHOD**, interference of nitro and nitroso groups on the, for estg active H 2815
- Zinc, diphenylbenzidine as an internal indicator for the titration of, with $\text{K}_4\text{Fe}(\text{CN})_6$, 356, diphenylamine as a qual reagent for 2214
- Zinc hydroxide, equil between cryst, and aq solns of NH_4OH and NaOH 1419
- Zinc oxide, reduction of mixed Cu_2O and, 1432, heat of formation of, 2792 reduction equilibria of, and CO (correction) 3189
- Zirconium (Mellor, book review) 1122

PROCEEDINGS

OF THE

American Chemical Society

1927

EASTON, PA.
MACK PRINTING COMPANY
1927

Proceedings

DIRECTORS' MINUTES

The Directors of the AMERICAN CHEMICAL SOCIETY met at the Chemists' Club, New York City, on November 27, 1926, at 3 P. M., with President James F. Norris in the chair and Directors Bancroft, Bigelow, Talbot, Teeple and Parsons present.

John E. Teeple was re-elected Treasurer for a period of three years.

The Secretary announced the gift of Five Thousand Dollars from the Chemical Foundation to enable the Industrial Journal to print without delay the accumulated and important manuscripts on hand. The Industrial Journal had accepted manuscripts to fill its pages until June, some of them of unusual importance to the chemical industries. The gift of Five Thousand Dollars will enable this JOURNAL to print all, except the manuscripts now on hand, not later than the February issue. The Directors approved the action of the Secretary and Business Manager in accepting the gift on their behalf and requested him to send their appreciative thanks to the Chemical Foundation and to Mr. Francis P. Garvan.

The Directors considered the advisability of holding an exhibit of chemical manufacturers, chemical apparatus, chemical books, etc., at each annual meeting of the SOCIETY at the risk and for the financial benefit of the general Society. In view of the success of the exhibit at Philadelphia and the success of similar exhibits by other organizations, the Directors referred the question of holding such an exhibit at our annual meeting to the business manager with power.

It was voted that \$500 be added to the salary of E. J. Craue and for the present that this addition be charged to the budget of the Second Decennial Index.

The following budget was then adopted:¹

ESTIMATED INCOME

	Budget 1926	Budget 1927
Dues.....	\$190,000.00	\$195,000.00
Subscriptions.....	26,000.00	29,000.00
Back Numbers.....	5,000.00	5,000.00
Reprints.....	3,000.00	4,000.00
Postage.....	5,000.00	5,500.00
Interest.....	6,000.00	8,000.00
Advertising.....	105,000.00	107,500.00
Monographs Royalties.		780.00
	<hr/> \$340,000.00	<hr/> \$354,780.00

EXPENDITURES

Journal American Chemical Society.....	49,728.00	\$ 51,334.00
Chemical Abstracts.....	103,000.00	107,900.00

CHARLES L. PARSONS, *Secretary*

COUNCIL

The following communication was sent to the Council on November 26, 1926:

AMERICAN CHEMICAL SOCIETY

Council of the American Chemical Society:

GENTLEMEN:

The following members have been nominated for the offices indicated for the years 1927 and 1927-1929. Kindly check your choice with an X and return in the inclosed ballot envelope. Ballot is void unless received on or before December 16, 1926.

By vote of the Council the names are arranged in alphabetical order.

Yours very truly,

CHARLES L. PARSONS, *Secretary*

President: 1927 only (one to be chosen) (alphabetically arranged): C. A. Browne, Irving Langmuir, S. W. Parr, George D. Rosengarten.

Directors: 1927-1929, inclusive. Nominees of local sections (alphabetically arranged). Vote for one Director in each of the following two geographical districts:

First District: (Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, Connecticut and Canada), Charles A. Kraus, James F. Norris, H. P. Talbot. *Third District:* (Pennsylvania, Delaware and Ohio), A. C. Fieldner, Charles L. Reese.

Councilors-at-Large: 1927-1929, inclusive (four to be chosen). (Ballot is void unless four are voted for) (alphabetically arranged): Edward Bartow, C. A. Browne, H. N. Holmes, S. C. Lind, H. S. Miner, R. B. Moore, Hugh S. Taylor, Gerald L. Wendt.

The returns of this ballot were counted on December 16 by a committee consisting of W. D. Collins, W. W. Skinner and Charles L. Parsons, and the following officers were elected:

President: George D. Rosengarten.

Directors: James F. Norris, Charles L. Reese.

Councilors-at-Large: Edward Bartow, C. A. Browne, S. C. Lind, H. S. Miner.

CHARLES L. PARSONS, *Secretary*

On recommendation of the Editor in Chief of the Journal of Physical Chemistry, Professor Harry B. Weiser and Professor John Johnston have been appointed Associate

Editors of the Journal of Physical Chemistry by action of the Executive Committee. They replace Arthur L. Day and W. Lash Miller whose terms expire on December 31, 1926.

MEMBERS ELECTED BETWEEN NOVEMBER 15 AND DECEMBER 15, 1926

Proceedings

Report of the Secretary of the American Chemical Society for the year 1926

The Society has held two general meetings during the year, one at Tulsa, Oklahoma, April 5 to 9, 1926, and one at Philadelphia, Pennsylvania, September 5 to 11, 1926. The meeting at Tulsa although not confined to any one Division was naturally largely given up to the chemistry of petroleum. It was well attended and was highly successful. The meeting at Philadelphia was the Fiftieth Anniversary Meeting of the American Chemical Society. It was the largest and most important meeting the Society has ever held. It has been fully described in the Society's journals. In connection with it a special Golden Jubilee Number of the American Chemical Society was issued on August 20 as No. 8-A of the Journal of the American Chemical Society. It summarized fifty years of chemistry in the United States and the influence of the American Chemical Society in its development. At this meeting many foreign members and chemists not members were present. The Divisions of the Society gave special programs and special symposia. Fourteen honorary memberships were conferred.

During the year numerous intersectional meetings were held, as has already been announced in the *News Edition*. In addition, the Rubber Division held a special meeting of its own in Akron, Ohio, on February 22 and 23, 1926, and the Cellulose Division and the Paint and Varnish Section also held special and separate meetings in Madison, Wisconsin, on May 28 and 29, 1926. These divisional meetings were successful, and owing to their specific nature were largely attended by the chemists in these branches of industry. The wisdom of encouraging these special division meetings was confirmed. By supplying this special need and demand of our membership greater loyalty to the American Chemical Society was secured. As predicted, this procedure has added interest to the work of the divisions and has enabled them to get together in large numbers for a study of their own special problems.

The membership figures on December 31, 1926, show an increase over those for 1925. The unpaid membership also has shown a distinct decrease. Owing to both of these factors an increased income in 1926 in membership dues of approximately \$10,000 was secured. There was a noteworthy increase also in non-membership subscriptions, but a decrease in the sale of back numbers owing solely to the partial exhaustion of the stock of the Society. The Society has continued to maintain an excellent financial standing for 1926, its income showing a balance over expenditures, as will be indicated in the audit of the Treasurer's report.

The success of the Monograph series still continues, additional monographs having been issued in 1926 with others in press.

Meetings of the Society will be held in 1927 as follows: Week of April 11, Richmond, Virginia; week of September 5, at Detroit, Michigan.

The local sections have continued active, most of them holding monthly meetings throughout the year, with the exception of the summer months. Their programs have been announced and printed in the *News Edition*. One new local section has been added during 1926; namely, the Fort Wayne Section, with headquarters at Fort Wayne, Indiana. One section, the Savannah Section, was discontinued on January 1, 1926.

Membership in the Society on December 31, 1925, was 14,381. On December 31, 1926, it was 14,704. Statistics follow:

Honorary members.....	22
Life members.....	21
Corporation members.....	393
Members paid 1926.....	12,952
Members unpaid 1925 and 1926.....	689
Members unpaid 1926.....	647
	<hr/>
	14,704

The number of members not in arrears registered in the local sections on November 30, 1925, was 10,408. The number on November 30, 1926, was 11,042. The number in each section for 1925 and 1926 is noted below:

Local section	Number of paid mem- bers, 1925	Number of paid mem- bers, 1926	Cash retained from balance 1925	Total receipts 1926

The table gives a summary of the sectional accounts for the year, shows the number of members in each local section for 1925 and 1926, the funds held over from 1925 account, and the total funds (which include the balances) charged to the 1926 account

During the past two fiscal years, December 1, 1924, to November 30, 1926, the Secretary has made the following collections

	1925	1926
Membership	\$188,126 50	\$198,060 00
Subscriptions	26,829 75	29,178 45
Back numbers	6,564 06	5,388 68

Reprints.....	4,029.78	4,576.79
Postage.....	5,109.41	5,443.00
Exchange.....	3.43	4.85
Decennial Index.....	760.00	625.25
Directory.....	261.00	86.00
Interest.....	1,490.81	2,241.99
	\$233,174.74	\$245,554.51

These amounts were duly transmitted to the Treasurer of the Society.

Several sets of *Chemical Abstracts* have been completed and sold during the year as well as complete sets of *Industrial and Engineering Chemistry*. Complete sets of the *JOURNAL* of the American Chemical Society are no longer available as it is impossible to fill in certain early numbers which are exhausted. Nevertheless, the Society has again sold a number of incomplete sets to the extent that they could be completed, and there is still a demand for such, as full sets are unobtainable. The stock has been kept in fair condition by the purchase of numbers needed to complete full volumes. Many volumes are already sold out and a number of other issues of all three of our journals are nearing exhaustion.

Back numbers are mailed direct from Easton, Pa., on orders sent through the Secretary's office. The following is the summary of the back numbers sent out by the Secretary during the year, together with the present stock of journals:

Copies of the Society's publications sent out from January 1, 1926, to December 31, 1926, aside from mailing lists.....	52,557
Copies of the <i>Journal</i> of the American Chemical Society in stock...	13,937
Copies of <i>Chemical Abstracts</i> in stock.....	32,199
Copies of <i>Industrial and Engineering Chemistry</i> in stock.....	16,756
Copies of the General Index, Vols. 1-20, J. A. C. S. in stock.....	58
Copies of the 25th Anniversary Number in stock.....	81
Copies of the Golden Jubilee Number in stock.	4,571
Volumes of First Decennial Index in stock.....	239

Respectfully submitted,
CHARLES L. PARSONS, *Secretary*

Report of the Treasurer

The Auditors' Report presented herewith shows that the Society as a whole, for the year 1926, kept its expenses within the limits laid down by the budget a year ago, while its income was a little larger than predicted a year ago.

The expenses of the Society now amount to about One Thousand Dollars per day, including Sundays, and as long as the income is approximately the same as the expenses we understand that the wishes of the Council and Directors are being followed. We should always remember, however, that this policy leaves us very little reserve, and while we can expand slightly in good years we will be forced to retrench in bad years.

The Officers and Editors who were charged with expending our money on our widely varied activities, have almost without exception, during this last year, kept their expenses just inside of their budget allowance in spite of the many demands made upon them, and the many lines of useful activity where they see that more money could be spent profitably. Probably no one but those intimately acquainted with the financial affairs of the Society realizes quite what an amount of time, thought and experience is required to accomplish this, or what a debt the Society owes to these various Officers and Editors who succeed in getting so much out of the funds at their disposal.

JOHN E. TRIPLE, *Treasurer*

Auditor's Report

New York, January 17, 1927

DR. J. E. TEEPLE, *Chairman Finance Committee*
 American Chemical Society
 50 East 41st Street, New York City

Dear Sir:

Pursuant to your request, we have made an audit of the books of account of the American Chemical Society, kept by its Treasurer, for the year ending December 31, 1926, and submit herewith the accompanying Condensed General Balance Sheet as of December 31, 1926, and Statement of Cash Received and Disbursed between January 1, and December 31, 1926—marked Exhibit "A" and Exhibit "B," respectively, which we have prepared therefrom, and hereby

CERTIFY that such statements correctly reflect the financial condition of the Society at December 31, 1926 and its financial transactions during the year as shown by the books of account.

Yours very truly,

F. W. LAFRENTZ & COMPANY
Certified Public Accountants

Report of the Editor of the Journal of the American Chemical Society for the Year 1926

The number of articles published by the Journal, and the number of pages devoted to them and to the Proceedings of the Society during the past five years, exclusive of the indexes and the tables of contents, have been as follows:

	Number					Pages				
	1922	1923	1924	1925	1926	1922	1923	1924	1925	1926
Proceedings.....	117	130	112	82	52
Physical and Inorganic.....	191	209	164	195	209	1844	1700	1396	1475	1619
Organic and Biological.....	148	212	203	243	249	1082	1384	1423	1578	1553
Book Reviews.....	47	57	74	63	77	48	66	69	55	70
Total.....						3091	3280	3000	3190	3294

It can be seen from the figures in this table that the average length of articles, exclusive of Notes, was 6.9 pages during the past year as compared with 6.9 pages in 1925, 8.0 pages in 1924 and 7.5 in 1923. It should be appreciated that this high average of compression is only secured at the cost of great effort, both by the Authors and the Editors.

Our total number of pages, including the 55 pages devoted to the indexes, exceeded by 49 pages the 3300 pages allotted in the Budget. This was possible as the result of a somewhat less cost per page for our printing.

The terms of Associate Editors C. L. Alsberg and H. H. Willard expired during the past year, but fortunately both were willing to accept reappointment for an additional term, so that the Society is assured of a continuation of their valuable services.

ARTHUR B. LAMB, *Editor*

Report of the Editor of Chemical Abstracts for 1926

During the past year 29,202 abstracts were published in *Chemical Abstracts*; these covered 3842 pages. For comparison these figures are given below along with corresponding figures for the nine preceding years..

	Year	1917	1918	1919	1920	1921
No. of abstracts.....		15,601	13,357	14,698	18,051	19,476
No. of pages.....		3,470	2,712	3,338	3,826	4,059
	Year	1922	1923	1924	1925	1926
No. of abstracts.....		23,212	24,256	25,607	26,426	29,202
No. of pages.....		4,365	3,924	3,740	3,618	3,842

The figures for pages of abstracts are not directly comparable in all instances because the printing style was changed from leaded to solid composition on June 10, 1923. It is clearly evident, however, that it has been necessary to exert ever increasing pressure for brevity in order to keep pace with the growing chemical literature within the space limitations necessarily imposed. Except for certain foreign patents we have kept pace in 1926

The increase of 2776 abstracts in 1926 over the number published in 1925 does not exactly represent the growth in the literature. This figure is a little large for that purpose because the effort exerted each year to make the current volume as complete a record for the year as possible was intensified during the latter part of 1926 since this year marks the end of a ten-year period. Every author whose work appeared in time is deserving of a place in the Second Decennial Index—that thought was expressed to the abstractors and their response was fine. The increase in number of abstracts during the ten years shown above is not exactly representative of normal literature growth either as recovery from the effects of the World War is involved. During the year immediately preceding the war (1913) 25,971 abstracts were published. In comparing this figure with the 29,202 abstracts published in 1926 it should be borne in mind that the patent literature was covered more thoroughly in 1913 than is now possible.

Of the 29,202 abstracts published last year, 23,103 are abstracts of papers and 6099 are abstracts of patents. The abstracts of papers have averaged 0.142 page in length as compared with 0.144 page in 1925 and 0.150 page in 1924; the abstracts of patents have averaged 0.055 page in length as compared with 0.058 page in 1925 and 0.069 page in 1924. It will always be wise carefully to conserve space, but it will be a good thing for the journal when abstracts can be reasonably lengthened.

The edition has been 14,800 copies per number during the most of 1926.

On October 20, there was published a revised "List of Periodicals Abstracted." The key to library files (225 libraries) and other information supplied are calculated to make as easy as possible the bridging of the gap between abstracts and full papers. The list includes data regarding 1246 periodicals. A copy was sent to each subscriber to *Chemical Abstracts*. Reprints are available.

Now that the second ten-year period (1917–1926) is completed the actual printing of the Second Decennial Index can be started. The compilation work progressed on schedule during 1926 and it was possible on December 31 to send the first of the copy to the printer. The printing contract was awarded in September to the Mack Printing Co. The printing schedule calls for the completion of the two volumes of author index (approximately 2870 pages) in 1927 and the issuing of the three volumes of subject index (approximately 4130 pages) in 1928.

The following editorial changes have occurred during 1926: Brian Mead, who has been capably assisting George L. Clark with the big section on General and Physical Chemistry, had to give up this work because of his departure from Cambridge, where Dr. Clark is located. E. K. Marshall, Jr., took over the section on Physiology early in the year, Andrew Hunter having resigned after long and faithful service and then later Dr. Marshall consented to take charge of the section on Pharmacology also during A. N. Richards' year in Europe; this is the first time that two sections have ever been handled by one man at the same time. F. C. Blanck and H. A. Lepper became editors

of the section on Foods in April, following the resignation of W. D. Bigelow and A. E. Stevenson; Dr. Bigelow had been an assistant editor ever since the beginning of *Chemical Abstracts* in 1907 so that it was a source of special regret to lose him; Mr. Stevenson was an excellent helper.

Other men who have been actively associated with *Chemical Abstracts* as assistant editors during the twenty years since its beginning are G. E. Barton, C. E. Munroe, L. A. Olney and A. H. Sabin. Those still active who have completed ten or more years in this service are Colin G. Fink, Edgar T. Wherry, William T. Hall, Chas. A. Rouiller, Paul E. Howe, Frank P. Underhill, Stanley R. Benedict, Philip B. Hawk, H. Gideon Wells, Alfred N. Richards, R. A. Gortner, Edward Bartow, W. O. Emery, F. M. Rogers and E. Scherubel. The number of abstractors and of assistant editors who were formerly abstractors whose period of service extends over ten years is too large to enumerate here. To all these men and to the many others who have given, or are giving, unselfishly of their time as abstractors or assistant editors, the editor wishes again to voice his gratitude and to express the belief that all who find *Chemical Abstracts* useful will join him in this. The amount of work done in a spirit of service to chemistry by the 300 folks represented below the top line of names on the *Chemical Abstracts* cover is very great.

Statistics for the various sections follow, figures being given for 1925 for comparison:

	1925		1926

Respectfully submitted,

E. J. CRANE

Report of the Editor of Industrial and Engineering Chemistry for 1926

Industrial and Engineering Chemistry enjoyed one of its busiest years in 1926, publishing 430 contributed articles, 94 editorials, and reviews of 135 scientific books. During the year 1384 pages—64 more than the usual annual volume—were published, the extra number having been made possible by the generosity of the Chemical Foundation, Inc. Following the Philadelphia meeting it became immediately apparent that unless ways could be found to add pages to the number authorized, the results of scientific and industrial work reported in accepted articles might be delayed for several months, with a probable disadvantage to industry as well as to research of a fundamental character. In accord with its policy to do whatever it can to promote the science of chemistry, the Chemical Foundation was able to make an allotment which has been used in the manner indicated.

The articles appearing during the year included many of outstanding value, and special mention may be made of four symposia. These were Future Trends in Industrial and Engineering Chemistry, Lubrication, Progress of the Dye Industry in the United States during the Past Decade and Raw Rubber.

The esteem in which this journal is held throughout the world may be measured by the rapidity with which surplus copies became exhausted, making it necessary for the Society to repurchase in order to have at hand a few complete sets for future needs.

The placement of the table of contents immediately inside the front cover, an innovation with Volume 18, has been much appreciated by the readers and in the make-up of the journal the effort to improve the appearance of the papers, ease of reading, and the conservation of the readers' time has been continued. There has been no change in the policy to devote the maximum percentage of space to articles of permanent value, and we are convinced that this is a policy acceptable to the membership and advantageous to our advertisers.

The News Edition with every issue more firmly establishes its place in the Society's activities. It serves well in conveying items of more than passing interest and offers the best medium through which to promulgate throughout the world the preliminary and final programs of the semiannual meetings.

The advertising pages have shown a very satisfactory volume of business and those of our readers who do not make a practice of examining these pages promptly upon receipt of the journal will find that they have missed much by not making the most of the information which they contain.

Two notable facts are the extent to which our list of nonmember subscribers in all parts of the world shows a gradual but consistent growth, and the extent to which articles first appearing in this journal are reprinted in the scientific, technical, and lay press everywhere. The editor appreciates the compliment thus paid to the authors

whose articles appear in the columns of *Industrial and Engineering Chemistry* and continues to cooperate heartily with all editors who find in these pages material which they consider worthy of reprinting for their own clientele.

The results that are being achieved would be impossible without the great amount of gratuitous service performed by many members of the Society in the interests of prompt and accurate publication. The divisions of the Society have performed valuable service in indicating members accepted as specialists who are willing to review contributed articles. Many men have given of their time to review books and assist in the decision of questions pertaining to modern technology, and wherever we have turned for advice, whether to our formally constituted board of advisors or to interested members of the Society, we have found an appreciated readiness to assist. The men who translate our foreign letters are particularly helpful. Notwithstanding considerable increase in the business of the office, it has been possible to perform the work on schedule time, thanks to the unstinted efforts of a devoted staff.

H. E. HOWE, *Editor*

Report of the Director of the A. C. S. News Service for 1926

The A. C. S. News Service is now well established as a national organization. Not only do representatives of the various press services and of local papers look to this service for abundant copy on the occasion of our semiannual meetings, but not infrequently the service is called upon to obtain opinions on topics of current affairs and to interpret the significant facts in current work as reported. While special efforts are made on the occasion of our meetings, a steady flow of material is maintained throughout the year with a result that must be gratifying to the membership of the Society. An event such as the Semicentennial Meeting calls for much extra effort but this was put forth by the managing editor and his staff, so that only those who are unable to read remained oblivious of the purport and features of the Philadelphia meeting.

The extent to which the material supplied by the A. C. S. News Service is used makes it altogether too expensive to purchase clippings, as was regularly done a few years ago, and today only an occasional purchase is made, covering a short period and merely for the purpose of checking the general results.

Most of the material supplied by the press is based upon papers presented before national meetings, regional meetings, and local sections, and articles appearing in *Industrial and Engineering Chemistry*. Where leading chemists are willing to give views on timely topics, these continue to be of great use to the News Service. The position of the Society is such that all of its activities constitute news, and through the efforts of the A. C. S. News Service chemistry is unquestionably gaining an increasing circle of interested friends.

H. E. HOWE, *Director*

COUNCIL

James F. Norris, just before terminating his office as President of the Society, appointed C. A. Browne, F. G. Cottrell, and H. J. Wheeler, a committee to cooperate with the Organizing Committee of the First International Congress of Soil Science to be held in Washington, D. C., June 13-22, 1927.

Gerald L. Wendt, of Pennsylvania State College, has been unanimously elected by the executive committee editor of *Chemical Reviews* to succeed W. A. Noyes who desired to be relieved from this duty. Dr. Wendt has accepted the editorship.

Proceedings

COUNCIL

President George D. Rosengarten has appointed Dr. Marston T. Bogert and Dr. Irving Langmuir to represent the American Chemical Society on the occasion of the celebration of the Two Hundredth Anniversary of the Founding of the American Philosophical Society, to be held in Philadelphia, April 27, 28, 29, 30, 1927.

Dr. Lauder W. Jones of Princeton, N. J., and Professor James M. Breckinridge of Nashville, Tenn., have been appointed by President Rosengarten the representatives of the American Chemical Society on the Council of the American Association for the Advancement of Science for 1927.

Proceedings

GENERAL MEETING MINUTES

The 73rd General Meeting of the American Chemical Society was held at Richmond, Virginia, from Monday, April 11, to Saturday, April 16. The Council meeting was held on the afternoon of the 11th; the general meeting on the morning of Tuesday, April 12; and general divisional meetings of the Biological and Organic Divisions; Industrial and Engineering Chemistry and Sugar Divisions; and the Physical and Inorganic Division, on the afternoon of the 12th. Regular divisional meetings were held all day Wednesday and Thursday. The details of the meeting will be found printed in the News Edition of *Industrial and Engineering Chemistry* for April 20 and May 10.

At the general meeting on Tuesday morning, by recommendation of the Council, the names of Wilhelm Ostwald and Walther Nernst were unanimously restored to the list of honorary members of the American Chemical Society. Also, Richard Willstätter having been duly proposed by ten members of the Society, and having received the endorsement in writing of a majority of the Council, was unanimously elected to honorary membership in the Society.

On Wednesday evening in the auditorium of the Jefferson Hotel an address by Dr. Victor C. Vaughan entitled "A Chemical Concept of the Origin and Development of Life," was delivered by his son, Dr. Warren Vaughan, Dr. Vaughan himself being unavoidably detained by illness. Some 1300 attended the lecture with 300 turned away on account of inability to secure standing room.

The registration showed 1317 members and guests present. The Society was welcomed by Attorney General Saunders on behalf of the State and by Mayor J. Fulmer Bright of the City of Richmond. A response by President Rosengarten followed.

On Monday evening a supper dance was enjoyed by some 400 members and guests.

On Tuesday evening an informal reception crowded the auditorium of the Jefferson Hotel to its limits. The members and guests at this reception were entertained by The Sabbath Glee Club, a colored organization, whose singing of negro spirituals will be long remembered by those who were permitted to be present.

The Garden Party on the afternoon of Wednesday, April 13, at the University of Richmond was especially enjoyed, as it gave the members an opportunity of meeting many Richmond people; of seeing the attractive grounds of the University; and of inspecting the new chemistry building which had been dedicated the previous Monday afternoon.

The dance on Thursday evening interspersed by colonial dances and costumes, by puppets of Miss Eleanor Fry, again crowded the auditorium.

On Friday some 300 attended the barbecue and fish fry at Williamsburg and viewed the interesting historical surroundings of colonial Virginia, with a special trip to Jamestown, some eight miles away. A smaller party, but none the less enjoyable, made a trip to the University of Virginia and Charlottesville and to Jefferson's old home at Monticello on Saturday.

The Agricultural and Food; Biological; Chemical Education; Dye; Gas and Fuel; Industrial and Engineering; Medicinal Products; Paint and Varnish; Petroleum; Physical and Inorganic; Rubber; and the Water, Sewage and Sanitation Chemistry Divisions held divisional meetings. Numerous luncheons and dinners were held by special groups.

Two hundred and ninety-five scientific papers and addresses were offered at the meeting. Possibly the chief feature that impressed all of those in attendance was the warm hospitality from the Virginia city and all its inhabitants in which the meeting was held. Every member attending the meeting felt that he was the personal guest of the Virginia Section.

CHARLES L. PARSONS, *Secretary*

DIRECTORS' MINUTES

The Directors of the American Chemical Society met in the Jefferson Hotel, Richmond, Virginia, Monday, April 11, at 9 P. M., with President Rosengarten in the chair and the following Directors present: W. D. Bancroft, W. D. Bigelow, James F. Norris, S. W. Parr, Charles L. Reese and Charles L. Parsons.

The Treasurer reported the Purchase of \$60,000 par value of Temporary Investments, as follows:

Purchased Jan. 28, 1927:

\$10,000 N. Y. City 3 $\frac{1}{2}$ %—1954—at 90 $\frac{7}{8}$ %
 \$10,000 N. Y. City 4s—1959—at 99 $\frac{1}{8}$ %
 \$10,000 N. Y. City 4 $\frac{1}{2}$ %—1964—at 102 $\frac{7}{8}$ %
 \$10,000 Federal Land Bank 4 $\frac{1}{2}$ %—1937—at 100 $\frac{7}{8}$ %
 \$10,000 Federal Land Bank 4 $\frac{1}{2}$ %—1933—at 101 $\frac{1}{8}$ %
 \$10,000 American Telephone & Telegraph Coll. Trust 4s—1929—at 98 $\frac{1}{4}$ %

Receipts for the Endowment Fund of

\$5000 from the Philadelphia Section
 \$1000 from the Delaware Section
 \$1138.47 from the Committee

making a total of \$36,138.47. This has been invested as of February first in the real estate mortgage we hold, in which the rest of the Fund participates. This investment releases a corresponding amount of funds for the General Fund which will be permanently invested in the near future.

The Treasurer also reported that the income from the Endowment Fund had accumulated to the extent of \$1,674.75 and that a reduction of twenty-five cents per hundred-weight had been made in the price of the paper for the journals of the Society. The report was approved and accepted by the Directors and the Treasurer was instructed to await special appropriations by the Directors at a later date of the income from the Endowment Fund to the journals of the Society.

The Directors voted that the Society should not hold an exposition at the Detroit Meeting of the Society owing to the peculiar conditions there, but that they were quite willing that the Detroit Section should do so if it saw fit and would coöperate with the Society's business manager in the matter of procedure in order that it might be coördinated with Society policy.

The Directors then adjourned.

CHARLES L. PARSONS, *Secretary*

COUNCIL MINUTES

The meeting of the Council of the American Chemical Society was called to order by President Rosengarten at 10.00 A. M., in the Jefferson Hotel, Richmond, Va., on Monday, April 11, with the following Councilors and substitutes present:

Ex-Officio.—W. D. Bancroft, W. D. Bigelow, George C. Brown, Marston T. Bogert, F. B. Carpenter, W. D. Collins, E. J. Crane, M. L. Crossley, Charles H. Herty, B. S. Hopkins, H. E. Howe, E. F. Kohman, John R. Murlin, James F. Norris, W. A. Noyes, S. W. Parr, Charles L. Parsons, H. A. Shonle, Edgar F. Smith.

Councilors-at-Large.—Roger Adams, Edward Bartow, E. M. Billings, A. M. Comey, W. Lee Lewis, S. C. Lind, Harlan S. Miner.

Local Sections.—Akron, A. M. Hamblet. *Central Pennsylvania*, E. D. Ries. *Chicago*, D. K. French, W. S. Hilpert (subs. for W. R. Smith), Walker M. Hinman (subs. for David Klein), Wm. Hoskins, Charles D. Hurd (subs. for Paul Van Cleeft), F. W. Sullivan, Jr. (subs. for H. E. Barnard), E. H. Volwiler, S. C. Langdon (subs. for H. G. Walker). *Cincinnati*, Charles R. Bragdon, C. F. Long (subs. for Martin H. Fischer). *Cleveland*, Hippolyte Gruener, O. F. Tower. *Colorado*, G. H. Whiteford

(subs. for L. D. Roberts). *Columbus*, W. C. Ebaugh, Wm. Lloyd Evans (subs. for Wm. McPherson). *Connecticut Valley*, Joseph S. Chamberlain, Mary L. Sherrill (subs. for C. R. Hoover). *Delaware*, J. L. Bennett, Charles L. Reese. *Detroit*, H. C. Hamilton, Oliver Kamm. *Georgia*, L. B. Lockhart (subs. for T. C. Law). *Illinois-Iowa*, H. A. Geauque (subs. for O. K. Smith). *Indiana*, Edgar B. Carter. *Iowa*, L. Chas. Raiford. *Kansas City*, F. B. Dains, Carl I. Johnson (subs. for H. P. Cady). *Lehigh Valley*, G. A. Menge, Charles C. Nitche. *Lexington*, R. N. Maxson. *Maine*, C. A. Brautlecht. *Maryland*, J. C. W. Frazer, Neil E. Gordon, A. H. Marshall. *Michigan State College*, Arthur J. Clark (subs. for Ward Giltner). *Minnesota*, M. C. Sneed. *Nashville*, J. M. Breckenridge. *New York*, S. P. Burke, C. R. Downs, Thomas B. Freas, Martin H. Ittner, James Kendall, D. H. Killeffer, Sidney D. Kirkpatrick (subs. for Chas. A. Lunn), Herbert R. Moody, Marie Reimer, R. R. Reushaw, Foster Dee Snell, F. W. Willard (subs. for A. W. Thomas), W. W. Winship (subs. for J. G. Davidson), Lois W. Woodford (subs. for B. F. Brooks). *North Carolina*, A. S. Wheeler. *Northeastern*, Winthrop C. Durfee, Gustavus J. Esselen, Jr., Arthur J. Hohman, Arthur D. Holmes, Robert W. Neff, Lyman C. Newell (subs. for W. L. Jennings), John A. Seaverns (subs. for L. A. Pratt), Wilhelm Segerblom. *Northern West Virginia*, C. A. Jacobson. *North Jersey*, Herbert H. Baldwin (subs. for F. W. Zons), Robert P. Fischella (subs. for L. V. Redman), C. O. Johns, David Wesson. *Northwestern Utah*, Frank K. Cameron. *Philadelphia*, C. S. Brinton, J. Bennett Hill, J. Spencer Lucas, Hiram S. Lukens, Horace C. Porter, Wm. Stricker, Walter F. Jaggart. *Pittsburgh*, A. C. Fieldner, J. H. James, Alexander Silverman. *Purdue*, A. R. Middleton. *Rhode Island*, Robert P. Chambers. *Rochester*, W. R. Bloor (subs. for H. Le B. Gray), H. F. Clarke. *Saint Joseph Valley*, J. A. Nieuwand. *Saint Louis*, L. McMaster (subs. for F. R. Ball), Percival Robertson (subs. for E. J. Sheppard), L. A. Watt. *South-eastern Texas*, L. S. Bushnell (subs. for H. B. Weiser). *Southern California*, Walter A. Schmidt. *South Jersey*, R. E. Rose. *Syracuse*, R. A. Baker. *Toledo*, Harold E. Mersereau (subs. for George H. Anderson). *University of Illinois*, D. B. Keyes, A. M. Buswell. *Vermont*, P. Conant Voter (subs. for S. F. Howard). *Virginia*, Edwin Cox (subs. for H. K. McConnell). *Washington*, D. C., V. K. Chestnut, W. Mansfield Clark. *Western New York*, L. F. Hoyt (subs. for J. A. Handy), Walter Wallace (subs. for E. R. Riegel). *Wisconsin*, J. H. Mathews (subs. for Homer Adkins), George J. Ritter (subs. for L. F. Hawley).

A petition in due form was received for the formation of a local section with territory comprising the Island of Porto Rico and with headquarters at Mayaguez, P. R., to be known as the Porto Rico Section. The Council authorized the granting of a charter to the Section.

A petition in due form was received for the formation of a local section to be known as the Ohio Northern Section, with territory comprising the Counties of Hardin, Hancock, Putnam, Allen and Auglaize in the State of Ohio, and with headquarters at Ada, Ohio. The Council authorized that a charter be granted the Section.

A petition was also received in due form for the formation of a section to be known as the Princeton Section, with headquarters at Princeton, N. J., and comprising territory in Mercer County within five miles from Princeton, N. J. The Council authorized that a charter be granted the Section.

The Council voted to authorize the formation of a Paint and Varnish Division of the American Chemical Society, the Paint and Varnish Section having held six successful meetings with a large and enthusiastic attendance and having duly petitioned to be given divisional status. The following by-laws were presented, and having been found to be in conformity with the Constitution and By-Laws of the American Chemical Society were approved by the Council:

BY-LAWS OF THE DIVISION OF PAINT AND VARNISH CHEMISTRY

ARTICLE I—MEMBERSHIP

Membership in the Division, shall be open to all members of the American Chemical Society, and any member of the Society shall, upon request to the Secretary of the Division, be registered as a member of the Division.

ARTICLE II—OFFICERS

Section 1.—The officers of the Division shall be a chairman, a vice-chairman, a recording secretary and an executive committee.

Section 2.—The chairman, vice-chairman and secretary shall be members of the Executive Committee ex-officio.

Section 3.—The Executive Committee shall consist of three registered members of the Division and the members ex-officio, provided by Section 2 of this article. The chairman of the division shall be chairman of the Executive Committee.

Section 4.—At the first session of the Division coincident with the annual meeting of the Society and following the report of the Secretary, the chairman shall appoint from the members present, at the meeting, a committee of three, whose duty it shall be to nominate officers for the ensuing year. This committee shall present the list of nominations immediately preceding the election of officers at the last session during that annual meeting.

Section 5.—All officers of the Division shall be elected annually by ballot at the last session of the Division held during the annual meeting of the Society, and shall take office at the close of the meeting, following the report of the Secretary, the chairman shall appoint from the members present, at the meeting, a committee of three, whose duty it shall be to nominate officers for the ensuing year. This committee shall present the list of nominations immediately preceding the election of officers at the last session during that annual meeting.

Section 6.—The Executive Committee shall fill any vacancies occurring through death or resignation among officers of the Division.

Section 7.—It shall be the duty of the chairman to represent the Division in the Council of the Society, to preside at meetings of the Executive Committee, to carry into effect the decisions and recommendations of that committee, to preside at stated meetings of the Division, and to report to the Society at its regular meetings.

Section 8.—In the absence of the chairman, the duties of the office shall devolve upon the vice-chairman, with one exception, he can attend Council Meetings in the absence of the chairman, but as Councilors have no proxy he has no vote.

Section 9.—It shall be the duty of the recording secretary to keep a record of the proceedings of the Division and of the Executive Committee, to maintain a list of registered members, to send to registered members such notices as the business of the Division may require, and to transmit to the Secretary of the Society the names of all the officers and standing committees of the Division within three weeks of their appointment; and, in like manner, to notify the Secretary of the Society of any change of officers or standing committees during the year.

Section 10.—The recording secretary shall be the custodian of the files of the Division. He shall have charge of the funds of the Division and shall make all disbursements, subject to the authorization of the Executive Committee. He shall report to the Division at its annual meeting.

Section 11.—The Executive Committee shall conduct the business of the Division and direct its activities. The committees shall at each general meeting of the Society, and as early as may be, hold a meeting to consider the affairs of the Division and receive reports of its committees. The voting majority of the Executive Committee shall be responsible for all expenditures which it may authorize, except so far as the action of the council shall previously have provided for such expenditures.

ARTICLE III—MEETINGS

There shall be a meeting of the Division at each general meeting of the Society. Business affecting the organization of the Division shall be transacted only at the meeting coincident with the annual meeting of the Society.

The order of business shall be as follows:

- Reading of minutes.
- Report of executive committee.
- Report of secretary.
- Report of Committees and discussions.
- Reading of papers.
- Miscellaneous Business.

And at the annual meeting:

- Appointment of Nominating Committee.
- Report of Nominating Committee.
- Election of officers.
- Unfinished business.

The regular order of business of the Division may be suspended at any session by the consent of three fourths of the members of the Society present.

ARTICLE IV—SPECIAL COMMITTEES

Section 1.—The Chairman shall with the advice and approval of the Executive Committee, appoint from time to time standing committees of the Division to consider, conduct and report upon such special matters as may be delegated to them. The following committees shall be appointed at the annual meeting or as soon thereafter as may be expedient.

1. Committee on Programs.
2. Committee on Research Problems.
3. Committee on Advertising.

Section 2.—The recording secretary of the Division shall be chairman of the program committee.

ARTICLE V—PAPERS

Section 1.—All titles and outlines of papers must be sent to the recording secretary of the Division at least fifteen days before the program must be sent to the Secretary of the Society.

Section 2.—All papers must be sent to the recording secretary of the Division at least thirty days before the meeting. The exact date will be definitely stated in the preliminary program announcement of each meeting.

Section 3.—Papers shall not be presented on the program at the regular meeting of the Society unless they have been approved by the program committee.

ARTICLE VI—PUBLICATIONS

The official organ of the Division shall be the *Journal of Industrial and Engineering Chemistry*.

The executive committee may at its discretion, provide for the issue of other non serial publications for distribution to registered members of the Division or for sale.

ARTICLE VII—ASSESSMENTS

The Executive Committee may at its discretion impose dues not to exceed three dollars (\$3.00) per year upon registered members of the Division, said dues to be collected by the Secretary and the receipts therefrom to be devoted to the purposes of the Division.

ARTICLE VIII—AMENDMENTS

These by-laws may be amended at any annual meeting of the Division by a three-fifths vote of the registered members present, provided two weeks notice of the proposed amendment with the text thereof has been sent to the registered members of the Division. Amendments to be effective, must be approved by the council and accepted by that body as not inconsistent with the constitution and by-laws of the Society.

It was unanimously voted that the Council recommends to the General Assembly that the names of Walther Nernst and Wilhelm Ostwald be restored to the list of Honorary Members of the American Chemical Society.

Upon recommendation of the Executive Committee, it was voted that rebates paid to local sections on first membership dues secured and forwarded to the Secretary under the regulations established by the Council shall be limited to applicants residing within the territory of the local section which makes claim for rebate.

The following motion was passed at the Philadelphia Meeting:

"A motion that the spring meetings for 1929 and 1930 be omitted was referred to the Executive Committee for consideration and report at the Richmond Meeting."

The Executive Committee reported as follows:

The Executive Committee, after carefully considering the subject of whether the Society shall hold one or two meetings a year, and having read all published arguments presented from the local sections, is unanimously of the opinion that the present plan of at least two meetings a year should be continued as long as the Society has invitations from its local sections and there is the big demand for general meetings of the Society throughout the country that today exists.

They believe that the subject should be considered from the standpoint of service to the science and to the profession rather than from the standpoint of the convenience of individual members. Indeed, they believe that the welfare of the individual member is thus conserved, as two meetings a year bring the meetings twice as often to those chemists who are unable to attend at a distance and the average member's chance of attending is therefore twice as good. They believe it important that as many members as possible come in personal contact with the work of the Society and that the Society's prestige and influence be exerted as often as possible upon the different sections of our country in order that the message of chemistry may be brought not only to the chemist but to the public.

Furthermore, being hosts to the parent society is important to a local section, as it increases local interest and prestige and enables many chemists to attend who would never do so otherwise. They believe that the programs, even with two meetings a year, are well attended and the demand for place has grown. More and more papers, and more and more important papers, are being presented at every meeting, and no meeting of the Society in recent years has failed to have a lasting influence in the development of American chemistry and American chemists. Even with two meetings a year, the programs are already too crowded and the difficulty of finding meeting rooms conveniently located and of sufficient size is great. With one meeting a year, these difficulties would be increased to an extent that they could be handled only in the very largest cities and by our larger sections. Even these larger local sections could scarcely expect a meeting oftener than once in twenty or twenty-five years. To deny the smaller sections the opportunity of a general meeting, or to deny the less populous sections of the country a general meeting from time to time, seems unfair to those sections and those regions. One meeting a year would of necessity lead to this result. Also two meetings are necessary to handle effectively the business of the Society.

The chief plea against two meetings a year appears to be that it is hard for individuals to attend two meetings and to travel the distances required, also that it keeps members from attending the meetings of other chemical organizations. These reasons do not appear valid to the Executive Committee, and they can neither approve handicapping the American Chemical Society in favor of other organizations, nor in keeping the opportunity of attending general meetings from many members of the Society because some find it impossible to attend.

The Council voted unanimously to accept and adopt the report of the Executive Committee.

An invitation from the Columbus Section for the American Chemical Society to meet in Columbus, Ohio, in the spring of 1929 was unanimously accepted.

The Secretary gave notice that he had on record an invitation from the Georgia Section that the Society meet in Atlanta in the spring of 1930 and that invitations had already been announced for the fall meeting of 1929 in Chicago and 1930 in Cincinnati. These invitations were continued on the table pending the time when they might be constitutionally considered.

The Council voted that in view of the special conditions at Detroit it was inexpedient for the Society itself to hold an exposition in Detroit.

S. W. Parr was elected a member of the Executive Committee to fill the unexpired term of George D. Rosengarten. This position was made vacant by his election to the presidency of the Society.

The Executive Committee recommended to the Council that the following report of the Committee on Entrance Requirements presented at the Philadelphia meeting (see *Proceedings, 1926*, p. 47) be adopted.

After extended discussion of the report the Council simply voted that it be accepted with thanks.

The report of the Committee to consider the admission of non-members of the Society to American Chemical Society Meetings, with minor changes in wording suggested by the Membership Committee, was adopted as follows:

Report of Committee to consider the admission of Non-Members to American Chemical Society Meetings.—Your Committee has carefully considered the questions referred to the Divisional Officers Group at the Tulsa Meeting in the spring of 1926, and recommends as follows:

The practice of permitting non-member chemists, resident in the United States, to register at and attend National, Divisional and Regional Meetings, should be continued.

In order to facilitate the classification of registrants at National, Divisional and Regional Meetings, it is recommended that all registrants be required to state on the registration form whether they are members in good standing of the American Chemical Society, and if not, whether they are chemists.

Your Committee recommends that individuals who are American Chemists, but are not members of the Society be required to pay a higher registration fee, and that such persons be provided with distinctive badges, in order to differentiate them from members of the Society and from foreign and non-chemist guests. It is further recommended that the Secretary of the Society be instructed to write to each such registrant a personal letter urging him to join the Society, and enumerating the various reasons for so doing.

Your Committee is of the opinion that admittance to Divisional sessions in National and Regional Meetings be limited to registered individuals.

It is suggested that the Council definitely adopt the policy of not permitting chemists who are resident in the United States but not members of the Society, to present papers at Regional, Divisional or General Meetings of the Society.

Your Committee recommends that the practice of electing associate members to local sections be continued, but that such associate members be denied the privilege of voting and holding office. It is felt that the principle of associate membership could well be employed by officers of local sections for the ultimate induction of new members into the National Society.

H. T. Clarke, *Chairman*, M. T. Bogert, B. S. Hopkins, W. J. Kelly, S. W. Parr, H. B. Weiser, R. E. Wilson.

The following regulations proposed by the committee to consider regulations for the election of honorary members in the Society, and consisting of Marston T. Bogert, *Chairman*, and Messrs. Roger Adams, John Johnston, Arthur D. Little and Julius Stieglitz, were adopted by the Council as procedure to be followed in the proposal and election of honorary members:

(a) Any person whose achievements in Chemistry entitle him to special recognition as an authority in theoretical or applied chemistry, may be nominated for election as an Honorary Member. Such nomination must be presented in writing, signed by at least ten members of the Society, and must set forth in detail the scientific accomplishments upon which the nomination of the candidate is based.

(b) All such nominations shall be filed with the Secretary of the Society, who shall refer them immediately to the Executive Committee.

(c) Upon receipt of every such nomination, the Executive Committee shall designate promptly a special committee (a separate committee for each individual case) of seven members of the Society, five of whom are recognized leaders in that branch of chemistry in which the candidate has achieved his reputation and which is the basis of his nomination, and two others eminent in other branches of chemistry. This special committee shall investigate the merit of the nominee and report its findings to the Executive Committee, who shall in turn transmit it verbatim, together with a report of its own recommendations, to the Council. Unless at least six of the seven members of the special committee approve the nomination, the Executive Committee is instructed to reject it.

(d) Report of the Executive Committee to the Council provided for in (c), after presentation to the Council shall be laid on the table as a special order for the next succeeding meeting of the Council.

(e) Only those individuals whose nominations have been approved by six of the seven members of their special committees can be recommended by the Council for election as Honorary Members, and this recommendation must include the written endorsement of the nominee by at least a majority of the membership of the Council.

(f) Nominations for Honorary Members, recommended by the Council as prescribed above, shall be presented at the General Meeting immediately following the adjournment of that Council meeting at which the nominations were recommended, and shall not be acted upon finally until the next succeeding semi-annual meeting.

(g) Not more than two Honorary Members shall be elected at any one meeting.

(h) The total number of Honorary Members shall not exceed thirty-five.

The report of the Editor of *Scientific Monographs* and the report of the Editor of *Technologic Monographs* were read to the Council, giving a statement of progress in the publication of Monographs and plans for future procedure. These reports were ordered filed.

Other Committees of the American Chemical Society reported as follows:

Committee Advisory to the Bureau of Mines and Bureau of Standards on Non-Ferrous Metals.—William B. Price, the representative of the Society on this Committee, reported the subjects that had been discussed at the Bureau of Standards during the past year. He further reported that no meeting was held at the Bureau of Mines.

Committee Advisory to the War Department.—The Committee Advisory to the War Department has been in conference with the Secretary of War on the matter of the Geneva Protocol, which was referred by him to the Secretary of State, and the result of this conference has been published in the form of letters to and from Secretary Kellogg in the *News Edition* for December 10, 1926 and January 10, 1927.

The Committee has also been in conference with the Quartermaster General with further reference to the dyeing of uniforms, experiments regarding which are still in progress.

Committee on Analysis of Commercial Fats and Oils.—The Committee reported that its report with detailed methods was published in the December, 1926, issue of *Industrial and Engineering Chemistry* and that the Committee was continuing its work.

Committee on Chemical Education.—The Committee of Chemical Education is so closely allied with the Senate of Chemical Education that it is difficult to report upon its work as a separate unit. A special committee of the Senate was appointed at the Philadelphia Meeting of the Society to report any improvements in this alliance. Both the Committee and Senate would appreciate suggestions from the Council.

The organizations are now functioning as follows: The members of the A. C. S. Committee of Chemical Education are ex-officio members of the Senate and the chairman of the said Committee is also chairman of the Senate. After a measure has been passed by a majority of the Senate it is placed before the A. C. S. Committee acting as a separate body. If a majority of the committee pass on it favorably it is taken by the Chairman to the Council for its approval. If it is not passed by a majority of the Committee it goes back to the Senate and if passed by a two-thirds vote is taken directly by the said chairman to the Council.

This type of an organization is to prevent the Council being bothered with trivial matters, and at the same time allow the Senate to make a direct appeal to the Council. It seems logical that the Senate should have a Council hearing on a two-thirds vote since they are a true representative cross-section of the country both geographically and educationally.

The alliance covers all measures whether they originate in the Senate or A. C. S. Committee. This point is well illustrated by the projects which are now before these two bodies. The two principle projects which have been developed during the past year are: (1) A revision of the Correlation of High school and college chemistry; and (2) Research Institute for Chemical Education. The former was started in the committee while the latter originated in the Senate.

Correlation of High School and College Chemistry.—The correlation syllabus has been revised according to the copy attached and has been passed by the Senate and is now before the Committee for their final approval. If you get no further notice before the Council Meeting please accept this report as final and present it to the Council for their approval.

Research Institute of Chemical Education.—The Research Institute of Chemical Education has been approved by the Senate by a letter ballot. It is now before your Committee of Chemical Education. If you get no notice to the contrary before the Council Meeting it will have been approved by the Committee and you are hereby requested to present the project for the approval of the Council.

Find full description of the Institute attached. (For description see *Journal of Chemical Education* for January, 1927.)

The Chairman of the Committee on Chemical Education in presenting the above report offered on behalf of the Senate of Chemical Education the following resolution:

The A. C. S. Committee on Chemical Education, in cooperation with the Senate of Chemical Education, moves that the Council of the American Chemical Society approve the establishment of an Institute for Chemical Education with the understanding that all plans, including the method of the appointment of the Board of Trustees, the ways and means of financing, the type of organization, the location of the Institute and its relation to the cooperating institute or institutions be submitted to the Council by the Senate and Committee of Chemical Education before any definite action is taken.

After discussion, the Council voted to refer this motion to the Executive Committee with the request that they report at the Detroit Meeting of the Council.

Committee on Chemical Engineering Education.—For any intelligent presentation of what educational training is most suitable for the development of a chemical engineer, it would seem wise at the outset to make brief reference to the term "Chemical Engineer." To attempt the formulation of a definition, however, would be simply to thrash over the disputations of the last 10 years and all to little or no purpose, for the simple reason that definitions grow and are not made, and for the further reason that definitions of any sort and in any circumstance are not easily made. It is a question whether they should be attempted at all except as they develop themselves, and grow out of experience. Certainly in any new field they should be left sufficiently flexible to respond to developing conditions. In any event or at any time a definition can only with safety be expressed in very general terms, and the broader the field the more general the definition must be.

For example, an engraver is "One who engraves." (Webster). That definition is safe. It very wisely does not attempt to tell whether such a person works on tombstones or is a Roycroft. Suppose you try to define a lawyer. The moment we attempt anything but a broad and comprehensive statement we will begin to draw boundaries between the fundamentalist who thinks in terms of the underlying principles of justice and equity, and the mere manipulator or operator.

Again it is very difficult to define the term "Engineer." Construction and operation have so largely featured his activities that he has for the most part left the fundamentals behind or transformed them to working formulas. He has in fact left a large part of the field of physics to one side, and all of Chemistry, therefore it is quite evident that a Chemical Engineer who utilizes the whole field of Chemistry and a goodly portion of the field of physics cannot be defined simply as another type of engineer.

However, notwithstanding the difficulties involved in the matter of definition, at the most a subordinate feature, it is not only possible but highly important that the situation be carefully studied and a broad and comprehensive view taken of this new and tremendously important field of activity. It is both appropriate and essential at this evolutionary and indeed revolutionary stage of development, that the American Chemical Society should set forth, so far as possible the fundamental factors which deserve consideration at the present time, in meeting the need of suitably trained men who can function properly under this designation.

We would like to set forth a few observations bearing upon the case as follows:

(1) The American Chemical Society with a membership of approximately 15,000, over 15 per cent. of whom classify themselves as chemical engineers should have a dominating voice in formulating the requirements for the training of a chemical engineer.

(2) The field of constructive development and production now opening along chemical lines is so broad in scope and so great in potential magnitude, and carries with it such vast possibilities for human welfare that it should not be narrowed to any adjunct or appendage of existing groups but be given full freedom of development in its own right and in its own sphere.

(3) It will be unfortunate for all concerned if small or inconsequential differences divide our councils, for chemically speaking there is nothing more clearly evident than that in the future as in the past, "In union there is strength."

(4) It is doubtful if at any time hard and fast rules for the training of Chemical Engineers may wisely be formulated. At least in the present stages of development a flexibility should be maintained that shall meet the wide variation both in the requirements of the field and in the educational facilities for meeting them.

(5) It seems to be the opinion of not only educators but industrial executives that a chemical engineer should have a thorough and extensive training in chemistry, physics and mathematics. Very little time should be spent in any specialized subject. Practice schools including the testing of large scale equipment of all types are fast becoming popular as did the large scale process laboratory of a few years ago. The committee recognizes the value of these new types of instruction but as stated above the extreme importance of teaching the very fundamental sciences should be persistently observed.

(6) This committee is not in favor of setting up an approved list of chemical engineering schools. Such a list is bound to result in discord, personal animosities and worst of all have a tendency to stifle individual initiative and standardize the teaching of chemical engineering throughout the country. This standardization of education has already produced disastrous results in this country and every effort to prevent its spreading further should be made.

(7) For the benefit of those small institutions which are not familiar with the growth and progress of chemical engineering it would be wise to suggest various worth-while curricula and also to make additional suggestions from time to time.

(8) In order to prevent duplication of effort which would be extremely serious in this particular case, the committee would recommend that they confer with the committee on Chemical Engineering Education of the American Institute of Chemical Engineers to the end that they may utilize the very excellent review and results of many years of work by the American Institute Committee and incorporate as much as possible in a report for the American Chemical Society. Furthermore, that this report on Chemical Engineering Education should be published by the American Chemical Society and distributed to all its members. This is of course with the assumption that the report will be accepted by the American Chemical Society.

Committee on Cooperation with the Chemical Warfare Service.—The Committee held its last general meeting in June 1926, since which time the procedure recommended by the committee has been followed. This has involved meetings of the several subcommittees at the Arsenal, each group concentrating for two or more days upon the phases of the work with which it is most familiar and at the same time obtaining a general impression of research in progress and of conditions in general. In addition, individuals have been called upon by the Arsenal for advice and suggestions and members of the scientific staff of the Arsenal have also been sent out to call upon consultants and other specialists in their own laboratories and plants. Arrangements are now being made for an early meeting of the entire committee at the Arsenal.

Corrosion Committee.—The Committee reported progress.

Endowment Committee.—The Committee reported that the Endowment Fund had been increased by something over \$7,000 during the past year. The Committee has held meetings, discussed procedure, and has been making plans towards the further development of its campaign.

Exchange Committee.—The Committee reported 41 new exchanges made in the past year, the list being submitted to the Council for filing.

Finance Committee.—Your Finance Committee has to report that the year 1926 showed satisfactory operation from the money point of view. The receipts were somewhat larger than was anticipated when the budget for the year was drawn, and the expense was slightly less than the budget allowances. This excellent situation changed a slight deficit which appeared in the budget as drawn into a small surplus when the year of operation was ended.

The income and expenses of the Society now are each about \$1000 per day for the 365 days of the year. This is exclusive of various Trust Funds, such as the Decennial Index Fund, Endowment Fund, Morris Loeb Museum Fund, etc. The situation means that the Society is running at almost an even balance of income and expenditures. Daily income has just about doubled since the present Treasurer took office, and expenses have advanced at about the same rate.

The various Trust Funds of the Society are now in the following condition:

Decennial Index Fund unexpended	\$63,709.40
Endowment Fund	36,138.47
Morris Loeb Museum Fund	25,992.25
Life Membership Fund	6,235.04
Priestley Memorial Fund	1,115.75

Guaranteed Reagents Committee.—During the year 1926-7 the committee has continued the preparation of specifications for reagents to be used in careful analytical work. The specifications prepared during the year will be submitted for publication in *Industrial and Engineering Chemistry*.

It is recommended that the name of this committee be changed to Committee on Analytical Reagents, which will indicate better the present work of the committee.

Committee on Hazardous Chemicals and Explosives.—The Committee reported that it has continued its services as a consultant for the Committee on Hazardous Chemicals and Explosives of the National Fire Protective Association and submitted attached to its report a copy of the annual report rendered by the Chairman of that Committee, which was a tentative report and is still under consideration.

Industrial Alcohol Committee.—The Committee reported through its Chairman, Martin H. Ittner. Their report will be found printed in full in the April 20th issue of the *News Edition*.

Committee on Institute for Chemo-Medical Research.—The report of the Committee presented by Chairman, Charles H. Herty, is as follows:

The Committee on an Institute for Chemo-Medical Research begs to report that the outstanding development during the past year was the introduction of a bill in the U. S. Senate by Senator Ransdell of Louisiana which aims to carry out the principles of the Committee's original report through the creation by Congress of a National Institute of Health within the Public Health Service through the expansion of the Hygienic Laboratory.

In a speech on the floor of the Senate at the time of the introduction of a bill Senator Ransdell expressed his indebtedness to our original report for his inspiration in this matter and quoted at length from the report. A reprint of Senator Ransdell's bill and speech is attached to this report as exhibit A.

Following conferences between Senator Ransdell, Surgeon General Cumming of the U. S. Public

Health Service and the Chairman of this committee, Senator Ransdell decided to introduce a new bill combining his original bill with the so-called Parker bill H.R. 10125, a purely administrative measure. This combined bill exhibit B S. 5835 was introduced in the Senate by Senator Ransdell on March 2, 1927.

It is the purpose of the Committee to give Senator Ransdell all possible help in the work of public and official education which must be carried out as an essential factor in the success of this legislation.

The Chairman offered the following resolution, which was unanimously passed:

"WHEREAS the prevalence of sickness among our people, with attendant suffering and economic losses, points clearly to the need of a greater amount of fundamental research and for the alleviation of this condition, and

"WHEREAS all are subject to sickness, all should participate in providing for this necessary fundamental research, therefore be it

"Resolved that the Council of the American Chemical Society approves the principles embodied in the bill S. 5835, introduced in the 69th Congress by Senator Ransdell, providing for a National Institute of Health and for needed administrative reforms in the United States Public Health Service, and urges its early and favorable consideration by the 70th Congress."

Membership Committee.—The Committee reported as follows.

Individual Members elected 1926.....	1,898
Corporation Members elected 1926.....	64
Members Resigned 1926.....	551
Deceased Members 1926.....	66
Total Membership at end of year 1926.....	14,704
Members dropped for delinquency on January 1, 1927.....	66 ⁶

Metric System Committee.—During the year the Metric Committee has devoted its main activity to educating our people to the purchase of chemicals in Standard Metric Packages. Between 25 and 50 thousand Chemrules have been now distributed, and one has been placed in the hands of every chemistry teacher in California, Illinois, Maryland, Virginia, District of Columbia, New York, Pennsylvania and the New England States. Several apparatus firms list the Chemrule in their catalogs and report a ready demand for it. It has been received with favor. A few papers have been presented on various phases of the advance of Metric Measures and the attempt has been made to secure a sum of money for the further prosecution of this work. An article in the *Journal of Chemical Education* has been arranged for.

Committee on Nomenclature, Spelling and Pronunciation.—During the past year your Committee on Nomenclature, Spelling and Pronunciation has continued to receive many requests for information on subjects relating to its field of activity and has endeavored in each case to help. In editing *Chemical Abstracts*, particularly in the indexing, it is necessary for this office to try to keep informed as to best usage in chemical names and spellings. It is not a heavy additional task, therefore, to maintain a kind of clearing house for this kind of information. Individual members of your committee, particularly Dr. Austin M. Patterson, frequently help.

Last fall the report of the Committee on the Nomenclature of Pectin, of the Agriculture Food Division, was referred to your general committee on nomenclature. After a study of this report by each of the sixteen members of your committee certain recommendations were made to the pectin committee which led to the attached revised report. The definitions relating to pectin now have the approval of the general committee and it is recommended that they be adopted as tentative for one year after publication. The pectin committee has done a very thorough piece of work and it has been a pleasure to cooperate with it.

The report referred to above is recorded here as a means of international reference.

DEFINITIONS WRITTEN BY THE COMMITTEE ON NOMENCLATURE OF PECTIN OF THE AGRICULTURE-FOOD DIVISION

Pectic Substances.—A group designation for those complex carbohydrate derivatives which occur in plants, or are prepared from plants and which are characterized by the presence of galacturonic acid units. In the naturally occurring pectic substances, the galacturonic acid units apparently exist in an acid reacting complex associated with arabinose and galactose units. This acid complex may occur as a free acid or as a metallic salt, but usually occurs as a methyl ester.

Protopectin.—The term applied to the water insoluble, unhydrolyzed pectin substances in the state in which they occur in plant tissues. *Protopectins* are rendered soluble by treatment with enzymes, acids or certain other reagents, whether by peptization or hydrolysis not being known. The substances thus rendered soluble are designated collectively as *pectin*; it is not known whether or not the *pectins* are different chemical individuals from *protopectins*.

Pectin.—The term applied to the water-soluble, methylated pectin substances occurring in plant tissues or to the methylated pectic substances obtained by restricted treatment of *protopectin* with *protopectinase*, acids or other reagents, the treatment being so regulated as to produce maximum solution of pectic substances with a minimum cleavage of methyl ester groups. The product may be a mixture of substances of varying methyl ester content; the term *pectin* or *pectins* is accordingly a group designation for all intermediate pectic substances between *protopectin* and *pectic acid*. It is proper, however, to refer to an individual of the group as a *pectin*.

Pectic Acid.—The term applied to the pectic substances obtained by the hydrolysis of *pectin* with the complete elimination of the methyl ester groups. Pectic acid may be variable in composition according to the type of hydrolysis employed; accordingly there may be a number of *pectic acids*, all of which are ester-free.

Protopectinase.—The term applied to the enzyme which hydrolyzes or dissolves *protopectin* with the resultant separation of the plant cells from each other, usually spoken of as maceration. Presumably the product of this hydrolysis is pectin. The term *protopectinase* supercedes the older term "pectosinase" with which it is synonymous.

Pectase.—The term applied to the enzyme which converts *pectin* into *pectic acid*, the latter becoming a gel, especially in the presence of calcium (or barium or strontium) salts.

Pectinase.—The term applied to the enzyme which hydrolyzes *pectin* and *pectic acid* into their simplest soluble cleavage products, which are probably arabinose, galactose and galacturonic acid.

STATEMENT TO ACCOMPANY REPORT OF THE COMMITTEE ON PECTIN NOMENCLATURE

The nomenclature for the pectic substances was arrived at after considerable discussion and correspondence. Since similar discussions are likely to arise again, it appears desirable that a statement be made of the reasons which guided the committee in the wording of each of the definitions.

Pectic Substances.—This name has been used in recent literature by von Fellenberg, Sucharipa, and others, and appears to be almost satisfactory general designation. It appears undesirable that the term *pectin* should be retained as a loose general designation for all substances of this type; this term should rather be restricted to the soluble substances defined under *pectin*, thus obviating the need of the expedient so frequently used in the past, of referring to *soluble pectin* in order to distinguish *pectin* from *protopectin*.

The substances are designated as "carbohydrate derivatives" in contradistinction from "carbohydrates." Pectic substances are distinguished from polysaccharides in general by the presence of carboxyl groups. These carboxyl groups are now known to reside in sugar acid units which presumably originate by the oxidation of alcoholic groups of sugar units. Accordingly it appears consistent with the physiological origin of pectic substances, as well as with their chemistry, to designate them as carbohydrate derivatives.

As far as is known, galacturonic acid units are the only acid units found in pectic substances. It is true that further studies may disclose the presence of other acids and it may prove necessary at a later date to make the definition more general by substituting "hexuronic acid" for "galacturonic acid." Such a generalization appears undesirable in view of the limits of our present knowledge.

The present definition of the pectic substances is intended to confine the term to the gelatinizable substances of the types that are found in fruits, in the succulent edible vegetables, and in cell wall tissues generally. It is intended to exclude plant mucilages, algin-like substances from marine algae, cactus siliques, etc., although these bodies are apparently closely related, chemically, to the pectic substances. From the meager data available, it appears that these substances contain other acid groups than galacturonic acid; for example, Sven Oden reports that presence of a pentonic acid in a preparation from marine algae, and Spoehr asserts that glucuronic acid occurs in cactus. The definition of pectic substances as substances containing galacturonic acid appears to effect the desired distinction from these other classes of bodies.

As far as the committee is aware, all naturally occurring pectic substances contain arabinose and galactose units but in the case of laboratory preparations, the carbohydrate units of the original pectic substance may be partly or wholly split off by the hydrolytic treatment employed. The definition of pectic substances has been worded so as to recognize these facts.

Protopectin.—The original pectic substance has been variously designated as *pectose*, as *protopectin*, and as *pectinogen*. Pectose was named by Frey in 1840, protopectin by Tschirch in 1908, and pectinogen by Schryver and Haynes in 1914. The name pectose accordingly takes priority and is strongly established in the literature of plant physiology. Chemically it is an unfortunate term since the suffix *ose* is almost exclusively reserved for the crystalline sugars (with one important exception—cellulose—which is apparently too firmly established to be changed). Since *protopectin* was proposed by Tschirch in 1908, it has been accepted and used by von Fellenberg, Neuberg, Ehrlich, Sucharipa, and in fact, by practically all pectin chemists of continental Europe. A canvas of American pectin chemists indicates that nearly all of them prefer this term. Some English investigators, on the other hand, prefer and use *pectinogen*, and one American worker has expressed a preference for this term on etymological grounds. Although the derivation would suggest that it refers to the original pectic substance, and although it has been so used, the term pectinogen was created to apply to a soluble pectin isolated by a definite type of treatment. In view of the fact that this term has been used in a dual sense whereby confusion has arisen, and of the fact that the term protopectin takes priority and is already better established, the selection of protopectin as the designation for the original pectic substance appears logical and satisfactory. The term pectinogen is legitimately applied to a soluble pectin prepared by the treatment described by Schryver and Haynes.

Pure protopectin has never been isolated for the reason that it has no known solvents and therefore cannot yet be separated from the accompanying and likewise insoluble cell-wall tissue. Nevertheless, the existence of this substance has been assumed ever since pectic substances were known. From the results of investigations on apple pomace and unripe apples, which appeared to indicate that all of the pectic substances in these materials are water-soluble, Tutin concluded that protopectin has no real existence. It is to be noted that Tutin's investigations were confined to a single type of material, and that, even as applied to this material, his conclusions have been questioned by Carre. Sucharipa, on the other hand, has brought forward direct evidence which apparently indicates that the insoluble protopectin is a pectic substance in combination with cellulose, and that the soluble form is obtainable only after separation from the cellulose by hydrolytic treatment. The committee's conception of the nature of protopectin rests to a large extent upon the evidence submitted by Sucharipa, which in our opinion, is sufficient to justify the recognition of protopectin as a distinct class of pectic substances.

A different view has been recently advanced concerning the nature of the original pectic substance found in the cell walls of plants. According to this view the substance which has been designated as protopectin, is regarded as essentially the same substance as pectin. The proponents of this view reject the conception that the conversion of insoluble pectic substance to pectin under the action of acids or other reagents is necessarily a process of hydrolysis; it is argued that possibly the original undissolved pectin is so strongly adsorbed by the cell-walls, that it cannot be extracted with water whereas it can be extracted by acid. On the basis of this viewpoint, it is contended that evidence is lacking for the existence of protopectin as a separate substance differing from pectin.

It is the opinion of the committee on Pectin Nomenclature that the traditional view, *i. e.*, that the conversion of the original undissolved pectic substance into dissolved pectin is a process of hydrolysis, is the simplest explanation of the observed facts; furthermore, that there is a considerable amount of experimental evidence in support of this traditional view. Strong support for this view is found in Sucharipa's observation that, during treatments which convert the undissolved pectin of plants into soluble forms, a quantity of cellulose is simultaneously rendered soluble in ammoniacal copper oxide solution, and this in regular proportion to the quantity of pectin dissolved. The behavior of plant tissues containing insoluble pectic substances when subjected to the action of enzymes, is especially consistent with the traditional view. On the other hand, it must be admitted that the conception of protopectin as a colloidally adsorbed pectin may be the correct one. However, until evidence is forthcoming which will definitely indicate that protopectin has no real existence as a substance distinct from pectin, investigators will continue to require some term to describe the undissolved pectic substance of the cell wall of plants. Accordingly, it appears to the committee that the definition of protopectin as a separate substance should be retained, but expressed in such terms as will indicate that possibly it may be chemically the same as the soluble pectine.

Pectin.—The definition here given is in conformity with the traditional use of the term in its more restricted sense. There has been some questions as to the advisability of including in this class those members of the pectin family that are free in nature, especially since they tend to show acid characteristics. There are two objections to such a classification: (1) the classification, to be scientific, should be based upon chemical composition or some other accurately ascertainable characteristic, rather than upon commercial value, and (2) it would be very difficult to determine where to draw the line between pectin and pectic acid. Accordingly, the chemical classification has been retained and the presence of methyl ester content is assumed to characterize pectins and to distinguish them from pectic acids which are consequently assumed to be free from methyl ester. (This classification has been used by Sucharipa in his recent monograph, "Die Pektinstoffe," Serger & Hempel, Braunschweig, Germany. See p. 95.)

In stating the type of hydrolysis that produced pectin from protopectin, it is not the intention of the committee to define pectin as the product of a treatment. The defining characteristics of pectins are their methylated condition and (with the possible exception of some slightly methylated pectins), their water-solubility; the phrase "restricted hydrolysis" is introduced to distinguish the preparative treatment of pectins from treatments that would result in pectic acids.

Sucharipa classifies the pectins into (1) *free pectin*, occurring as such in the plant and removable by simple water solution, and (2) *hydrolysis pectin*, resulting from protopectin by treatment with hydrolyzing agents. Chemically, they are distinguished by the fact that the free pectin retains arabinose units while the hydrolysis pectins do not, the pentose units having split off during the hydrolysis. (See citation above.)

The classification offered by the committee affords opportunity for later subdividing the pectins as proposed by Sucharipa, or in other ways. The committee does not consider it advisable to recommend any subdivision of these main groups at present. The committee regards its present task to be the clarification of the general terms used with references to the pectic substances and the grouping of the various recognized pectic substances into their general classes on the basis of their chemical similarity. Once this is accomplished, it will be comparatively easy to decide upon the further subdivision of the groups and to fit individual substances into the general scheme.

Pectic Acid.—Doubt has been expressed as to whether all substances heretofore classified as pectic acids are completely free from methyl ester. If the classification is to have a sound chemical foundation, it appears necessary to assume that we have a sharp separation into *pectins* which are esters and completely de-esterified *pectic acids*. The reasons have already been discussed under the section entitled *pectin*. Further researches may, of course, necessitate reclassification of some of the substances now known as pectic acids, since, if it is found that they still retain methyl ester groups, they will then be regarded under the definition as acid esters, or *pectins*.

The methyl-ester-free pectic acids are probably variable in composition according to the amount and kind of non-methoxyl groups (i. e., arabinose, galactose, etc.) that are retained with them. According to the type of hydrolysis by which they are formed, we may expect to find the groups of the original pectin split off or retained in varying proportion. The pectic acid contained in the calcium pectate of Carre and Haynes, the cytopectic acid of Clayton, Norris and Schryver, and the pectic acid of Wichmann and Chernoff are all regarded as pectic acids under the definition given, but they probably differ in composition as they differ in preparative treatment.

Protopectinase.—In order to conform to the term protopectin, it appears desirable to discontinue the traditional name *pectosinase* for the enzyme which acts upon it, and to substitute the new term *protopectinase*. Although the older term is well established in the literature, it is believed that the introduction of a new term will not cause confusion as the naming of enzyme and substrate follows the usual convention and the significance of the term is self-evident.

Pectase.—In this definition is retained the significance that has been attached to the term ever since it was first stated by Frey. Mention of gel formation gives expression to the recognized coagulating effect of the enzyme.

Pectinase.—This definition also is the traditional one given by Frey. It appears to the committee desirable that these definitions be restated at this time in essentially their original forms.

It has been suggested to the committee that recommendations be made that the terms *metapectin* and *parapectin* be dropped. The committee is of the opinion that these terms are already obsolete and that no useful purpose will be served by making any formal statement concerning them.

Committee on the Nomenclature of Pectin.—C. S. Brinton, U. S. D. A. Food and Drug Inspection Laboratory, Philadelphia.; H. J. Wichmann, U. S. D. A. Food and Drug Inspection Laboratory, San Francisco, Calif.; J. J. Willaman, Division of Agric. Biochem., University of Minnesota, St. Paul, Minn.; C. P. Wilson, Research Lab., Calif. Fruit Growers Exch., San Dimas, Calif.; W. H. Dore (Chairman), Div. Plant Nutrition, Agric. Expt. Sta., Univ. Calif., Berkeley, Calif.

Committee on Occupational Diseases in Chemical Trades.—The Committee reported certain recommendations for the reorganization and procedure of the Committee, which were referred to the President for such action as he deemed wise upon consultation with the Executive Committee.

Paper Committee.—The Committee on Paper for the publications of the American Chemical Society respectfully reports that each of the papers used for the Society's publication is equal in all respects to that used for the past several years.

Patent and Related Legislation Committee.—The Committee made no report.

Committee on Preparation and Publication of a List of Ring Systems Used in Organic Chemistry. (Joint with the National Research Council.)—Publication of the List of Ring Systems still waits on the final adoption of the "Proposed International Rules for Numbering Organic Ring Systems" (see *J. Am. Chem. Soc.*, 47, 543-61 (1925)). The "period of criticism" expired in February 1927 but there may be delay in adoption due to the facts that the Germans have not had an opportunity to vote on the matter and that some chemists favor making exceptions of certain well known systems such as anthracene and purine. Through cooperation with the *Chemical Abstracts* office the manuscript list has been kept up to date; some work remains to be done on the literature of the period 1899-1907 and on the new Beilstein.

Prize Essays Committee.—The fourth Prize Essay Contest for accredited secondary school students was formally launched on October 6, 1926, when letters with booklets and display posters were distributed to 14,423 public and private high schools, all of which schools had previously been sent a gift set of the reference books. The Society has little appreciation of the enormous amount of work necessary carefully to revise and check our school lists. This process during the past year has resulted in the addition of 3503 new secondary schools, to the principal of each of which a special letter was sent with a booklet announcing the fourth contest and offering to supply the set of reference books without charge if the school were interested.

New state committee chairmen were secured in several states this year, some of the former chairmen having asked to be relieved, and other changes being made at the instance of our committee. Some of the state chairmen enter into the work of the contest with enthusiasm, writing personal letters to the high school chemistry teachers, speaking at state teachers' meetings, broadcasting explanations of the contest, and discussing the topics in a series of radio talks, as well as addressing high school student bodies in their own localities. In the states of Pennsylvania and Washington college professors were placed at the call of any high school wishing to be addressed on topics in chemistry and prepared to pay railroad expenses. Many state superintendents of education have officially sanctioned the project and have urged participation in the contest in their bulletin to high schools. In some states our chairmen are inactive with the exception of examining the essays at the close of the contest.

A direct reflection of the good results achieved through the distribution and sale of books by the Chemical Foundation is to be found in the increased number of essays submitted this year on the topic "The Relation of Chemistry to Industry." Approximately 50 per cent. of the purchasers of "Chemistry in Industry" have been high schools and high school students. To date Volume I is in its 55th thousand, Volume II in its 45th thousand, "Chemistry in Agriculture" in its 30th thousand, and 125,000 sets of the five reference books have been sold or given away. Certain individual books in the sets have reached a still higher figure.

Our state chairmen this year comment on the improved quality of the essays and it is apparent that school authorities are devoting more attention to selecting and submitting only their representative essays. For example, one school in Pennsylvania prepared 240 essays, but submitted only 6. It is therefore impossible to estimate exactly how many high school students have participated in this year's contest. But the growth of interest from year to year is apparent and the results appear to justify the expenditure of time, money, and effort involved in the contest.

A partial return indicates that approximately six thousand essays have been actually submitted to state and territorial committees this year, and our records show that approximately 12 per cent. of the secondary schools to which books have been distributed have participated in this year's contest. States having a smaller number of high schools participate per school in much greater proportion than states having several hundred high schools. For instance, New Mexico with 51 secondary schools this year submitted 49 essays, whereas Iowa with 865 schools submitted only 127 essays.

CONTEST FOR UNIVERSITY AND COLLEGE FRESHMEN

It will be recalled that this year the first contest limited to freshmen in our colleges and universities was held as a part of the Prize Essay Contest. Heretofore all classes have been eligible, but the results this year indicate that the new policy is a wise one. In the 1925-26 contest when all classes were eligible to participate, only 360 essays were submitted for the entire country. This year from the freshmen alone 477 essays have been received. These are fairly well apportioned among the six topics.

Our lists show 871 colleges and universities eligible to participate but of these 736 were not represented in this year's contest. Fifteen per cent. or 135 colleges and universities were represented in this year's contest, but it is difficult to approximate the actual number of participants. For instance, 228 essays were prepared at Syracuse University, but only 38 were submitted. North Dakota Agricultural College prepared 200 and submitted 32. Pennsylvania State College wrote 300 and submitted 40, and at the University of Maryland 350 were written and but 31 submitted.

NORMAL SCHOOLS AND TEACHERS' COLLEGE COMPETITION

Two hundred and fifty-eight normal school and teachers' colleges received individual invitations to participate in this new contest, each invitation being accompanied by booklets, display posters and a gift set of the five reference books. Essays from fifty of these schools to the number of 133 have been received from these teacher-training institutions. The committee considers this showing most representative and is confident that a majority of the 208 schools which did not participate this year can readily be persuaded to participate in future contests.

After four years' experience with the various contests sponsored by the American Chemical Society and made possible through the generosity of Mr. and Mrs. Francis P. Garvan, your committee is unanimous in its belief that if the contest is not as successful as it should be, two principal causes are responsible. First, many sections of the American Chemical Society remain inactive so far as the contest is concerned and but a small minority of the local sections consider the contest any of their affair. It is perfectly obvious that the large amount of work incident to the contest could not be carried out but for the very generous support given the committee by numerous individuals and several local sections. The facts remain, however, that the majority of our members seem to feel that after having accepted responsibility for the contest and approving the appointment of a committee, their duty has been performed and they are quite content to let the committee and any others who will perform the work, so long as their own effort is not involved. It ought to be possible to have chemists generally appreciate that one of the results of this contest is the education of the very men by whom they are employed and that they have a direct interest in the education of these executives. More than 40 per cent. of the reference books offered at nominal cost in connection with the Prize Essay Contest have been purchased by executives, financiers and other business men. But this has not been due—with a few notable exceptions—to the efforts of the chemists themselves.

The second difficulty is in the lack of interest on the part of teachers, whether they be in high schools, teachers' colleges, or universities. In some instances the teachers of science together with the teachers of English have realized the potentialities of the Prize Essay Contest as an aid to their own work and the results have been very gratifying, both to the committee and to the teachers themselves, not to mention the measurable benefit to the students. If, for example, teachers in schools generally would show the same enthusiasm for the possibilities of the contest as we have found in Honolulu, all concerned—chemists, teachers and students—would soon come to realize that in this contest we have one of the best opportunities possible for carefully laying the foundation upon which the future progress of American chemistry may very largely rest.

The committee is very glad to be able to transmit to the president and council of the Society the offer of Mr. and Mrs. Francis P. Garvan to sponsor a Prize Essay Contest for the academic year 1927-28 along substantially the same lines as the previous contests, the principal change being in the contest for the college and university freshmen. This coming year will see in place of the one cash prize for the best essay in each of the six groups, three prizes as follows: first, five hundred dollars; second, three hundred dollars; and third, two hundred dollars. This places the prizes for this contest on the same basis as prevail this year for the normal schools and teachers' colleges and the committee believes this will contribute directly to a greater interest on the part of students.

The committee wishes again to thank sincerely the national chairman and the national committee members, the state chairmen and the state committee members, as well as the large group of

individual chemists who have rendered indispensable aid in furthering the work in which we are so deeply interested.

The Council unanimously instructed the Secretary to write to Mr. and Mrs. Francis P. Garvan and express the appreciation of the Society for their continued support of this important work.

Committee on the Revision of Methods of Coal Sampling and Analysis. (Joint with the Society for Testing Materials.)—The Committee reported that their procedure regarding the methods for determining the fusibility of coal-ash had been accepted by the Supervisory Committee on Standard Methods of Analysis and considered their work completed.

Committee on Standard Apparatus.—During the year 1926-7 the committee has made recommendations on a few questions of sizes and shapes of apparatus. Through the coöperation of members of the Association of Scientific Apparatus Makers of the United States of America it has been possible to issue an illustrated report which gives the recommended standard sizes and shapes adopted by the committee. Most of the material was published, without illustrations, in *Industrial and Engineering Chemistry*, vol. 13, page 1070, 1921, and vol. 14, pages 654 and 738, 1922. With the publication of the comprehensive report it will be possible for the committee to survey the field, take up items that have not been considered, and recommend standard dimensions for items that are now listed as "large" or "small," or without any indication of dimensions.

Committee on Standard Methods for the Examination of Water and Sewage to Coöperate with the Committee of the American Public Health Association.—No actual revision work of Standard Methods for the Examination of Water and Sewage is now in progress. A revision according to the usual procedure will be made in 1928. Looking forward to such revision this committee has collected data on the strength of soap solutions used in rating Zeolite water softeners and data on the significance of the albuminoid ammonia test.

The data on soap solutions were presented before the Water Sewage and Sanitation section at the Philadelphia meeting and a resolution was adopted favoring an establishment of a standard soap for this purpose.

Committee on Standardization of Biological Stains.—The representative of the American Chemical Society on this Committee reported as follows:

The Commission on the Standardization of Biological Stains has had a very prosperous year. Further progress has been made along the lines of work previously undertaken. The Standardization of the stains themselves has progressed to the point where thirty seven (37) of the most widely used stains are being certified, against twenty-eight (28) a year ago. The work necessary to the establishment of standards for the stains has led to the development of considerable new information in regard to the dyes themselves and their reactions and properties, from both a chemical and a biological viewpoint. As an example of this, the discovery of the double compounds of basic dyes with phenols may be noted. Formerly it was supposed that the phenol served as a mordant pure and simple. But it has been shown that this idea is false. What really takes place is a combination of the dye with the phenol, forming a new compound with staining properties differing widely from those of the original dye. (*Vide Stain Technology*, 1, pp. 77, 98, 116 (1926).)

The new journal, *Stain Technology*, published by the Commission, made its appearance last January and regularly each quarter since. In the first volume are about thirty (30) articles and notes dealing with new methods or investigations of older methods. More than fifty per cent. of these have been voluntary, unsolicited contributions and the results of work independent of that carried on by the Commission itself. The Journal has been well received and promises to have a successful future.

The Biologists are now more than ever firmly convinced of the value of the closest coöperation between themselves and chemists. And the work of the Commission has shown that the chemist can learn much by working alongside the biologist. Both types of scientific work have been benefited largely by this association and the future is bright with the promise of further important developments of interest to both sciences. It is therefore recommended that this Society continue its representation on the Commission by appointing a successor to the present representative, who is unable to serve longer in this capacity.

Committee on Standardized Methods for Vitamin Research.—The committee appointed by the American Chemical Society for the study and possible standardization of methods of investigating vitamin values has held no meeting and recommended no official action during the past year.

Because the whole subject of vitamin investigation is still in such a formative stage, the committee will, doubtless, be slow to make recommendations to the Society for formal adoption of standard methods. At times, however, the existence of the committee seems to serve a useful purpose in proving a sort of clearing house for views on this subject, as, for instance, in connection with the consideration of methods for vitamin A as included in the last revision of the U. S. Pharmacopoeia.

Supervisory Committee on Standard Methods of Analysis.—The report of the Committee on the Analysis of Commercial Fats and Oils has been published in full in *Industrial and Engineering Chemistry*.

The report of the Committee on Coal Sampling and Analysis, covering the methods for determining the fusibility of coal ash, has been accepted by the committee.

It was voted to request the President to appoint a committee of five to be known as the Committee on Coöperation with Industrial Museums. President Rosengarten appointed Marston T. Bogert, *Chairman*, H. E. Howe, William Hoskies, Charles L. Reese, and Gerald L. Wendt.

The Council unanimously voted their appreciative thanks to the Virginia Section; its officials; and the chairman and members of the committees in charge of the Richmond Meeting for their boundless hospitality and unusual attention to the welfare of the members in Richmond. The Secretary was instructed to send the thanks of the Society to the chairman of the committees for the Richmond Meeting and individually

to numerous citizens and organizations of Richmond, a list of whom was furnished him by the local section.

The Council then adjourned.

CHARLES L. PARSONS, *Secretary*

COUNCIL

President Rosengarten has appointed S. W. Parr as the representative of the American Chemical Society on the Sectional Committee on the Classification of Coal of the American Society for Testing Materials.

Proceedings

GENERAL MEETING MINUTES

The Seventy-fourth General Meeting of the American Chemical Society was held at the Statler Hotel, Detroit, Michigan, from Monday, September 5 to Friday, September 9, inclusive.

A full account of the meeting will be found in the News Editions of *Industrial and Engineering Chemistry* for September 10 and 20.

The Council meeting was held on the afternoon of September 5. On Monday evening there was also a formal reception and dance at the Hotel Statler.

Four general divisional meetings were held on Tuesday afternoon and divisional meetings on Wednesday, Thursday morning and Friday morning, as outlined in the News Edition for August 20.

The boat ride on the Detroit River on Tuesday evening with approximately a thousand present was thoroughly enjoyed, the occasion being enlivened by music, dancing, bridge and other amusements.

On Wednesday evening President Rosengarten, at the Cass Technical High School, presented his annual address entitled "Reflections." This was followed by an address by Charles F. Kettering on "The Functions of Research," both of which will be published in *Industrial and Engineering Chemistry*.

The registration showed 1618 members and guests present.

On Thursday evening a special feature entertainment enlivened by vaudeville performers, dancing, music, etc., filled the ballroom of the Statler Hotel to overflowing. On Thursday afternoon and Friday numerous trips were arranged to industrial establishments in Detroit and to the University of Michigan at Ann Arbor.

A special ladies' program, already printed, was a feature of the meeting.

All divisions of the Society met in divisional meetings, details of which, as well as of numerous social gatherings, including luncheons and dinners of affiliated groups, will be described in the News Edition and in the regular edition of *Industrial and Engineering Chemistry*.

The divisions elected officers as follows. These will be found regularly published in the opening pages of each issue of the *Journal of the American Chemical Society*.

BIOLOGICAL: Chairman, Paul E. Howe; Secretary, M. X. Sullivan; Executive Committee, H. B. Lewis, A. P. Lothrop, Icie G. Macy, J. R. Murlin, H. A. Shoule, S. D. Wilkins.

CELLULOSE: Chairman, L. E. Wise; Vice-Chairman, J. L. Parsons; Secretary, E. C. Sherrard; Executive Committee, H. LeB. Gray, B. Johnsen.

CHEMICAL EDUCATION: Chairman, B. S. Hopkins; Vice-Chairman, H. R. Smith; Secretary, R. A. Baker; Assistant Secretary, L. J. Wood; Treasurer, E. M. Billings; Executive Committee, L. W. Mattern, Wm. McPherson, W. Segerblom.

COLLOID: Chairman, H. B. Weiser; Secretary, F. E. Bartell; Executive Committee, W. D. Bancroft, R. H. Bogue, R. A. Gortner, W. D. Harkins, H. N. Holmes, J. H. Mathews, S. E. Sheppard, E. B. Spear.

DYE: Chairman, M. L. Crossley; Vice-Chairman, E. K. Bolton; Secretary-Treasurer, H. T. Herrick; Executive Committee, C. G. Derick, L. A. Olney.

FERTILIZER: Chairman, E. W. Magruder; Vice-Chairman, Wm. H. Ross; Secretary, H. C. Moore; Executive Committee, J. E. Breckenridge, H. R. Kraybill, E. W. Magruder, A. R. Merz, H. C. Moore, A. J. Patten, Wm. H. Ross.

- GAS AND FUEL:** Chairman, A. C. Fieldner; Vice-Chairman, S. P. Burke; Secretary-Treasurer, O. O. Malleis; Executive Committee, G. G. Brown, R. S. McBride.
- HISTORY OF CHEMISTRY:** Chairman, Lyman C. Newell; Secretary, Tenney L. Davis; Executive Committee, C. A. Browne, Geo. L. Coyle, F. B. Dains.
- INDUSTRIAL & ENGINEERING CHEMISTRY:** Chairman, R. J. McKay; Vice-Chairman, R. E. Wilson; Secretary-Treasurer, E. M. Billings; Executive Committee, T. A. Boyd, Jr., J. Bennett Hill, W. J. McAdams, Walter Schmidt, J. R. Withrow.
- LEATHER AND GELATIN:** Chairman, Arthur W. Thomas; Vice-Chairman, Frank L. DeBeukelaer; Secretary-Treasurer, August C. Orthmann; Executive Committee, Norman C. Hertz, S. E. Sheppard.
- MEDICINAL CHEMISTRY:** Chairman, A. W. Dox; Vice-Chairman, Frederick Fenger; Secretary-Treasurer, A. E. Osterberg.
- ORGANIC:** Chairman, William Lloyd Evans; Secretary-Treasurer, F. C. Whitmore.
- PAINT AND VARNISH:** Chairman, W. T. Pearce; Vice-Chairman, P. E. Marling; Secretary-Treasurer, E. W. Boughton; Executive Committee, J. S. Long, J. R. MacGregor.
- PETROLEUM:** Chairman, J. B. Hill; Vice-Chairman, F. W. Padgett; Secretary-Treasurer, Carl L. Johnson; Executive Committee, C. O. Johns, R. R. Matthews.
- PHYSICAL AND INORGANIC:** Chairman, George L. Clark; Vice-Chairman, Victor K. LaMer; Secretary-Treasurer, Ward V. Evans; Executive Committee, G. S. Forbes, J. H. Hildebrand, W. H. Rodebush, H. S. Taylor, H. B. Weiser.
- RUBBER:** Chairman, H. L. Fisher; Vice-Chairman, Arnold H. Smith; Secretary-Treasurer, H. E. Simmons; Executive Committee, E. R. Bridgewater, J. M. Fry, Stanley Krall, W. G. Nelson, H. A. Winkelmann.
- SUGAR:** Chairman, F. J. Bates; Secretary-Treasurer, F. W. Zerban; Executive Committee, J. F. Brewster, D. L. Davoll, H. I. Knowles, W. B. Newkirk, S. J. Osborn, J. W. Schlegel.

CHARLES L. PARSONS, *Secretary*

DIRECTORS' MINUTES

The Directors of the American Chemical Society met in the Statler Hotel, Detroit, Michigan, Monday, September 5, 1927, at 8 P.M., with President George D. Rosengarten in the chair and Messrs. W. D. Bancroft, W. D. Bigelow, S. W. Parr, Charles L. Parsons and John E. Teeple present.

The rate schedule for reprints as tabulated and already put in force by Editor Lamb was approved by the Directors as follows:

No. copies	REPRINTS PER PAGE		Covers
	JOURNAL OF THE AMERICAN CHEMICAL SOCIETY 8 pp. or less per page	9 pp. or more per page	
50	\$.20	\$.14	\$1.77
100	.32	.24	2.05
150	.45	.33	2.33
200	.51	.42	2.60
250	.59	.50	2.88
300	.67	.58	3.16
350	.76	.66	3.43
400	.84	.74	3.71
450	.92	.82	3.99
500	1.00	.90	4.26
550	1.08	.98	4.54
600	1.16	1.06	4.82
650	1.24	1.14	5.10
700	1.31	1.21	5.37
750	1.39	1.29	5.65
800	1.47	1.37	5.93
850	1.55	1.45	6.20
900	1.62	1.52	6.48
950	1.71	1.60	6.76
1000	1.71	1.60	7.03
Extra M's.	1.14	1.14	6.71

The request of Editor E. J. Crane for an additional allotment of \$3,050 for the 1927 budget of *Chemical Abstracts* was granted with instructions to the Treasurer to transfer any available income of the Endowment Fund toward meeting this appropriation, taking the balance from current funds of the Society.

The Treasurer reported the following transactions since the last Directors' meeting, which were duly approved:

1. The sale of \$1900 par value First, Third and Fourth Liberty Bonds, net of \$1978.85 from Decennial Index Fund.
2. The receipt of a check for \$250.00 from the Virginia Section, in June 1927, for the Endowment Fund.

The meeting then adjourned.

CHARLES L. PARSONS, *Secretary*

EXECUTIVE COMMITTEE MINUTES

The Executive Committee met in Parlor A of the Statler Hotel, Detroit, Michigan, at 2 o'clock, Sunday, September 4, 1927, with President Rosengarten in the chair and Messrs. A. M. Comey, E. J. Crane, H. E. Howe, Wm. McPherson, S. W. Parr, Charles L. Parsons and John E. Teeple present.

The Committee considered the resolution referred to them at the Richmond Meeting covering the establishment of an Institute of Chemical Education and formulated a report to the Council which will be found printed in the Council proceedings of September 5.

President Rosengarten having asked the advice of the Executive Committee covering a request from the American committee for participation in the international "Maison de la Chimie" for the use of his name as a member of the Committee, it was voted that it was their unanimous opinion that he should decline the use of his name and influence on the basis that his acceptance would tacitly commit the American Chemical Society to a procedure it could not approve. The full vote with reasons therefor will be found in the Council proceedings of September 5, it having also been unanimously adopted by the Council.

The Committee having requested the Directors of the Society to meet with them, the above personnel was increased at 3 o'clock by Directors W. D. Bigelow and W. D. Bancroft, and the situation regarding the relation of the Society to the Division of Chemical Education and the *Journal of Chemical Education* was discussed. As the Executive Committee of the Division of Chemical Education was also in session the meeting adjourned to await their deliberations.

The Directors and the Executive Committee met again at 10 o'clock on the morning of September 5 and after receiving the report of the deliberations of the Executive Committee of the Division of Chemical Education, as made to the President and the Secretary the previous evening, the entire body voted as follows:

"That the Executive Committee and Directors in joint sessions are unanimously appreciative of the attitude of loyalty to the Society shown by the Executive Committee of the Division of Chemical Education in their conference with the President and the Secretary on the evening of September 4, as reported to us; express our realization of the good work of their Division in the cause of chemical education; recognize fully the importance of that work to the cause of American chemistry, and pledge their best endeavors to enable the Division to publish the *Journal of Chemical Education* under their control and auspices."

It was also unanimously voted to approve the acts of the President and the Secretary in connection with the relation of the Division of Chemical Education to the

American Chemical Society, as contained in the correspondence with the officers of the Division from April 25, 1927, to August 5, 1927, inclusive.

The Committee then adjourned.

CHARLES L. PARSONS, *Secretary*

COUNCIL MINUTES

The meeting of the Council of the American Chemical Society was called to order by President George D. Rosengarten at 2 P.M. on Monday, September 5, 1927, in the Statler Hotel, Detroit, Michigan, with the following councilors and substitutes present:

Ex-Officio.—W. D. Bancroft, W. D. Bigelow, F. B. Carpenter, E. J. Crane, M. L. Crosley, F. B. Dains, R. P. Dinsmore, Geo. Shannon Forbes, Charles H. Herty, B. S. Hopkins, H. F. Howe, E. F. Kohman, S. W. Parr, Charles L. Parsons, Edgar P. Smith, John E. Teeple, John Arthur Wilson.

Councilors at-Large.—Roger Adams, Erle M. Billings, A. M. Comey, Harlan S. Miner, Frank C. Whitmore.

Local Sections.—*Alabama*, John R. Sampey (subs. for B. B. Ross). *Ames*, F. E. Brown (subs. for W. F. Coover). *California*, Robert N. Wenzel (subs. for C. L. Alsborg). *Central Pennsylvania*, E. D. Ries. *Chicago*, H. E. Barnard, W. V. Evans (subs. for Wm. Hoskins, Sr.), D. K. French, Paul N. Leech (subs. for Paul Van Cleeft), S. L. Redman (subs. for David Klein), W. R. Smith, E. H. Volwiler, H. G. Walker, Robert E. Wilson. *Cincinnati*, L. W. Bosart (subs. for G. D. McLaughlin), F. C. Broeman (subs. for C. R. Bragdon). *Cleveland*, Hippolyte Gruener, J. D. Morron, O. F. Tower. *Colorado*, R. G. Gustavson (subs. for L. D. Roberts). *Columbus*, Wm. McPherson. *Cornell*, A. W. Browne. *Delaware*, Cole Coolidge (subs. for Charles L. Reese). *Detroit*, H. C. Hamilton, George W. Winchester. *Erie*, John L. Parsons (subs. for Charles H. Reese). *Fort Wayne*, Eskel Nordell. *Georgia*, J. Samuel Guy (subs. for Thomas C. Law). *Illinois-Iowa*, O. K. Smith. *Indiana*, Edgar B. Carter. *Iowa*, L. Chas. Raiford. *Louisiana*, C. E. Coates. *Maine*, C. A. Brautlecht. *Maryland*, E. Emmet Reid. *Michigan State College*, Arthur J. Clark. *Midland*, William J. Hale. *Milwaukee*, A. C. Orthmann. *Minneapolis*, E. P. Harding (subs. for M. C. Sneed), G. H. Montillon (subs. for C. H. Bailey). *Nebraska*, B. Clifford Hendricks (subs. for F. W. Upson). *North Jersey*, C. O. Johns, A. V. H. Mory (subs. for J. G. Lipman). *New York*, S. P. Burke, C. R. Downs, C. M. Hoke (subs. for T. B. Freas), William Haynes (subs. for Martin H. Ittner), James Kendall, D. H. Killefer, Charles A. Lunn, R. R. Renshaw, Foster Dee Snell, S. D. Swan (subs. for H. B. Lowe), Arthur W. Thomas, M. C. Whitaker (subs. for B. T. Brooks), Lois W. Woodford (subs. for Marie Reimer), F. W. Zerbahn (subs. for H. R. Moody). *North Carolina*, A. S. Wheeler. *Northeastern*, C. R. Boggs (subs. for W. L. Jennings), G. J. Esselen, Jr., Arthur J. Hohman, Arthur D. Holmes, Robert W. Neff, Wilhelm Segerblom. *Northern West Virginia*, A. R. Collett (subs. for C. A. Jacobson). *Omaha*, L. B. Parsons (subs. for Wm. Harr). *Philadelphia*, J. Bennett Hill, Henry S. Lukens, J. Spencer Lucas, Joseph Rosin (subs. for C. S. Hinton), O. L. Shinn (subs. for Horace C. Porter), Walter T. Taggart, James G. Vail (subs. for Wm. Stericker). *Pittsburgh*, J. H. James, Alexander Silverman. *Princeton*, Robert N. Pease (subs. for C. P. Smyth). *Purdue*, R. E. Nelson. *Rhode Island*, N. W. Rakestraw (subs. for R. F. Chambers). *Rochester*, E. K. Carver (subs. for Hans T. Clarke). *Saint Joseph Valley*, J. A. Nieuwland. *Saint Louis*, T. R. Ball. *Southeastern Texas*, Harry B. Weiser. *Southern California*, Walter A. Schmidt. *South Jersey*, R. E. Rose. *Syracuse*, R. A. Baker. *Toledo*, George H. Anderson. *University of Illinois*, A. M. Buswell, D. B. Keyes. *University of Missouri*, Herman Schlundt. *Vermont*, S. Francis Howard. *Washington*, D. C., L. H. Adams, W. Blum, W. Mansfield Clark, L. E. Warren (subs. for V. K. Chesnut). *Western New York*, V. L. Robinson (subs. for E. R. Riegel), Lester F. Hoyt (subs. for J. A. Handy), F. L. Koethen. *Wisconsin*, L. F. Hawley.

The Council voted to authorize the Section of History of Chemistry to form a Division of History of Chemistry and the following by-laws were adopted:

BY-LAWS OF THE DIVISION OF THE HISTORY OF CHEMISTRY

ARTICLE I

Membership

Membership in the Division shall be open to all members of the American Chemical Society, and any member of the Society shall, upon request to the Secretary of the Division, be registered as a member of the Division.

ARTICLE II

Officers

Section 1. The officers of the Division shall be a chairman, a recording secretary, and an executive committee.

Section 2. The chairman and the secretary shall be members of the Executive Committee ex-officio.

Section 3. The Executive Committee shall consist of three registered members of the Division and the members ex-officio, provided by Section 2 of this article. The chairman of the Division shall be chairman of the Executive Committee.

Section 4. At the first session of the Division coincident with the annual meeting of the Society and following the report of the Secretary, the Chairman shall appoint from the members present at the meeting a committee of three whose duty it shall be to nominate officers for the ensuing year. This committee shall present the list of nominations immediately preceding the election of officers at the last session during that annual meeting.

Section 5. All officers of the Division shall be elected annually by ballot at the last session of the Division held during the annual meeting of the Society, and shall take office at the close of the meeting at which they were elected. They shall hold office for one year or until their successors are elected. Voting by proxy or by letter shall not be allowed.

Section 6. The Executive Committee shall fill any vacancies occurring through death or resignation among officers of the Division.

Section 7. It shall be the duty of the chairman to represent the Division in the Council of the Society, to preside at meetings of the Executive Committee, to carry into effect the decisions and recommendations of that committee, to preside at stated meetings of the Division, and to report to the Society at its regular meetings.

Section 8. It shall be the duty of the recording secretary to keep a record of the proceedings of the Division and of the Executive Committee to maintain a list of registered members, to send to registered members such notices as the business of the Division may require, and to transmit to the Secretary of the Society the names of all the officers and standing committees of the Division within three weeks of their appointment; and, in like manner, to notify the Secretary of the Society of any change of officers or standing committees during the year.

Section 9. The recording secretary shall be the custodian of the files of the Division.

Section 10. The Executive Committee shall conduct the business of the Division and direct its activities. It shall at each general meeting of the Society, and as early as may be, hold a meeting to consider the affairs of the Division and to receive reports of its committees. The voting majority of the Executive Committee shall be responsible for all expenditures which it may authorize, except so far as the action of the Council shall previously have provided for such expenditures.

ARTICLE III

Meetings

There shall be a meeting of the Division at each general meeting of the Society unless for special reason omitted by vote of the Executive Committee. Business affecting the organization of the Division shall be transacted only at the meeting coincident with the annual meeting of the Society.

The order of business shall be as follows:

Reading of minutes.
Report of Executive Committee.
Report of Secretary.
Reports of Committees and discussions.
Reading of papers.
Miscellaneous business.

And at the annual meeting:

Appointment of Nominating Committee.
Report of Nominating Committee.
Election of officers.
Unfinished business.

The regular order of business of the Division may be suspended at any session by the consent of three-fourths of the members present.

ARTICLE IV

Papers

All titles and abstracts of papers and all manuscripts must be in the hands of the recording secretary of the Division on or before the date stated in the preliminary program announcement of each meeting.

ARTICLE V

Assessments

The Executive Committee may at its discretion impose dues not to exceed three dollars (\$3 00) per year upon registered members of the Division, said dues to be collected by the Secretary, and the receipts therefrom to be devoted to the purposes of the Division.

ARTICLE VI

Amendments

These by-laws may be amended at any annual meeting of the Division by a three-fifths vote of the registered members present, provided two weeks' notice of the proposed amendment with the text thereof has been sent to the registered members of the Division. Amendments to be effective must be approved by the Council and accepted by that body as not inconsistent with the constitution and by-laws of the Society.

The Division of Chemistry of Medicinal Products submitted new by-laws somewhat changed from their old by-laws and changing the name of the Division to the "Division of Medicinal Chemistry." The by-laws were duly approved as follows:

BY-LAWS OF THE DIVISION OF MEDICINAL CHEMISTRY

ARTICLE I

Name and Object

Section 1. This Division shall be known as the Division of Medicinal Chemistry of the American Chemical Society.

Section 2. The objective of this Division shall be the advancement of knowledge of the chemistry and pharmacology of substances used in medicine.

ARTICLE II

Membership

Section 1. Any member of the American Chemical Society may become a member of this Division by requesting the Secretary of the Division to enroll him therein.

Section 2. A member in good standing is one who has been accepted by the Secretary and has paid the yearly dues.

ARTICLE III

Officers

Section 1. The officers of this Division shall be a Chairman, a Vice-Chairman and a Secretary-Treasurer, who shall constitute the Executive Committee,

Section 2. The duties of the Chairman, Vice-Chairman and Secretary-Treasurer shall be those that usually pertain to their positions.

Section 3. The officers shall be elected at the last regular session of the Division held during the annual meeting of the American Chemical Society.

Section 4. At the first session of this Division during an Annual Meeting the Chairman shall appoint a nominating committee of three members in good standing to nominate two candidates for each office of the Division—Chairman, Vice-Chairman and Secretary-Treasurer. The committee shall report at the call of the Chairman.

Section 5. The Chairman of the Division is ineligible for renomination by this Committee.

Section 6. The Executive Committee shall act for the Division in the interim between meetings of the Division and shall have power to fill all vacancies caused by the death, resignation or removal of an officer, and shall perform all other duties assigned thereto.

ARTICLE IV

Meetings

Section 1. Meetings of the Division shall be held at each general meeting of the American Chemical Society, unless cancelled by the Executive Committee for good and sufficient reasons.

Section 2. The order of business at any business meeting shall be:

- a. Reading of minutes of previous meeting.
- b. Report of Executive Committee.
- c. Report of Secretary-Treasurer.
- d. Appointment of Nominating Committee, if required.
- e. Reports of Committees.
- f. Unfinished business.
- g. New business.
- h. Election of officers, if required.

ARTICLE V

Committees

The Chairman shall, with the advice and consent of the Executive Committee, appoint the Nominating Committee and such other standing and special committees as may be authorized by the Division.

ARTICLE VI

Publications

All papers presented to this Division, must, if intended for publication, be submitted to a journal published under the auspices of the American Chemical Society. If the Editor of this journal does not deem the article suitable for publication therein, or wishes to release it, the Secretary shall advise with the author regarding the place of publication.

ARTICLE VII

Papers

Section 1. Every title of a paper submitted for inclusion in the program of any meeting of this Division shall be accompanied by a 100-word abstract of the paper and the name of the laboratory in which the work was done.

Section 2. The Executive Committee may require the full manuscript of a paper before inclusion of the title in the program, if the abstract does not clearly indicate the nature of the paper.

Section 3. Non-members of the American Chemical Society may be placed upon the program of the Division when they are not American chemists, and then only, by vote of the Executive Committee.

Section 4. The time for the presentation of a paper shall be limited to ten minutes and the time for discussion of any paper shall be limited to five minutes. The Executive Committee may extend upon the program the time for the presentation of any paper. The time for discussion of any paper may be extended by vote of the Division. The Executive Committee may provide on the program for formal, prepared discussions of any paper. No paper shall be read from manuscript.

Section 5. The Secretary shall, two weeks before the date of a general meeting, send abstracts of the papers submitted to all members of the Division in good standing.

ARTICLE VIII

Dues

The dues for all members of this Division in good standing shall be one dollar (\$1.00) per year to cover postage and provide for the distribution of Abstracts of papers to be presented.

ARTICLE IX

Amendments

Amendments to these By-Laws may be proposed at any general meeting and shall be voted upon at the next general meeting.

A proposal that a Section of Chemical Economics be organized was discussed and, without formal vote, was referred to the Division of Industrial and Engineering Chemistry, under the auspices of which a symposium will be held, probably at the Swampscott Meeting, to determine the interest of the subject in the hope that it may ultimately lead to the formation of a Section and, later, a Division of the Society.

The following were re-elected for a term of three years, 1928-1930:

A. B. LAMB, Editor JOURNAL OF THE AMERICAN CHEMICAL SOCIETY.

E. J. CRANE, Editor *Chemical Abstracts*.

H. E. HOWE, Editor *Industrial and Engineering Chemistry*.

W. A. Noyes, Editor *Scientific Monographs*.
H. E. Howe, Editor *Technologic Monographs*.

F. A. Liddbury, A. D. Little, and C. E. K. Mees were re-elected associate editors of *Technologic Monographs* for the term 1928-1930.

Roger Adams and E. W. Washburn were re-elected associate editors of the JOURNAL OF THE AMERICAN CHEMICAL SOCIETY.

H. S. Taylor and W. A. Patrick were elected the American Chemical Society's representatives on the editorial board of the *Journal of Physical Chemistry* for a term of two years, replacing G. A. Hulett and Irving Langmuir, whose terms expire in December, 1927.

Wm. McPherson was re-elected a member of the Executive Committee of the Council, term to expire in December, 1930.

The Council authorized the establishment of a South Carolina Piedmont Section upon the receipt of the necessary signatures, as required by the Constitution, under definite designation of headquarters, the territory to include that part of the State of South Carolina west of the Counties of Lancaster, Kershaw, Richland, Lexington and Aiken, and including these Counties.

The Council having received an invitation from the Minnesota Section and from the President of the University of Minnesota to hold the 1929 fall meeting in Minneapolis unanimously voted to accept the invitation.

The President of the Society having been asked to lend his name to the national committee being organized to secure the financial participation of the United States in the erection of a "Maison de la Chimie" in Paris, of an international nature, and intended to house the "International Office of Chemistry," the formation of which is being undertaken through diplomatic channels, the President called upon the Secretary to read various documents bearing upon the matter and to give a history of the recent movements looking toward the creation in one of the capitals of Europe of what appeared to be a movement for the international control of chemistry. Following the complete statement, which included the request of the President of the Society for the advice of the Executive Committee, the following action of the Executive Committee was unanimously endorsed by the Council:

President George D. Rosengarten of the American Chemical Society having asked counsel of his advisors regarding a communication from M. Maurice Leon, vice-chairman of the "American Organization Committee for American Participation in a Maison de la Chimie" requesting the use of his name as a member of the committee, the Executive Committee of the Society unanimously advise him to decline for the reason that his acceptance would tacitly commit the American Chemical Society to a project it cannot approve.

The American Chemical Society is glad to honor the name and accomplishments of Marcelin Berthelot and in evidence thereof has appointed two of its own past presidents to represent it at the Centenary Celebration on October 25, 1927. An international "Maison de la Chimie" and "An International Office of Chemistry" nationally conceived with predetermined control and location in Paris is an entirely different matter to which the American Chemical Society cannot give its adherence, even

tution were not assessed upon the rest of the world.

The American Chemical Society believes that if an International Office of Chemistry, having as its object the centralization of influence of chemical science, both pure and applied, is ever deemed desirable or necessary, it should be inspired through cooperative action of the world's scientific chemical organizations and not by governments through political channels.

The American Chemical Society does not approve any world centralization of control of chemistry and believes that the future progress of chemistry can best be served as heretofore by harmonious cooperation of national organizations.

The Society specifically disclaims any discourtesy to the organizers of the present movement but believes the underlying principle to be so detrimental to continued international cooperation that it would be lacking in probity if it did not make its judgment known.

It was voted that the Secretary be directed to inform the State Department and

other governmental departments before whom the question of the "International Office of Chemistry" had been brought of the Society's opinion.

The report of the Committee on the first Institute of Chemistry of the American Chemical Society was presented as follows and accepted with the sincere thanks of the Council to all those who have been active in furthering the interests of this successful experiment:

REPORT OF THE COMMITTEE ON THE INSTITUTE OF CHEMISTRY

To the Council of the American Chemical Society:—

The first session of the Institute of Chemistry of the American Chemical Society was held at Pennsylvania State College July 5 to 29, 1927. It is impossible to give a complete report in small compass because the activities of the four weeks were so numerous and so complex that space is not available. For this reason and because the outstanding events have been fully reported in the News Edition as well as in popular newspaper and magazine press only a summary is herewith presented.

Following discussion between individuals, and on receipt of a guarantee from the Chemical Foundation that funds would be available to pay a part of the expected costs, a proposal for such a session was made to the Executive Committee by Secretary Parsons early in February. After authorization by this Committee President Rosengarten appointed a special committee to have general charge. This is composed of G. L. Wendt, chairman, C. E. K. Mees, C. M. A. Stine, F. C. Whitmore, W. R. Whitney, F. W. Willard and the following members, *ex officio*: George D. Rosengarten, President, Chas. L. Parsons, Secretary, H. E. Howe, director of the news service, B. S. Hopkins, chairman of the Division of Chemical Education, and N. E. Gordon, chairman of the Committee on Chemical Education. The committee met in New York on March 15 and in Wilmington on May 17. The actual management was intrusted to G. L. Wendt as director, F. C. Whitmore as associate director, and A. W. Kenney as executive secretary. The program was arranged by the committee as thus organized, and special features were in the following hands: publicity, Mr. D. H. Killefer; office management and room reservations, Mrs. Marion L. Kenney; housing and commissary, Mr. Gordon Harris; recreation, Mr. Sherwood L. Reeder. In addition to these an office staff of eleven persons was required. The Pennsylvania State College, which had submitted the only invitation for the meeting, agreed to conduct the financial affairs through the offices of the treasurer, the purchasing agent and the comptroller of the college.

The scheduled program contained four main series of meetings: the daily conferences, the public evening lectures, the popular motion pictures, and the intensive courses of study. No detailed comment on these meetings is possible here but all programs have been published in the News Edition of *Industrial and Engineering Chemistry*. The attendance at the conference varied from 81 to 158 with an average of 125. There were 18 public evening lectures, held daily except Saturday and Sunday, at 8 p.m. The entire membership of the Institute was usually in attendance with many others from the college faculty, the summer session students, and residents of the town of State College also present. The attendance varied from 75 to 350 with an average of about 150. The motion picture performances were given at 6:30, preceding the public lectures, on 18 different days with 33 different titles. This feature was relatively of the least interest to the members of the Institute but was popular with the students of the college summer session and the residents of the town. The capacity of the theatre was 375 and it was almost invariably crowded to the doors, with many standing.

The intensive courses of study were scheduled in connection with the summer session of the college. Twenty such courses in advanced chemistry, biochemistry and physics were conducted by the Institute and 24 additional more elementary courses in the college summer session were open to Institute members, so that 44 different courses were announced. While the average number taking these courses for credit was only about five, due to the small number to whom this feature appealed, the attendance at all courses was much larger. Most members of the Institute even if present for only a week or even a day, made a habit of attending the lectures in these courses regularly and leaving no hour of the day free. Many of the courses therefore regularly had audiences of thirty to fifty, largely composed of transients.

A total of 415 persons registered for the Institute, of whom 29 were of the Pennsylvania State College. The membership, exclusive of invited speakers, represented all portions of the country from New Hampshire and Porto Rico to California and Washington. There was about an equal division between industrial and academic interests represented. The average period of attendance was about 8 days so that the average number present throughout the four weeks was 125.

With so varied and enthusiastic a membership the activities outside the schedule were almost numberless. A partial list would include—exhibits and demonstration lectures by a number of industrial firms; special informal lectures by Dr. F. C. Whitmore; on the atom and the benzene ring, informal games and organized tournaments in golf, tennis, bridge and chess, informal parties at fishing, swimming, mountain hikes, automobile tours, baseball; pretzels and punch in one of the fraternity houses every evening at nine; a daily mimeographed newspaper with gossip and announcements of the program for the following day; organized automobile tours to the Priestley home and grave at Northumberland, Pa., to Penn's Cave and Woodward's Cave, and to Livonia; a special afternoon conference on the Institute itself, for criticisms and suggestions; a "Simp-odium," or mock conference on "The Contribution of the X-Ray to the Pretzel-Benders' Problem," conducted by the younger members on the last evening of the four-week session; a reception for President and Mrs. Rosengarten on the opening night and At-Homes every Sunday on the lawn of the director; several informal dances, a "Children's" masquerade party; and those earnest discussions of chemistry and everything else by small groups far into the night.

Because of the lack of adequate hotel facilities in State College the Institute rented six of the large new fraternity houses adjoining each other on "Locust Lane" and operated them to furnish living quarters for the membership. Undoubtedly the community life thus made possible was the most important single item in the success of the Institute. During the sessions on catalysis these proved inadequate and the chapter house of the Alpha Chi Sigma fraternity was thrown open to take care of the overflow. The kitchens and dining rooms were operated in three of the houses. One house was reserved for women and one for married couples. Married people with children were provided accommodations in furnished houses or with residents of the town.

While some 7000 printed announcements were distributed, hundreds of mimeographed letters were sent to college and industrial executives, posters were sent to several hundred colleges, and articles were written for general and technical journals, the chief reliance for publicity was on the A. C. S. News Service through the News Edition and especially through the daily press. The response of the press

was most gratifying and included not only a very general publication of the news releases in all parts of the country but also frequent editorial comment, news photographs and at least one Sunday rotogravure photograph. No attempt was made to collect newspaper clippings but many hundreds were nevertheless received which show that very few, if any, scientific meetings have had such continued and widespread publicity. National journals such as *Time*, the *Outlook*, *The Literary Digest*, and the *Nation* gave frequent comment on the news from the Institute. The publicity staff prepared 47 special news releases for the daily press, every one of which was widely used. These were kept on file and at the end of the session 26 sets were sold at a price of \$5.00. It is significant that orders for these transcripts included foreign sources.

The demand for the publication of papers delivered at the Institute has been so great that efforts will be made to publish them as an annual volume.

Two speakers were present, on invitation, from England and one from Germany. They were extraordinarily successful in creating international good will and built friendships that went far beyond personalities.

The original budget of the Institute called for an expenditure of about \$15,000 on an expected income of about \$10,000. The accounts are not yet finally closed (August 31, 1927) but only minor items remain which will not exceed \$200 in expenditures nor \$50 in receipts. The balance sheet as of this date shows that while the estimate of receipts was nearly correct the expense far exceeded expectations. Total receipts amounted to \$10,287.67, while the total expenditures were \$23,698.26. This leaves a deficit at present of \$13,410.59.

TABLE OF INCOME AND EXPENDITURES
(As of August 31, 1927)

Program Account		Expenditures	
Receipts			
From Fees	\$3,298.25	Academic Salaries	\$9,530.00
Sale of News Releases	105.00	Administrative Salaries	4,375.78
Sale of Equipment and Surplus supplies	327.47	Office Rent	160.00
TOTAL	\$3,730.72	Theatre Rent	300.00
		Postage	202.27
		Telephone and Telegraph	313.25
		Office Supplies	443.96
		Printing	766.33
		Travel	301.39
		Furniture and Equipment	267.72
		Freight and Express	68.46
		Miscellaneous	117.74
		TOTAL	\$16,846.00
		Deficit	\$13,116.18
Housing and Commissary Account		Expenditure	
Receipts			
Room Rent	\$2,315.25	Salaries and Wages	\$1,720.00
Board	4,241.70	Rent of Houses	2,438.23
TOTAL	\$6,556.95	Supplies	2,693.13
		TOTAL	\$6,851.36
		Deficit	\$294.41
Total Receipts	\$10,287.67	Total Expenditures	\$23,698.26
		Total Deficit	\$13,410.59

The 4.4% loss in the housing and commissary account is due primarily to the wide fluctuation in attendance which necessitated renting the houses for the entire period though some were used for only a brief period, and to the impossibility of anticipating the attendance for any single day, which caused waste in the kitchens. The large deficit in the program account seems inevitable since fees cannot be materially raised. Even without academic salaries, i. e., without the staff of lecturers who gave courses throughout the session, the receipts in this account are \$3,586.18 less than the purely administrative expenses, i. e., the fees provided less than half the administrative expenses and none of the academic. Both of these items, however, can probably be reduced in subsequent sessions and a larger attendance will increase the receipts without increasing the expenditures materially.

G. L. WENDT, Chairman

The following by-law, having been duly presented under constitutional requirements, was unanimously adopted by the Council:

By-Law 23. The Endowment Fund of the Society shall, under Article 4, Sec. 2, of the Constitution of the Society, be collected and administered in two parts: (1) a Permanent Fund, the income of which alone may be expended only to help meet the Society's constantly growing needs for funds to record the results of chemical research in its publications; and (2) a Revolving Fund limited to \$100,000 to insure the publication of successive decennial general indexes to *Chemical Abstracts*, the sales of which shall be credited to the fund until the \$100,000 has been reached or replenished. Any excess above \$100,000 in the Revolving Fund at the end of any fiscal year may be used for the same purposes as the income of the Permanent Fund.

The Executive Committee having had referred to it at Richmond a proposal that an Institute for Chemical Education be established reported as follows, and the report was referred to the Society's Committee of Chemical Education:

At the Richmond meeting the Council referred to the Executive Committee for consideration and report the recommendation of the Committee on Chemical Education that there be approved an Institute for Chemical Education. Although the resolution specifies that in all financial details such an Institute shall be subject to final approval by the Directors and in other matters to the approval of

the Executive Committee or the Council, the committee feels that as referred to it details concerning such an Institute are as yet too nebulous to enable intelligent action to be taken. While it is understood that the discussion of such a research institute, both in the Senate of Chemical Education and in the Committee on Chemical Education, centered around the tentative plan published in the *Journal of Chemical Education* in January, 1927, it has been stated in conversation by several members both of the Senate and of the Committee, that there is a lack of agreement with respect to the plan published. However, resulting discussion has brought forward several points worthy of further consideration.

Therefore, while the Executive Committee feels that the matter is not in a form sufficiently definite to enable it to give either a negative or affirmative answer, it has seemed best to present in this report to the Council a suggestion for the initiation of work in which we are all interested, with the recommendation that the Committee on Chemical Education give it careful study and consideration, with the hope that from it will come a more definite plan upon which the Council and the Directors can take action.

In common with the teaching of other subjects, instruction in chemistry involves content and method. As compared with other subjects, particularly other sciences, the content of chemistry would seem to differ from them more than the method of teaching and since it is always wise to initiate new enterprises with ample caution, the committee feels the Society would only be justified in centering its attention on the content phase of the problem.

Just as it is recognized that accounts of progress in the field of chemistry must be interpreted to the lay public and to the chemists themselves if their work chances to fall outside the given specialty, so it must be recognized that this material seldom appears in a form which makes it easy for the busy teacher, particularly in high and secondary schools, to assimilate it and further interpret it to classes. Even if originally presented in a form suitable for such use, there is generally a considerable period during which authorities disagree and the teacher is at a loss to know which point of view is accepted by the majority of those competent to judge. It is also true that many secondary school teachers have little time in which to read sufficiently widely or to attend the scientific meeting necessary to maintain a broad view of chemistry as it develops, and they gradually become less efficient in the presentation of the subject to succeeding classes.

It is felt therefore that some agency which might be styled, for example, Bureau for Promotion of Chemical Education, might be established primarily for the purpose of presenting in a form most useful to teachers those new theories, principles, and results of investigations upon which there is a fair consensus of opinion, summaries of the status of advance in special lines of chemistry, and specially prepared accounts of the latest discoveries considered either as a matter of information or of subject material for teaching purposes.

The committee feels that in initiating such work, the expense incident to the establishment of a particular center or the erection of a special building should be avoided, but that if sufficient funds can be made available someone should be selected as a manager for this activity, his principal duty being to ascertain those who have been most successful in doing the particular bit of work that needs to be done at the moment, securing this cooperation, allocating the work, correlating the results, and devising the best means of placing such results in the hands of teachers. He should also devise means for encouraging teachers to utilize this material, and inaugurate a follow-up system whereby it could be ascertained how widely the material is being used and whether the results seem to indicate that the right procedure is being followed.

The committee also feels that rather than risk the permanent employment of a small group of men for this work, it would be wiser, especially in the initial stages of such activity, funds being available, to arrange for the retaining of well known talent on a temporary basis, permitting them to conduct their part of the work in their present locations and providing funds for such necessary travel as might be involved in arranging the material assigned to them. For example, let us suppose that Professor A has demonstrated his ability as a teacher in colloid chemistry. If funds were available, the manager would approach Professor A to bring together in a form believed suitable for the teacher all of the material in some field of colloid chemistry and would arrange with his college or university for the services of Professor A taking over all or such part of the salary obligations as circumstances might dictate. At the close of the work Professor A would take up his full teaching or other duties at his accustomed post. In this fashion the services of a large number of well qualified men could be obtained without running the risk of choosing the wrong men in the beginning, and in time certain men would prove so adept in work of the kind that wisdom might indicate their employment on a full-time basis for the Bureau. A valuable by-product would be the creation of a number of widely scattered centers of interest in this work.

The method of publishing and placing this specially prepared material in the hands of the teachers would have to depend upon circumstances. Conceivably existing mediums of publication like the *Journal of Chemical Education* would present one of the best methods for disseminating this material. Reprints, pamphlets, and monographs offer other methods.

Unquestionably teachers profit greatly from a multiplication of contacts and the less experienced teachers can be greatly helped by demonstrations of method. We therefore suggest for further consideration a proposal whereby certain teachers who have made a brilliant success at their work can be brought in contact with larger groups of teachers. It might be feasible to hold at irregular intervals state or regional meetings of chemistry teachers at which lectures and demonstrations involving the method of teaching would be given over a week-end period. On such occasions educators should be provided to discourse on methods of teaching, teachers could give demonstration lectures, with experiments, with motion pictures, and with other aids to teaching, and a helpful part of such a program would be an open forum on some selected topic. While the appearance of such teachers before actual classes might be very helpful, these appearances should take the form of special lectures to the class rather than a demonstration of methods of teaching, for if the latter were done the regular teacher might be caused some embarrassment and conceivably suffer from comparisons that would be made by the pupils between the special and the regular class sessions. However details of any demonstration must obviously be left for future consideration.

To encourage and indeed to insure attendance upon such meetings of teachers, funds might be wisely expended in meeting, say, one-half the actual travel expense of teachers who under such circumstances could probably obtain a part or all of the remainder from their school boards or others in authority. Should this prove too great a burden, it is possible that such expenditure could be limited to those especially invited, not because they can contribute much but because they really need experience, or it might be limited to those below a certain predetermined salary level.

Such meetings would not only insure better contact between teachers of the area but would bring them in contact with these specialists, who in turn could advise the director of the Bureau of conditions found, of the reaction to the work being done, of new problems requiring consideration, etc. Obviously the Bureau would arrange such meetings, tours of the teachers selected, and other details.

As for research in the methods of teaching, it would seem possible that this could be given some attention without involving the Society in research in the field of pedagogy. The various schools of education are at work in this field and it might be useful to summarize and correlate their findings and advice, but since it seems evident that the best research in methods of teaching chemistry is actually going on in the class rooms of all successful, inspiring, and keen teachers, the first steps that might be taken under this Bureau for the extension of Chemical Education would be to secure and publish descriptions of the methods employed in those schools where the results with students indicate the success of the method.

It would seem highly desirable, indeed necessary, for the Committee on Chemical Education to seek the advice of the most successful teachers of chemistry as to the present needs in teaching, considering the problem from the viewpoint of secondary schools and of institutions of higher learning. In a matter of such import it is very needful to have the advice of competent persons not interested in the exploitation of any particular idea.

The committee offers the above suggestions to the council for reference to the Committee on Chemical Education, in the belief that a plan somewhat as outlined would avoid many of the errors that might be made in initiating a more ambitious project requiring far greater funds. It would postpone for some time decision as to whether or not the Bureau as a whole need to have a definite location, and such a plan would provide both the means and the time for the selection of such small staff as might ultimately prove desirable to carry on such work as the Bureau might ultimately perform with the greatest success for the extension of chemical education.

Names of members deceased since the last meeting, as printed in Proceedings, were presented to the Council and the Council stood a moment in respectful silence.

The following was then read to the Council and will be acted upon in due course, as required by the Constitution:

PROPOSED AMENDMENTS TO THE CONSTITUTION OF THE AMERICAN CHEMICAL SOCIETY

Purpose. To provide for the office of President-elect who shall serve for one year as an ex-officio member of the council, the Executive Committee and the Board of Directors. This plan would enable the President-elect to become thoroughly familiar with society matters and give him an opportunity to arrange his personal affairs before serving his one-year term as President. The arrangement automatically provides only one term for a President, and yet removes the objection previously urged against bringing in each year a new man, unfamiliar with the affairs of the Society. The plan also provides a more logical person to serve in place of the President in case of his disability, instead of allowing the office to pass to that one of the many Vice-Presidents who may happen to have been a member of the Society for the longest time.

ARTICLE IV

Officers and Manners of Election

Section 1. Insert "a President-elect" after the word "President," and change "nine directors" to "ten directors."

Section 2. Change "President" to "President-elect."

Section 3. Insert "the President-elect" after the word "President."

Section 4. Change "President" to "President-elect" in paragraphs 1, 3 (twice), 4 and 11.

Change the first clause of paragraph 13 to read:

"The terms of the officers so elected shall be as follows: For the President-elect, one year beginning with the first day of January following, after which he shall automatically become President for one year, or until his successor shall have been duly chosen."

Also add paragraph 14 as follows:

"If the President-elect for any reason be unable to serve, or to assume the Presidency, his place shall be filled by letter ballot of the council from among the other three who received the greatest number of nominating ballots for President-elect in the previous election."

Section 6. Change to read: "In case of absence, death, or inability of the President to perform the duties of his office, his position shall, during his disability, be filled by the President-elect."

ARTICLE V

Section 2. Add "the President-elect" after "the President."

AMENDMENTS TO THE BY-LAWS

By-Law 3, in the first paragraph of the amendment constituting the executive committee, insert "President-elect" after "President."

At the first election subsequent to the adoption of the amendments providing for a President-elect, the person receiving the largest number of votes of the Council shall become President, and the person receiving the second largest number shall become President-elect.

The Council then voted its thanks to W. P. Putnam, Chairman of the Executive Committee; to L. W. Rowe, Chairman of the Local Section, together with all other committee chairmen, assistants, and members of the Detroit Section responsible for executing the vast amount of detail work incident to so large a meeting; also to the considerable number of industrial and social organizations in Detroit and elsewhere who were patrons of the Detroit convention and who otherwise assisted in making the meeting possible.

The Council then adjourned.

CHARLES L. PARSONS, *Secretary*

President Rosengarten has appointed Prof. Marston T. Bogert, of Columbia Uni-

versity, New York City, as a delegate to represent the American Chemical Society at the "Seventh Congres de Chimie Industrielle," to be held at Paris, France, October 16 to 22, 1927. Also, Professor Bogert has been appointed a delegate to represent the Society at the "Centenaire de Marcelin Berthelot," to be held at Paris, France, October 23 to 26, 1927.

Proceedings

COUNCIL MINUTES

At the Los Angeles meeting of the American Chemical Society in August, 1925, the Division of Industrial and Engineering Chemistry appointed a committee to look into the situation of automobile exhaust in relation to the hazards of carbon monoxide escaping therefrom and the waste of gasoline incident to allowing automobile engines to run while standing.

The Committee reported as follows:

"There are over 2,000,000 trucks and taxicabs in the United States whose drivers keep engines running while parking. This practice results in a loss of more than \$80,000,000 per annum and the escape of carbon monoxide in excess of 250,000,000,000 cubic feet. Aside from the monetary loss, we already have more than a comfortable amount of carbon monoxide in congested thoroughfares from 15,000,000 or more passenger cars. Exhaust gases average over 7% CO.

"At the Los Angeles meeting in 1925, your division appointed a committee whose report has been delayed because of the illness of the Chairman. This Committee now makes the following recommendations:

"1. That your division ask the President of the American Chemical Society to appoint a representative who, with similar representation from the National Safety Council, the American Automobile Association, the American Medical Association, the United States Chamber of Commerce, and such other organizations as the President may select, shall constitute a committee with duties that shall include:

"(a) The encouragement of use of automatic starting devices for trucks and taxicabs as cranking is dangerous and feared by many drivers.

"(b) The encouragement of researches towards the lowering and possible elimination of carbon monoxide in exhaust gases.

"(c) The giving of adequate publicity regarding the dangers of carbon monoxide poisoning, and the necessity of fuel economy, through the public press and various other channels.

(Signed) Alexander Silverman, *Chairman*,
Erle M. Billings
A. C. Fieldner"

The Division of Industrial and Engineering Chemistry at the Detroit meeting in September, 1927, approved the report and President Rosengarten has appointed Professor Alexander Silverman of the University of Pittsburgh the representative of the American Chemical Society on the joint committee which is being appointed to study the situation.

CHARLES L. PARSONS, *Secretary*

President Rosengarten has appointed Prof. E. W. Rockwood, of the University of Iowa, Iowa City, Iowa, the Society's representative at the inauguration of Dr. Herbert John Burgstahler as President of Cornell College, Mount Vernon, Iowa, on November 18, 1927.
